To produce a desirable micro execution flow across these scheduling dimensions, the core of the scheduler module is a profiling-guided scheduling policy, which utilizes runtime profiling of worker characteristics to search for the optimal execution mode of each worker. Based on the determined execution mode, the Controller assigns workers to accelerators, manages inter-worker connections, and orchestrates the execution flow by dispatching function invocations to the corresponding workers. To realize this, two mechanisms named elastic pipelining and context switch are devised to enable spatial and temporal orchestration of workers, respectively. Adaptive communication utilities such as point-to-point communication and data channel act as the data plane to support scalable worker interactions. The entire system leverages Ray [33] to remotely launch and control workers.

3.2 Workflow Construction Interface

The design philosophy of RLinf is to maximize system flexibility to achieve high efficiency, which is also the guideline for RLinf's programming interface design. To this end, unlike traditional graph-based declarative programming [1] that sac-

```python
class Worker:
  def send(self, obj, dst, async_op)
  def recv(self, src, async_op)
  @overload
  def onload(self)
  @overload
  def offload(self)

class RolloutWorker(Worker):
  def generate(self, in_channel, out_channel):
    with self.device_lock:
      batch_size = 0
      while batch_size < self.total_batch_size:
        batch = in_channel.get()
        res = self.model.gen(batch)
        out_channel.put(res)
        batch_size += batch.size
```

(a) A typical RLinf worker.

```python
class RLWorkflowRunner:
  def __init__(self):
    cluster = Cluster(num_nodes=4, devices_per_node=8)
    self.rollout_group = RolloutWorker.launch(cluster)
    self.actor_group = ActorWorker.launch(cluster)
    self.data_ch = Channel.create("Data")
    self.rollout_ch = Channel.create("Rollout")
  def run(self):
    for batch in batch_iterator:
      self._update_rollout_weights()
      self.data_ch.put(batch)
      self.rollout_group.generate(
        in_channel=self.data_ch,
        out_channel=self.rollout_ch
      )
      self.actor_group.train(self.rollout_ch).wait()
```

(b) A workflow runner example.

Figure 5: RLinf workflow programming interface.

rifices control flow flexibility, debuggability and transparency for optimization opportunity, RLinf adopts a procedural programming paradigm that enables developers to flexibly express workflows imperatively. An example workflow based on this interface is shown in Figure 5. As shown, an RL program based on RLinf consists of two parts: (1) worker programs that define the logic of each RL component (e.g., simulator, LLM generation, actor training), and (2) a workflow runner that orchestrates the overall workflow by invoking the workers' core functions and defining inter-worker interactions.

Figure 5a demonstrates a typical worker implementation atop RLinf. The base `Worker` class provides communication primitives such as `send` and `recv` for inter-worker communication. All workers that inherit from the base class automatically gain the capability to communicate with other workers (§3.5), which is also the foundation for higher-level communication facilities like the data channel. To manage limited device resources like GPU memory, all workers are required to implement resource management functions (`onload` and `offload`) for acquiring and releasing the resources.

After implementing workers, developers can compose the overall RL workflow as in Figure 5b. First, the runner launches workers on a cluster of nodes and devices in an SPMD manner. The scheduler module decides the placement of each worker process before its launch, which can also be manually specified if desired. All processes of the same worker are collectively managed via the `WorkerGroup` abstraction of RLinf (e.g., `rollout_group`), which automatically assumes the public functions defined in the worker class and dispatches them to all (or a selective portion) of the worker processes if invoked. The functions of a `WorkerGroup` are inherently asynchronous and return a result handle, whose `wait` primitive provides synchronization barriers, enabling computation at a certain data granularity. For example, in GRPO training, rollout can proceed per query, but normalization must aggregate all responses for a query, which pauses the pipeline at this step until normalization completes. The core facility for connecting the data flow among distributed worker groups is the data channel (detailed in §3.5), which decouples the control and data flows of dependent components, enabling highly flexible programming while exposing a broad optimization space, as shown below.

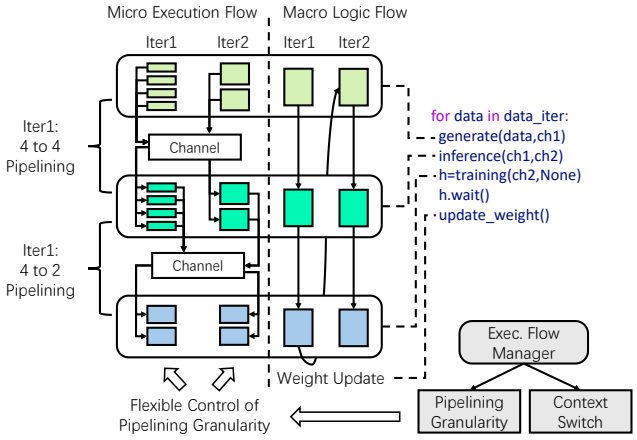

Figure 6: The M2Flow execution logic.

3.3 M2Flow Transformation

The programming interface shown in Figure 5b offers a flow-like programming model, with which developers describe the high-level, logical control and data flows among workers. Having obtained the logical flows, RLinf follows the M2Flow paradigm to transform the logical flows (i.e., how should the workers run) into the concrete execution flow, i.e., where (spatial) and when (temporal) should the workers run. In this section, we focus on two enabling mechanisms of M2Flow transformation and flexible scheduling—elastic pipelining and context switching. In §3.4, we will describe the scheduling policy that determines the optimal execution flow.

Based on the programmed workflow, the key idea of M2Flow transformation is to control the spatial and temporal scheduling of workers by throttling their data processing granularity and concurrent resource accesses, respectively.

Spatial Scheduling via Elastic Pipelining. For spatial scheduling, workers can be executed in a pipelined manner with a different number of accelerators/devices. To maximize

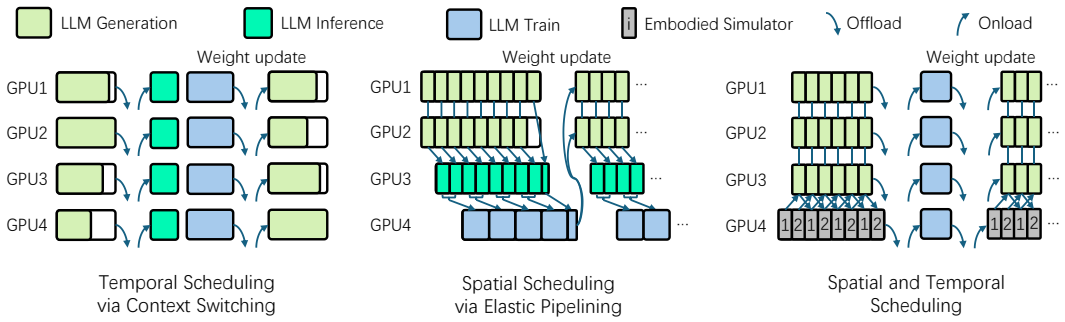

Figure 7: Spatial and temporal scheduling of workers.

pipeline flexibility, RLinf introduces elastic pipelining to enable workers to flexibly process data at different granularity with the given device resources. Elastic pipelining builds upon our insight that in RL training and agentic scenarios, most workers follow the SPMD pattern, allowing execution across varying batch sizes. For instance, LLM serving engines like SGLang and vLLM can process a single prompt or a list of prompts at a time, and inference (i.e., prefill-only computation of a model) similarly supports single-batch or multi-batch execution. This flexibility enables the Execution Flow Manager of RLinf to achieve flexible pipelining of a worker task via dynamic data granularity—output data can be forwarded once a configured size of data batch is ready, allowing downstream workers to start earlier with smaller batches or later with larger batches. Notably, the scheduling space is further affected by individual worker's internal computation semantics. For example, training workers operate with both the micro-batch and global-batch concepts—the micro-batch defines forward/backward units, while the global-batch determines when model updates occur.

Temporal Scheduling via Automatic Context Switching. Beyond spatial scheduling, RLinf also supports natural temporal multiplexing of devices via automatic context switching, further expanding the scheduling space. Context switching enables workers that cannot co-reside in the same accelerators with limited device resources (e.g., GPU memory) to share devices by executing sequentially. In RLinf, this is realized via a distributed device lock of the data channel facility, i.e., `device_lock` as shown in Figure 5a. This lock serves as the primitive to throttle concurrent resource access by multiple workers that are on the same devices and have data flow dependencies, i.e., producers and consumers of the same channel. Before using device resources, a worker must acquire the lock, whose state is globally consistent to all workers and can only be changed atomically, thus ensuring exclusive access to the resources. Upon lock acquiring, the worker's device resources are automatically loaded by calling the `onload` function of the worker if the resources have been offloaded. After completing its task, the worker releases the lock and offloads its resources via the `offload` function to free up device resources for child workers in the workflow. Unlike a conventional lock, the device lock leverages the data channel's data dependency information to define lock acquiring priority, i.e., child workers that depend on the outputs of parent workers can only acquire the lock after the parents have enqueued data and released the lock, so as to avoid lock contention and deadlock. Also, it utilizes device placement information from the Controller to avoid unnecessary resource loading and offloading when workers are placed on different devices.

M2Flow Execution. Figure 6 shows how M2Flow manages execution. The workflow is written imperatively, i.e., a for loop iterating over main logic, with three workers, i.e., rollout, inference, and training. A rollout task such as `generate(data, ch1)` processes data and enqueues results to channel `ch1`. The Execution Flow Manager can divide the input data into smaller chunks, allowing workers to process outputs at a smaller data granularity. Alternatively, tasks can be coalesced into fewer, larger sub-tasks with larger data chunks to realize different temporal scheduling. Meanwhile, the device lock enables automatic resource management among workers with data dependencies, enabling spatial scheduling via context switching.

With M2Flow, user-defined workflows can be orchestrated across a complete spatial–temporal scheduling space. Figure 7 illustrates several representative execution modes suited to different RL workloads and configurations.

The left part of Figure 7 shows pure temporal scheduling, where each worker occupies all accelerators. Once a worker completes its task, it is swapped out and the next worker is swapped in. For the illustrated case, since inference and training share the same model weights, no offloading or reloading is required. This mode is particularly useful when a worker must use all devices to be runnable, such as a large model's training. It also maximizes resource sharing among collocated workers and avoids inter-worker pipeline imbalance. However, it suffers from GPU idleness due to long-tail effects, e.g., the longest response length in the rollout stage determines the overall completion time of the stage. This mode is therefore suboptimal when the workload exhibits high variance in component runtime, as is typical in long-context reasoning or open-ended embodied rollouts.

The middle part illustrates spatial scheduling, where workers are assigned to separate GPUs. Because workers depend on one another, pipelining is applied to mitigate idle time.

Achieving efficient pipelining requires balancing resources across workers so that their execution times align. Spatial scheduling effectively hides the long tail of dynamic stages by overlapping them with downstream components, but it may introduce compute and memory imbalance when one component dominates GPU memory (e.g., training with optimizer states) while others underutilize their allocation. In such cases, dedicating disjoint GPU sets to every component forces compute-light components to retain GPUs they cannot fully exploit, leading to overall resource waste.

Finally, RL workflows are often too complex for purely temporal or spatial scheduling to remain efficient. M2Flow therefore supports hybrid scheduling, as shown on the right of Figure 7. Some workers are distributed across GPUs with pipelined execution, but once the workers' stage completes, they can be swapped out and replaced by successors to continue the workflow. Hybrid scheduling preserves resource sharing for the subset of components with large memory footprints (e.g., training and inference that share weights), while pipelining the dynamic, long-tail-prone components (e.g., generation, simulators) on dedicated devices to mask their variability. This trade-off can be applied at fine granularity, with the choice for each component aligned to its compute and memory profile, its position in the dependency graph, and the dynamicity of its inputs.

3.4 Scheduling Policy

RLinf offers a large scheduling space through flexible orchestration of workers, thus finding the most efficient execution mode is challenging. To this end, RLinf introduces two modules: the profiler and the scheduler. The profiler is used to measure and estimate the execution characteristics of each component under different numbers of GPUs. The scheduler then utilizes this information to compose an overall execution plan, containing specific GPU assignments and pipelining configurations. The two modules form a fully automated profiling-to-scheduling pipeline. After developers define the worker logic and workflow runner, RLinf runs offline profiling over a small set of representative data parallel sizes, extrapolates each component's execution time and memory usage, and passes the results to the scheduler, which finds the global execution plan before training begins. Users do not manually choose among temporal, spatial, and hybrid modes; they only declare the resource budget (§4) and, optionally, parallelism hints for very large models.

Profiler. The profiler measures each component's execution time and memory usage under different data parallel sizes, because data parallel size tends to have a positive (sometimes nearly linear) relation with the component throughput as data is consumed faster with the increasing data parallel size. For non-model components like simulators, the data parallel size is the number of instances. For model training and generation components, the profiler requires users to provide model parallel configuration to decide the data parallel size, which can usually be determined by the model size and GPU memory. With the profiled data, the profiler extrapolates the execution time and memory usage for larger data parallel sizes using polynomial extrapolation, outputting an execution time estimation function E for each component. This function is then fed to the scheduler for it to estimate each component's execution time and whether it can be fitted into memory given a selected number of GPUs. Moreover, during profiling, the overall RL workflow is also captured into a workflow graph in a just-in-time manner, by tracing the data flow among workers through the communication primitives.

Algorithm 1: Worker scheduling policy.

Input : Workflow graph G, execution time estimation function E for each component, and number of devices N.
Output : A worker schedule S_{best} and its estimated time T_{best}.

```
1  D_table ←{}; // graph map to (time, schedule)
2  G_dag ←ConvertCircleToNode (G);
3  T_best, S_best ←FindSchedule (G_dag, N, D_table);
4  Function FindSchedule(G, N, D_table):
5      if (G,N) in D_table then
6          return D_table[(G,N)];
7      end
8      if G is a node then
9          return E_node, S_node;
10     end
11     T_best ←+inf; S_best ←None;
12     for G_s, G_t in TraverseStCuts (G) do
13         /* G_s and G_t share the same gpus */
14         T_s, S_s ←FindSchedule (G_s, N, D_table);
15         T_t, S_t ←FindSchedule (G_t, N, D_table);
16         D_table[(G_s,N)]←(T_s, S_s);
17         D_table[(G_t,N)]←(T_t, S_t);
18         if T_best > T_s + T_t then
19             T_best ←T_s+T_t; S_best ←shared(S_s, S_t);
20         end
21         /* G_s and G_t use different devices */
22         for N_s, N_t in TraverseGpuNum (N) do
23             /* N_s+N_t equals N */
24             T_s, S_s ←FindSchedule (G_s, N_s, D_table);
25             T_t, S_t ←FindSchedule (G_t, N_t, D_table);
26             D_table[(G_s,N_s)]←(T_s, S_s);
27             D_table[(G_t,N_t)]←(T_t, S_t);
28             if T_best >PipeliningTime (T_s, T_t) then
29                 T_best ←PipeliningTime (T_s, T_t);
30                 S_best ←pipeline(S_s, S_t);
31             end
32         end
33     end
34     return T_best, S_best;
35 end
```

Scheduler. The scheduling policy of the scheduler is shown in Algorithm 1. The input of the policy includes the workflow graph G, the execution time estimation function E produced by the profiler, and the total number of GPU devices. Specifically, the scheduling algorithm recursively partitions the workflow graph into two subgraphs, G_s and G_t, connected by directed edges known as the *s–t cuts* [11]. For each parti-

tion, it evaluates the time cost of both the temporal and spatial scheduling policies. In the temporal scheduling, G_s and G_t share the same set of devices (e.g., GPUs)—G_s processes its batch, and upon completion G_t consumes its output. In the spatial scheduling, G_s and G_t are assigned to disjoint device sets and executed in a pipelined fashion. The scheduler uses the profiling results to find the optimal device allocation and data processing granularity for each subgraph. The algorithm then selects the most performant scheduling, and applies this process recursively until each subgraph reduces to a single node, at which point the node returns its profiled execution time under the assigned placement.

Modeling the execution time of G_s and G_t is the key to finding the optimal scheduling. In the temporal scheduling where workers share devices, the cost is the sum of G_s and G_t plus any resource offloading and reloading overhead. In the spatial scheduling, the runtime is estimated as

$$T_{\text{critical}} + (M/m - 1) \times T_{\text{bottleneck}},$$

where T_{critical} is the pipeline warm up and cool down time, $T_{\text{bottleneck}}$ is the runtime of the slowest subgraph, M is the total batch size, and m is the data processing granularity.

Before invoking `FindSchedule`, the workflow graph is preprocessed to collapse cycles into single nodes. When recursion reaches such a node, its computation is evenly partitioned across GPUs. This avoids exhaustive partition enumeration while still achieving near-optimal performance.

Algorithmic Complexity. Let V be the number of nodes in the post-collapse workflow DAG and N the number of devices. With memoization, the DP visits $O(V^2)$ distinct subgraphs for the chain-like workflows typical in RL, and each (subgraph, device-count) state takes $O(V \cdot N)$ time because it enumerates $O(V)$ s-t cuts and, per cut, iterates over device partitions $N_s + N_t = N'$. Summing over all $O(V^2 \cdot N)$ states yields an overall search cost of $O(V^3 \cdot N^2)$. For a given workflow, the search cost is $O(N^2)$ as the topology is fixed. We empirically validate this scaling up to 4096 GPUs in §5.2.

Adaptive Re-Profiling for Runtime Dynamicity. Some RL training is inherently dynamic: for LLM, as the model learns, the rollout response length distribution drifts, causing components such as generation to speed up or slow down over time. A static plan derived from initial profiling may therefore become suboptimal mid-training. To handle this, RLinf embeds a runtime profiler inside each worker that continuously records per-invocation execution time, and a lightweight controller routine that compares these measurements against the scheduler's estimated execution times. When the deviation exceeds a configurable threshold (15% sustained over a sliding window in our default configuration), RLinf checkpoints the training state, re-runs the scheduling algorithm with the updated profile, and resumes training under the new execution plan. In typical reasoning RL training, response-length drift is gradual and re-scheduling is warranted only after thousands of iterations, so the checkpoint-and-redeploy overhead is negligible relative to total training time. We quantify the sensitivity of RLinf to profile noise in §5.2.

3.5 Adaptive Communication

To support flexible worker orchestration, RLinf's communication layer needs to realize two key design goals. **(1) Flexible.** Any two workers should be able to communicate with each other, regardless of the worker placement and program logic. **(2) Adaptive.** Communication primitives should be able to adapt to arbitrary data living in different devices (CPUs and GPUs across nodes), while achieving maximum throughput of the underlying communication links.

However, existing collective communication libraries for GPU and CPU data, e.g., NCCL [36], Gloo [39], and MPI [12], fail to meet our goals as they are mostly built for standard communication patterns across a fixed number of processes in traditional model training and serving scenarios. In contrast, RL components manifest considerable spatial and temporal dynamicity. Spatially, components can collocate on the same device, or be distributed across different devices. Temporally, components can be launched or terminated at arbitrary times. However, state-of-the-art libraries like NCCL do not support flexible rank scaling and efficient intra-device communications. Furthermore, the data communicated between components can be complex data structures beyond standard contiguous GPU/CPU data buffers, e.g., a composition of multiple data buffers with varying sizes. Efficient handling of such data dynamicity is also missing in existing libraries.

Communication Protocol and Primitives. To achieve the design goals, we devise worker and data placement-aware communication protocol and primitives, which enhance existing CPU/GPU communication libraries in terms of both flexibility and performance in the RL scenario.

At the protocol level, RLinf features transparent connection lifecycle management, which avoids manual connection management as in traditional communication libraries, and handles dynamic worker placement and scaling automatically. Specifically, upon launch, each worker's placement, IP and port information will be registered into a global worker manager. Connections among workers are then established with the information lazily when workers invoke communication primitives to reduce connection overhead and enhance scalability. When a group of workers establish a connection, the connection metadata is maintained both locally by workers and globally by a connection manager. When a worker is terminated, the connection manager will notify all connected workers to teardown the connection and release resources.

At the primitive level, like existing libraries, RLinf offers both synchronous and asynchronous `send` and `recv` primitives for point-to-point communication, as well as collective communication primitives like `broadcast`. Differently, RLinf's primitives automatically exploit the worker

and data placement information of the communicating workers to select the most efficient communication backend, e.g., NCCL for GPU-GPU communication, zero-copy cudaIPC for intra-GPU communication, and Gloo for CPU communication. For data dynamicity, both the asynchronous and synchronous primitives support arbitrary Python objects as the communication payload, which are serialized and deserialized in a structure-aware manner, i.e., data buffers are extracted from the objects and communicated directly without serialization/deserialization overhead. Also, data structure information is piggybacked in the communication metadata to facilitate efficient deserialization at the receiver side.

Load-Balancing Data Channel. Atop the above communication primitives, we further build a high-level FIFO queue-like communication facility (termed *data channel*) for producer-consumer worker communication in the workflow. This enables decoupling of both the control and data flows of producer and consumer workers, which is essential for flexible pipelining. The data channel maintains its data queue in a special channel worker process, and can be accessed by any other worker processes by passing the channel handle. The channel supports both CPU and GPU data, and can be configured for offloading GPU data to CPU to reduce GPU memory consumption. Furthermore, the data channel is enhanced with load-balancing capability. Each item enqueued to the channel can be assigned a weight value, which is used to balance the load across multiple consumers dequeuing from the channel. The consumers can also define custom load-balancing policies, which are invoked by the channel upon each dequeue operation to select the desired items from the channel.

4 Implementation

RLinf is implemented in 20K lines of Python code. Among them, 5K lines are for the core worker, controller, and scheduler components. 2K for common workers such as rollout workers based on serving engines like SGLang, vLLM and HuggingFace Transformers, training actors based on Megatron and FSDP, and embodied simulators, which can be used out of the box for any future RL models and workflows. The remaining 13K lines are mostly rich support for various RL algorithms like PPO and GRPO. Notably, a typical workflow runner like the LLM reasoning RL workflow implementation is less than 100 lines of code, and requires no code changes to be scheduled both temporally and spatially.

Currently, RLinf supports not only traditional LLM-based reasoning RL, but also agentic RL with tooling, and embodied RL involving complex workloads like 3D rendering, physics simulation, and robotic control. For RL algorithms, RLinf supports popular algorithms like PPO [48], GRPO [49], DAPO [61], and REINFORCE++ [16], as well as some of their off-policy asynchronous versions. Table 1 summarizes the broader set of algorithms supported by RLinf,

Table 1: RL algorithm categories supported by RLinf.

Category	Algorithms
On-policy	GRPO [49], PPO [48], DAPO [61], REINFORCE++ [16]
Off-policy	Async PPO, SAC [14], CrossQ [5], RLPD [4], SAC-Flow [65], DSRL [56]
Imitation	DPO [41], Full-param SFT, LoRA SFT, VLM SFT, DAgger, HG-DAgger

covering synchronous on-policy methods, off-policy and asynchronous methods, and imitation learning. Notably, the M2Flow paradigm naturally generalizes to complex asynchronous algorithms and to agentic workflows with tool calls and multi-agent settings (e.g., Search-R1 [22], rStar2 [47]), simply by adapting the workflow to the components.

Differently, asynchronous algorithms differ in workflow structure from their synchronous counterparts: instead of executing lock-step phases, they run long-lived concurrent workers and synchronize weights non-blockingly. Despite this, expressing such workflows in RLinf remains concise:

```
class AsyncRunner:
  def run(self):
    self.update_rollout_weights()
    env_h = self.env.interact(
      self.env_ch, self.rollout_ch, self.actor_ch
    )
    rollout_h = self.rollout.generate(
        self.rollout_ch, self.env_ch
    )
    while step < max_steps:
      self.actor.run_training(self.actor_ch).wait()
      if step % sync_interval == 0:
        self.update_rollout_weights()
    self.env.stop(); self.rollout.stop()
```

The environment, rollout, and actor workers run as persistent asynchronous tasks streaming data through channels, while training proceeds concurrently without blocking on rollout completion. This shows that M2Flow's channel-based decoupling generalizes naturally to asynchronous settings.

For models, we have implemented support for language models like Qwen [40], multi-modal models like VLM [3], VLA models like OpenVLA [23, 24] and Pi0 [55], and world models like OpenSora [70] and Wan [57]. The rich RL workflow, algorithm and model support not only accelerates the development of new RL workflows with RLinf, but also demonstrates its generality, versatility and extensibility in practice.

Cluster Management and Device Allocation. RLinf leverages Ray to realize cluster management, launching worker processes on remote nodes, and dispatching worker function executions. RLinf does not rely on Ray for device allocation to workers, because Ray only supports rigid packed-style (i.e., consecutive devices) or spread-style (i.e., spread-across-node first) resource allocation [33], which are not flexible enough for today's complex and dynamic RL workflows. Instead, RLinf offers a flexible device allocation strategy, which allows each worker process to be allocated with any device or devices of any node across the cluster, by simply specifying the target devices' global IDs. Also, hardware devices be-

yond accelerators such as robot arms are also abstracted and managed as schedulable devices in the same manner as accelerators. This enables RLinf to scale on all kinds of hardware that foundation models can interact with.

Multi-Tenant Resource Boundary. In multi-tenant clusters, a cluster manager (e.g., SLURM, Kubernetes) assigns each job a fixed set of nodes. RLinf scopes its runtime to this allocation, and the scheduler explores execution modes only within it, so M2Flow does not alter the job's resource contract with the cluster manager. Within the allocation, the distributed device lock of the data channel (§3.5) enforces exclusive accelerator access when components share devices via temporal scheduling, preventing intra-job contention.

Heterogeneous Hardware Support. RLinf abstracts accelerators behind a unified hardware interface, allowing the scheduler to target clusters that mix GPUs/NPUs from different vendors (e.g., NVIDIA, AMD, Intel, Ascend, MUSA) and non-standard devices such as robotic arms. Nodes are grouped by hardware type, and a declarative placement configuration maps each workflow component to one or more groups. The profiler measures each component on its actual device type, so the scheduler accounts for heterogeneous execution times when searching the spatio-temporal plan.

Fault Tolerance. The distributed, multi-component nature of RLinf makes worker process crashes, node failures, and network issues unavoidable in long training runs. RLinf adopts checkpoint-based recovery: when any worker fails, it detects the failure via heartbeat and notifies the Controller, which halts the entire training job to prevent dependent workers from timing out or producing inconsistent state. Users can then restart from the latest checkpoint, and RLinf replays the offline profiling phase if the resource boundary has changed before resuming under a possibly updated execution plan.

Performance Profiling. Performance profiling support is not only crucial for developers to understand system bottlenecks, but also serves as the key to our scheduling policy. Thus, RLinf provides a worker-group-level timer for every public function invoked remotely by the workflow runner. The timer automatically captures the execution time of a worker function, whose value can be retrieved via the asynchronous handle returned by the corresponding worker group function; the values of all processes in the worker group will be reduced to a single value via a specified reduction method (e.g., mean, max, min). Beyond this, developers can also create custom timers for more fine-grained profiling of any code region, and retrieve the timer values similarly.

5 Evaluation

We extensively evaluate RLinf across math-reasoning and embodied RL workloads, covering four different models of different sizes (i.e., Qwen2.5 [40], Qwen3-MoE [59], Open-

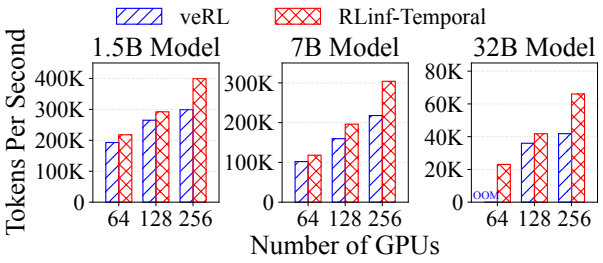

Figure 8: GRPO training throughput of Qwen2.5 on RLinf and veRL under different cluster scales and model sizes.

VLA [24], OpenVLA-OFT [23]), two RL algorithms (i.e., GRPO [49], PPO [48]), and multiple cluster scales. Overall, our key findings include:

- RLinf consistently outperforms state-of-the-art RL systems veRL [51] and Slime [71] by 1.07×∼1.70× on a variety of math-reasoning RL settings. The results also show that different RL settings favor different execution modes.
- RLinf demonstrates higher training throughput on embodied RL tasks in both ManiSkill [54] and LIBERO [27]. On LIBERO, RLinf achieves a 1.05×∼2.43× speedup over SimpleVLA-RL [25]; on ManiSkill, its hybrid mode yields up to 1.87× improvement over other strategies.
- The scheduling policy identifies the best execution mode within $7 \times 10^{-4} \sim 5.98s$ on the clusters of 8 to 1024 GPUs.
- The models trained with RLinf achieve SOTA or better benchmark scores after RL fine-tuning.

5.1 End-to-End Experiments

The end-to-end experiments run on a 32-node cluster, where each node is equipped with 8 NVIDIA H100-80GB GPUs, 2 Intel Xeon Platinum 8558 CPUs (2.1 GHz, 48 cores), and 2 TB of memory. Intra-node communication uses NVLink, while inter-node communication uses 8 Mellanox ConnectX-7 RDMA NICs per node, each providing 400 Gbps bandwidth with RoCEv2.

5.1.1 Reasoning RL Training

Experimental Setup. We evaluate using Qwen2.5 Models [40] distilled by DeepSeek-R1, covering sizes from 1.5B to 32B parameters and Qwen3-30B-A3B [59], which is an MoE model, and using the AReaL-boba-Data dataset [58], which integrates multiple standard datasets including DeepScaleR, Open-Reasoner-Zero, Light-R1, etc. We compare RLinf with two state-of-the-art open-source RL systems, i.e., veRL v0.5 [51] and Slime v0.1 [71]. To ensure fairness, all systems use SGLang [68] for rollouts and Megatron-LM [52] for training, with the same parallelism setting (e.g., tensor parallelism configuration). Training speed is reported in tokens/sec, defined as the total number of prompt and response

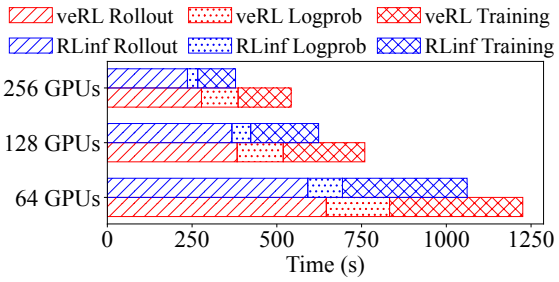

Figure 9: Latency breakdown of Qwen2.5 7B model training.

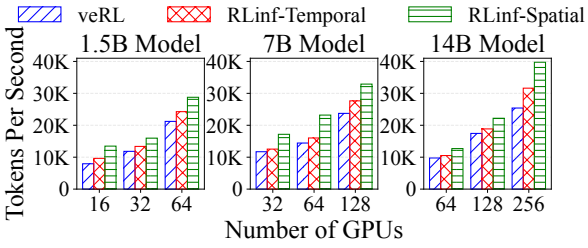

Figure 10: PPO training throughput of Qwen2.5 on RLinf and veRL under different cluster scales and model sizes.

tokens in a global batch divided by the iteration time. All performance results are averaged over 10 training iterations after warm-up.

Qwen2.5 with GRPO. We evaluate the Qwen2.5 1.5B, 7B, and 32B dense models on 64, 128, and 256 GPUs, respectively, using a rollout batch size of 512 and maximum sequence length 28672. As shown in Figure 8, RLinf in temporal mode consistently outperforms veRL across all model scales, achieving 1.10× to 1.58× speedups. Since RLinf 's temporal mode is similar to veRL's design, the gains primarily stem from faster rollouts enabled by larger KV-cache allocations (RLinf has better GPU memory management) and reduced synchronization overhead between upstream and downstream stages of the middle inference stage, as illustrated in Figure 9.

Figure 8 also shows that veRL scales poorly as GPU number increases, largely because inference becomes a growing bottleneck, with its proportion of total execution time rising from 15.2% to 19.9% when scaling from 64 to 256 GPUs. In addition, veRL's unoptimized rollout engine leads to excessive peak memory usage, forcing smaller KV-cache allocations and causing rollout time to decrease only sublinearly.

We also tested spatial mode, but it underperforms veRL by 44.3-68.6% for the 7B model, because rollout, inference, and training run on disjoint smaller sets of GPUs, slowing both rollout and training. With the long sequence length (i.e., 28672), the training stage also waits longer for the first batch of rollouts to be generated. In addition, the rollout batch size is relatively smaller, reducing the overlapping time.

Qwen2.5 with PPO. We train PPO with Qwen2.5 as both the actor and critic, using model sizes of 1.5B, 7B, and 14B, scaling from 16 to 256 GPUs. We use a rule-based reward, a maximum sequence length of 12288, and a rollout batch size ranging from 256 to 1024 depending on GPU count. RLinf-Spatial allocates GPUs in a 4:1:1:1:1 ratio for rollout, actor inference, actor training, critic inference, and critic training. Figure 10 presents the results. For the 1.5B model, RLinf-Spatial outperforms veRL by 69.6%, 35.0%, and 35.6% on 16, 32, and 64 GPUs, respectively. In contrast to the GRPO experiment, RLinf-Spatial surpasses RLinf-Temporal by 39.8%, 19.4%, and 18.6%.

For the 7B model, RLinf-Spatial outperforms both veRL and RLinf-Temporal by 38.7–60.7% and 19.0–44.8%, respectively. As shown in Figure 11, RLinf-Temporal exceeds veRL mainly due to speedups in "Others", which includes context-switch overhead (offload/onload), parameter resharding, advantage computation, and inter-stage synchronization. RLinf-Spatial performs faster than RLinf-Temporal because rollout, inference, and training overlap effectively. Although rollout in spatial mode is 39.3% slower than in temporal mode, inference and training finish quickly once rollout completes. The 14B model shows similar trends with smaller gains, i.e., RLinf-Spatial is 27.2–56.5% and 17.7–25.7% faster than veRL and RLinf-Temporal, respectively.

Qwen3-30B-A3B with GRPO. We evaluate the MoE model Qwen3-30B-A3B on 32, 64, and 128 GPUs with a rollout batch size of 1536 and sequence length 20480. We disable logprob recomputation, a common configuration in RL, which removes the inference stage. Since Slime is optimized for MoE RL training, we compare against two variants: Slime (spatial mode without pipelining, as Slime does not support pipelining) and Slime-Colocate (temporal mode). As shown in Figure 12, Slime is the slowest because rollout and training run on disjoint GPU sets with no execution overlap. For 32 and 64 GPUs, RLinf-Temporal performs similarly to Slime-Colocate, while RLinf-Spatial (1:1 rollout-to-training GPUs) is 31.2% and 7.2% faster than Slime-Colocate, respectively.

Figure 13 presents the performance breakdown. Spatial mode achieves shorter rollout time because temporal mode suffers from memory contention between rollout and training, forcing much smaller parallelism (i.e., *max_running_requests* of 128 vs. 256 in SGLang). In addition, RLinf-Spatial achieves good rollout–training overlap. On 128 GPUs, RLinf-Temporal outperforms Slime-Colocate by 3.7% due to better scaling from decoupled system design; both stages run slightly faster. RLinf-Spatial underperforms because rollout and training do not overlap well, where training continues for 80 seconds after rollout completes.

5.1.2 Agentic RL Training

To demonstrate RLinf's flexibility beyond standard reasoning workloads, we evaluate it on Search-R1-style [22] retrieval-augmented agentic RL workflows that require external tool calls and search interactions. Unlike the rigid structure of standard PPO or GRPO, these workflows introduce highly variable-length tool-call traces. RLinf seamlessly supports

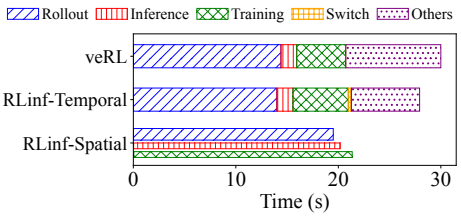

Figure 11: Latency breakdown of Qwen2.5 7B with PPO on 32 GPUs. The vertical width of bar presents the number of GPUs.

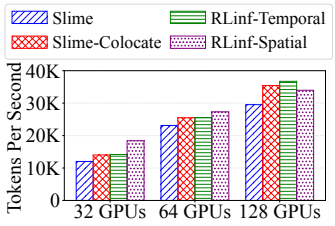

Figure 12: RL training throughput of Qwen3-30B-A3B on RLinf and Slime under different cluster scales.

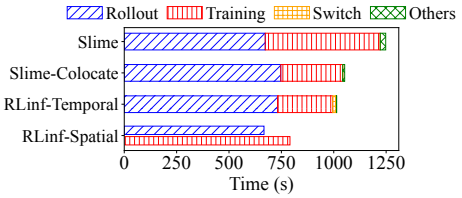

Figure 13: Latency breakdown of Qwen3-30B-A3B with GRPO on 32 GPUs. The vertical width of bar is proportional to the number of GPUs.

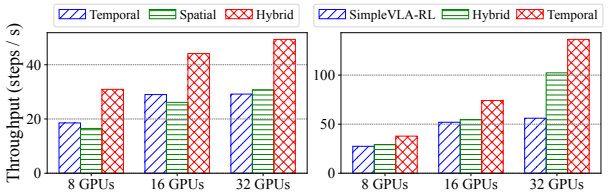

(a) ManiSkill (b) LIBERO

Figure 14: End-to-end throughput of RLinf and SimpleVLA-RL under different cluster scales.

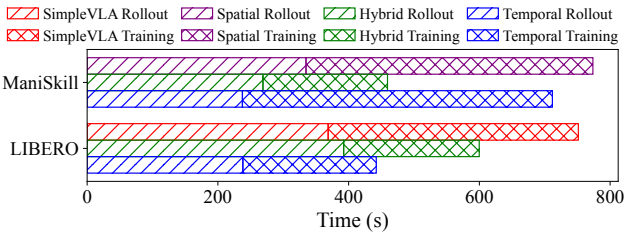

Figure 15: Latency breakdown of ManiSkill and LIBERO.

these complex patterns with its unified worker abstraction. By leveraging M2Flow to overlap generation, external tool invocation, and training steps, RLinf drastically improves execution efficiency.

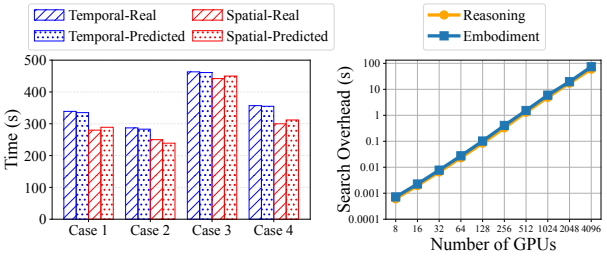
We compare RLinf against the official Search-R1 implementation [21], which is built on veRL. Both systems train Qwen2.5-3B with the Search-R1 agentic workflow on a single node with 8 NVIDIA H100 GPUs, using the same dataset and hyperparameters. RLinf achieves an end-to-end throughput of 67.3 requests/s compared to the 30.4 requests/s of the standard Search-R1 implementation, delivering a 2.2× throughput improvement.

5.1.3 Embodied RL Training

Experimental Setup. We evaluate on OpenVLA [24] and OpenVLA-OFT [23], two vision-language-action models that are supervised-finetuned using RL4VLA [28] and SimpleVLA-RL [25], respectively. We train OpenVLA on ManiSkill [54] and OpenVLA-OFT on LIBERO [27], two widely used embodied environments that emulate physical tasks such as pick-and-place. On LIBERO, we compare RLinf with SimpleVLA-RL (commit d001d) [25], which is built on veRL. On ManiSkill, no distributed RL baseline exists, so we compare different execution modes of RLinf. Training speed is reported in steps/sec, computed as the total number of environment steps divided by the iteration time.

ManiSkill Environment. We train OpenVLA on the "PutCarrotOnPlateInScene-v2" task [28] using 256 parallel ManiSkill environments, each stepping for 80 steps per iteration. Figure 14(a) reports end-to-end throughput across three execution modes in RLinf on 8, 16, and 32 GPUs. RLinf-Hybrid achieves 52.2–69.1% higher throughput than RLinf-Temporal and 60.7–87.2% higher than RLinf-Spatial. For ManiSkill environment, the per-step environment time remains nearly constant as parallelism increases (Figure 3b) and scaling parallel environments is primarily limited by GPU memory. Thus, dedicating GPUs to environment execution is advantageous. As rollout (i.e., environment and generation) and training all require GPU memory, temporally sharing GPUs between rollout and training is more effective. Thus, RLinf-Hybrid performs much better than the other two. In RLinf-Temporal, environments and generation must coexist in memory, constraining both the number of environments and the batch size, ultimately reducing GPU utilization. RLinf-Spatial splits GPUs across the components, forcing training to retain a sufficient number of GPUs, which leaves too few GPUs for rollout and significantly slows it down.

LIBERO Environment. We train OpenVLA-OFT on the public benchmark task groups provided by LIBERO, using 512 parallel environments, each running 64 steps per iteration. The results in Figure 14(b) show that RLinf-Temporal is 37.8%, 42.6%, 143.4% faster than SimpleVLA-RL on 8, 16, 32 GPUs respectively. As shown in Figure 15, both rollout and training are faster in RLinf-Temporal than in SimpleVLA-RL due to (1) the elimination of redundant environment initialization during rollout, and (2) the use of a single forward pass to compute both action and log probability, with only a modest memory increase. RLinf-Temporal also scales better thanks to its decoupled system design and more efficient implementation. In contrast to ManiSkill, RLinf-Hybrid performs worse



(a) (b)

Figure 16: (a) The real and predicted latency in different cases. (b) The search overhead under different cluster scales.

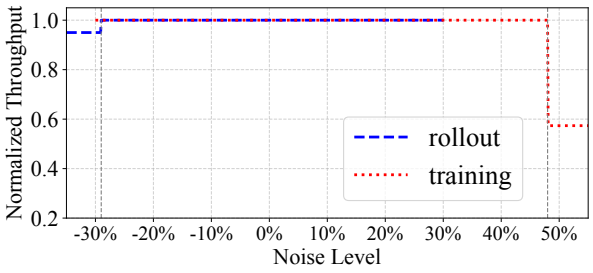


Figure 17: Sensitivity of RLinf's scheduling to profiling noise.

than RLinf-Temporal because LIBERO environment is CPU-intensive; allocating environments on a subset of GPUs limits the utilization of CPU cores, making its rollout stage even slower than that of SimpleVLA-RL.

5.2 Effectiveness of Search Policy

We evaluate the search policy along two dimensions: (a) the accuracy of end-to-end throughput estimates derived from profiling data, and (b) the search speed as the number of GPUs increases.

Estimation Accuracy. Figure 16(a) compares real and predicted iteration times across four Qwen2.5–GRPO settings. Cases 1 and 2 use the 1.5B model on 128 GPUs with temperatures 0.6 and 1.0, while Cases 3 and 4 use the 7B model on 64 GPUs with the same temperature settings. Temporal mode achieves estimation errors below 2% because its end-to-end time is well approximated by summing profiled worker times. Spatial mode with pipelining shows slightly higher errors (<5%), mainly due to response-length variability that causes pipeline imbalance. These errors are small enough that they do not change the ranking of feasible execution modes, allowing the search policy to consistently select the most efficient mode for the above end-to-end experiments.

Search Speed. Search complexity is dominated by the number of workflow-graph nodes and available GPUs. RL workflows typically have fewer than ten nodes, allowing our dynamic-programming search to finish quickly. For a graph with three nodes (e.g., Qwen2.5-GRPO or ManiSkill) and GPU counts ranging from 8 to 4096 (Figure 16(b)), search time grows polynomially with the GPU count, consistent with the $O(N^2)$ analysis in §3.4, and remains under 60 seconds on 4096 GPUs, demonstrating the efficiency of our algorithm.

Sensitivity Analysis. To evaluate RLinf's robustness against profiling inaccuracies, we conduct a sensitivity analysis by injecting synthetic noise into the profiled execution times for different phases and measuring the actual throughput of the resulting placement. The experiment runs on a 1.5B model trained with GRPO on 128 GPUs. As Figure 17 shows, RLinf maintains optimal throughput across a wide noise range.

Table 2: Evaluation scores of RLinf-math-1.5B/7B and open-source models. GPQA represents GPQA-diamond.

Model	AIME24	AIME25	GPQA	Avg.
1.5B models				
Base model	28.33	24.90	27.45	26.89
DeepScaleR [30]	40.41	30.93	27.54	32.96
AReaL [13]	44.42	34.27	33.81	37.50
FastCuRL [53]	43.65	32.49	35.00	37.05
RLinf	**48.44**	**35.63**	**38.46**	**40.84**
7B models				
Base model	54.90	40.20	45.48	46.86
AReaL [13]	61.66	49.38	46.93	52.66
Skywork [15]	66.87	52.49	44.43	54.60
Polaris [2]	**68.55**	51.24	43.88	54.56
AceMath [29]	67.30	**55.00**	45.57	55.96
RLinf	68.33	52.19	**48.18**	**56.23**

Specifically, it tolerates underestimated rollout times (negative noise) down to roughly -29% and overestimated training times (positive noise) up to roughly $+48\%$. Because GPU allocation is discrete, minor variations in estimated phase latencies do not shift performance bottlenecks enough to alter the optimal resource distribution; the search policy simply converges on the same physical placement. The throughput drops only occur when extreme noise tricks the algorithm into a suboptimal configuration. This confirms RLinf achieves optimal scheduling without requiring perfectly precise profiling.

5.3 Model Performance

We comprehensively evaluate the performance of the models produced by the reasoning and the embodied RL training, respectively, to demonstrate the effectiveness of RLinf. We emphasize that RLinf does not modify the underlying RL algorithms. The downstream task scores reported below serve only to confirm that RLinf trains models correctly, and that its higher per-iteration throughput translates into improved model quality within a fixed wall-clock and compute budget.

Reasoning RL Training. We applied GRPO training, a built-in RL algorithm in RLinf, on two base models, i.e., DeepSeek-R1-Distill-Qwen-1.5B and DeepSeek-R1-Distill-Qwen-7B, to improve their math reasoning ability. As shown

Table 3: OpenVLA model success rate results on ManiSkill3.

Model	Vision	Semantic	Position	Avg.
RL4VLA [28]	80.47%	75.00%	81.77%	79.15%
RLinf	**82.03%**	**78.35%**	**85.42%**	**81.93%**

Table 4: OpenVLA-OFT success rate after RL on LIBERO.

Model	Spatial	Object	Goal	Long	Avg.
OpenVLA-OFT(one-traj) [25]	56.45%	25.60%	45.59%	9.68%	34.33%
RLinf	**98.99%**	**98.99%**	**98.99%**	**94.35%**	**97.83%**

in Table 2, the models trained with RLinf achieve the best average performance compared to the baseline systems. RLinf 1.5B model outperforms the baselines across all the three benchmarks (i.e., AIME 24 [63], AIME 25 [64], GPQA-diamond [45]), improving by up to 20 points over its base model. RLinf 7B model achieves the highest performance on GPQA-diamond.

Embodied RL Training. We also evaluate the performance of the models after embodied RL training using RLinf. Table 3 and Table 4 present the evaluation results on the ManiSkill and LIBERO tasks by training OpenVLA and OpenVLA-OFT models respectively, using the PPO algorithm. For ManiSkill, the trained OpenVLA achieves higher success rate than the RL4VLA [28] baseline system. For LIBERO, we further train the publicly released OpenVLA-OFT model (one-trajectory fine-tuned version) from SimpleVLA-RL [25]. By comparing its task success rates with those of the model RL trained using RLinf, we find that RLinf significantly improves OpenVLA-OFT's performance on the LIBERO tasks.

6 Related Works

RL Training Frameworks. RL training frameworks adopt varying system designs to support large-scale alignment tasks [8, 38], typically falling into either task-colocated or task-separated execution modes. For task-colocated systems, DeepSpeed Chat [60] and veRL [51] put all training phases on shared GPUs for simplified orchestration. In contrast, task-separated systems like NeMo-Aligner [50] and Open-RLHF [17] divide components across devices to improve modularity and scalability. AReaL [13] further introduces an asynchronous model-update algorithm upon task-separated systems to increase training throughput. Unlike these frameworks, RLinf provides a more flexible component-to-device placement mechanism, enabling practitioners to explore and deploy more efficient execution configurations tailored to workload characteristics.

Distributed Training Systems for LLM. Distributed training frameworks for LLMs [26, 66, 67] and system-level optimizations for memory [7, 18, 32] and communication [6, 20, 31] have significantly advanced large-model scaling. Megatron-LM [52] combines tensor, pipeline, and data parallelism to improve scalability, while DeepSpeed [44] introduces the ZeRO family of techniques [42, 43, 46] that shard optimizer states, gradients, and activations to reduce GPU memory usage. Although distributed RL systems face similar multi-device scaling challenges, RL workflows are more dynamic due to interactive data generation and asynchronous updates, making system design and optimization substantially more complex.

Dataflow System. Traditional dataflow systems [9, 19, 34, 62] excel at large-scale data processing through static task graphs and centralized scheduling, making them efficient for batch and streaming workloads with predictable structures. In contrast, RL training pipelines feature dynamic task graphs and asynchronous components (e.g., data collection, policy updates), requiring more flexible coordination than existing systems. Modern frameworks such as Ray [33] fill this gap with actor-based execution and decentralized control, making them better suited for orchestrating complex RL workflows.

7 Conclusion

Reinforcement learning is poised to surpass pretraining as the driving force behind LLM progress, but its workflows are too diverse and dynamic for rigid execution models. RLinf shows that by decoupling workflow logic from execution through the novel macro-to-micro transformation mechanism, we can unlock both efficiency and programmability. Beyond RL, we see this approach as a blueprint for future AI runtimes: systems that flexibly orchestrate heterogeneous components, e.g., training, inference, simulation, and reasoning, under one unified execution framework. We believe RLinf marks an early step toward the operating system for AI workloads.

Acknowledgments

We thank our anonymous reviewers and shepherd for their invaluable suggestions. We also express our sincere appreciation to the RLinf open-source community. The continuous stream of code contributions, feature requests, and user experience feedback from our GitHub contributors has been vital to the system's success and optimization. Abstract

Modern reinforcement learning (RL) workloads, powering large language models, long-horizon reasoning, and agentic systems, exhibit extreme dynamicity due to heavy-tailed rollouts, irregular multi-turn tool interactions, and time-varying bottlenecks. Static resource allocations in today's distributed RL systems leave large fractions of compute idle and prolong training. This paper presents DynaRL, the first RL system that dynamically reallocates computation, memory, and communication resources across heterogeneous RL components. DynaRL models the entire RL pipeline with a dynamic hypergraph that serves as a centralized, continuously-evolving control surface. Supported by a unified resource migration interface and context-aware data routing, the scheduler reallocates GPUs from overprovisioned components to the current bottleneck via a combination of a multi-level scheduling algorithm and fine-grained resource migration. Comprehensive evaluation demonstrates that DynaRL improves end-to-end throughput on math-reasoning and agentic RL workloads by up to 1.98×, with negligible online scheduling overhead.

1 Introduction

Reinforcement Learning (RL) has rapidly expanded from traditional control and game-playing tasks [6, 7] to the foundation of modern reasoning and agentic systems [2, 15]. Today's RL workloads power large language/vision models, long-horizon planning agents [1], and tool-augmented agentic systems. As these workloads grow in scale and complexity, training increasingly relies on distributed clusters of hundreds of GPUs. However, unlike conventional deep learning workloads, RL pipelines integrate heterogeneous components, e.g., rollout generation, inference, multi-step tool calls, environment interactions, and policy optimization training, that interact in highly irregular and time-varying patterns.

This heterogeneity introduces substantial *dynamicity* throughout the pipeline. Rollout generation involves autoregressive model inference [17] whose response lengths exhibit heavy-tailed distributions, causing long-tail stragglers and significant GPU underutilization. Agentic RL amplifies this effect. Models repeatedly invoke external tools such as search engines, Python interpreters, or theorem provers [10], producing unpredictable multi-turn interaction traces that vary in both length and latency. These irregular interactions disrupt scheduling and create bottlenecks that cascade across the training pipeline. As our characterization shows, such dynamicity can waste up to 60% of available compute and create large oscillations in effective throughput.

Unfortunately, existing RL systems are largely static. They allocate GPUs to each component ahead of time and maintain this allocation throughout RL training. This static partitioning fundamentally mismatches the time-varying demands of modern RL workloads. When long-tail rollouts dominate, the GPUs assigned to rollouts become increasingly underutilized; when multi-turn interactions inflate generation load, rollout workers become severely underprovisioned; and when tool calls bottleneck progress, KV caches in inference engines are repeatedly evicted and rebuilt. The result is unstable throughput, inefficient resource usage, and prolonged training time.

This paper argues that *dynamic scheduling must become a first-class design principle* for next-generation distributed RL systems. RL training is inherently multi-component and feedback-driven, i.e., progress in one stage depends on the outputs and timing of others. If a system can observe runtime signals, detect shifts in bottlenecks, and reallocate resources in real time, while respecting dependencies and preserving training state, it can significantly improve end-to-end training efficiency and stability. However, enabling such dynamic management is challenging. RL components differ widely in structure, statefulness, and communication patterns; migrations must occur safely without violating components' execution semantics; and the training pipeline must remain efficient despite constantly shifting parallelism.

We present DynaRL, a unified runtime and scheduling system that dynamically reallocates computation, memory, and communication resources across heterogeneous RL components. At a high level, DynaRL *captures the entire RL pipeline*

in a single, continuously evolving runtime object and exposes it to the scheduler as a dynamic hypergraph that encapsulates both static structure and time-varying execution signals. Alongside this global control surface, DynaRL provides a unified resource-migration interface that lets the scheduler safely resize the parallelism of diverse components at interruptible points, using statefulness-aware migration strategies. Finally, it embeds context-aware data routing to attach semantic affinity and multi-step metadata to dataflow edges, preserving KV-cache locality and enabling multi-turn-aware request scheduling.

Built on these mechanisms, DynaRL employs a multi-level dynamic scheduling algorithm that detects overprovisioned components from hypergraph signals and reallocates their GPUs to the current bottleneck stage, by jointly adjusting resource allocation across components, within each WorkerGroup, and at the request data level, where it prioritizes short, late-stage tool calls to exploit KV-cache reuse and accelerate episode completion.

We implement DynaRL in around 7K lines of Python atop RLinf [22], an open-source general RL framework, integrating with existing inference engines (e.g., SGLang [32]) and training backends (e.g., Megatron-LM [20]). Our experiments on math-reasoning and multi-turn agentic RL workloads show that DynaRL consistently improves throughput over state-of-the-art RL systems such as verl and RLinf by up to 1.98× while adding less than 1% overhead for online scheduling and migration. We plan to release the full codebase of DynaRL.

This paper makes the following contributions:

- We characterize the dynamicity of modern RL workloads, demonstrating substantial long-tail rollouts, irregular multi-turn tool-use patterns, and resulting system inefficiencies across production-scale deployments.
- We design and implement DynaRL, the first system to realize dynamic scheduling for distributed RL pipelines via a unified control surface, safe migration mechanisms, and overprovision-driven scheduling.
- We comprehensively evaluate DynaRL on math-reasoning and multi-turn agentic RL workloads, showing significant throughput improvements over state-of-the-art RL systems.

2 Background and Motivation

2.1 Diverse RL Workloads

Distributed reinforcement learning. Reinforcement Learning (RL) has evolved from its early use in small-scale game-playing and robotic control to a key technique for training large foundation models for reasoning and decision-making. These workloads increasingly run in distributed settings to meet the compute and data demands of large models. Modern RL pipelines exhibit substantial structural diversity, as shown in Figure 1. A typical workflow comprises generation (producing rollouts given prompts), inference (computing log probabilities), and training (updating model parameters). However, the composition and dependencies of these components vary widely across algorithms. For example, GRPO contains only three major components, whereas PPO-based RLHF requires a substantially more complex seven-component pipeline with more data and control dependencies. This variability complicates system design and resource scheduling.

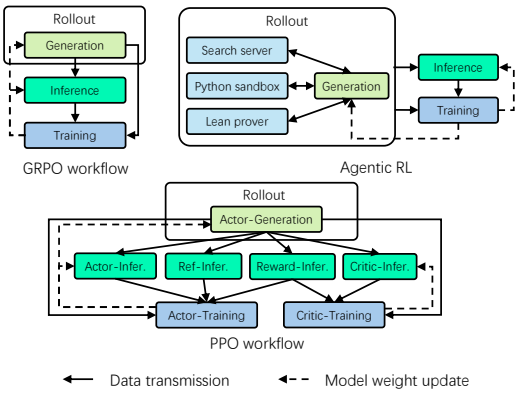

Figure 1: Diverse RL workflows in various scenarios.

Agentic reinforcement learning. Recent agentic RL approaches further expand workflow complexity by integrating external tools into the rollout process. Systems such as DeepResearch combine LLM generation with search engines, databases, and iterative refinement loops; math-reasoning pipelines may involve Python interpreters or theorem provers such as Lean [10]. These tool-augmented rollouts introduce fine-grained and highly irregular dependencies between components. As a result, the training pipeline frequently stalls while waiting for upstream results, creating severe workload imbalance and resource underutilization.

2.2 The Dynamicity Challenge of RL

Dynamic behavior is inherent and pervasive in RL training. An RL pipeline repeatedly generates solutions for given tasks, e.g., responses to prompts or actions to perform, which can vary significantly due to differing response lengths, unpredictable numbers of reasoning steps, and on-demand tool usages. In this section, we quantitatively analyze such dynamicity in production RL workloads and pinpoint two major sources of dynamicity in RL training, namely long-tail model generation and irregular external interactions.

Dynamicity in long-tail generation. Rollout generation with model inference is highly unpredictable—generation response length can vary significantly across queries, which is positively related to the computation time due to the auto-regressive nature of most modern foundation models. To deeply understand this, we studied the variation in gener-

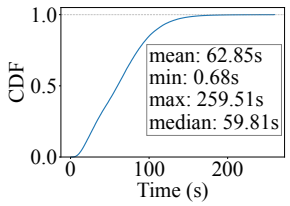

Figure 2: Decode time in a math-reasoning RL task.

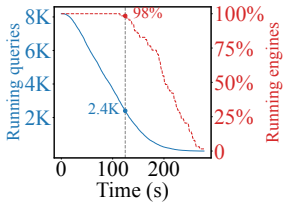

Figure 3: Running query and inference engine variation in a math-reasoning RL task.

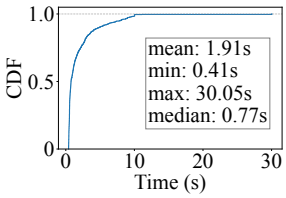

Figure 4: Tool call time in an agentic RL task.

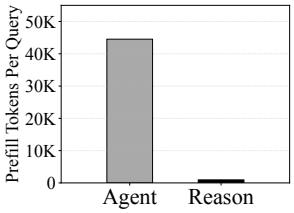

Figure 5: Average prefill tokens in a typical agentic RL and single-turn math RL.

ation response length in a typical math-reasoning RL task on a 1.5B-parameter language model using the GRPO algorithm, which involves a minimal number of components and no other interfering dynamicity like tool calls.

As shown in Figure 2, the decode time of math queries shows a skewed distribution. Only a small fraction of the queries reach near the maximum decode time (259.51s), while roughly 95% of the queries finish in under 150s (about 60% of that limit). Figure 3 further demonstrates the variation of running queries and running inference engine ratio (among 64 engines) during the rollout generation process.

Specifically, the blue curve tracks the number of active queries, while the red curve indicates the active engine ratio at the same time, which represents the percentage of engines still processing incomplete requests. As shown, at the middle of the generation, only less than 30% of queries remain unprocessed. The long-tail responses stall the entire rollout stage and introduce substantial computation waste. Moreover, because long-tail responses are evenly scattered across inference engine instances, many instances are highly underutilized, being stuck on the remaining one or two responses, and thus cannot be terminated to release resources. As in Figure 3, even when $<$30% of queries remain, almost all engines are still running. This idle time and underutilization can waste up to 60% of available computation, without considering KV-cache memory usage.

Dynamicity in irregular external interactions. Apart from generation dynamicity, emerging RL scenarios like agentic RL and embodied RL introduce another major source of dynamicity—irregular external interactions. Based on the generation results (in the form of commands or actions), the training pipeline needs to interact with external tools or environments like search engines, Python interpreters, program compilers, etc., to handle more complex tasks.

Such interactive workflows mostly follow the ReAct paradigm [28], where the model generates an intermediate output, optionally invokes tools, concatenates the tool results with prior context, and uses that as the next-turn input. Figure 4 shows the tool call time in a multi-turn agentic RL setting, which also yields a highly skewed distribution.

Worse still, the default scheduling policy in popular inference engines (e.g., SGLang and vLLM), i.e., First-In-First-Out, or FIFO, may further aggravate the resource waste problem. Engines such as SGLang mark a completed query's KV cache as evictable and can only reuse it if the next-turn input is scheduled promptly before it is evicted. Under FIFO scheduling, however, the second turn of the first query is often delayed for an unpredictable amount of time as it waits for all the first-turn interactions of the remaining queries to finish, causing severe KV cache thrashing and re-prefilling of tokens. Figure 5 compares the number of prefilled tokens per query during the training of agentic RL with multi-turn interactions and math-reasoning RL without interactions using SGLang. Under the same KV cache memory threshold (100 GB), we can clearly observe that tool-call interactions induce considerable re-prefilling due to KV cache thrashing.

2.3 Dynamic Scheduling as the Core

The increasing dynamicity in modern RL workflows has presented serious challenges for existing RL systems, which mostly rely on static resource partitioning for resource allocation—computation resources like GPUs are either physically divided or temporally multiplexed among different components ahead of training. With foundation models beginning to interact more and more with the real world to solve complex tasks, the dynamicity challenge motivates us to rethink the design paradigm of distributed RL systems.

We recognize that the RL training process involves multiple heterogeneous components, including rollout generation, tool interactions, inference, and policy optimization, which interact in complex and time-varying ways.

While this multi-component structure complicates scheduling, it also presents a key opportunity: resources can be dynamically reallocated to match the workload demands, improving overall efficiency. For example, when rollout generation is bottlenecked by long-tail responses, resources can be shifted to accelerate training.

Consequently, we argue that to achieve high efficiency and stable convergence, a distributed RL system must be able to dynamically coordinate computation, memory, and communication resources across nodes and GPUs. This requires a runtime that can observe, predict, adapt to workload variations

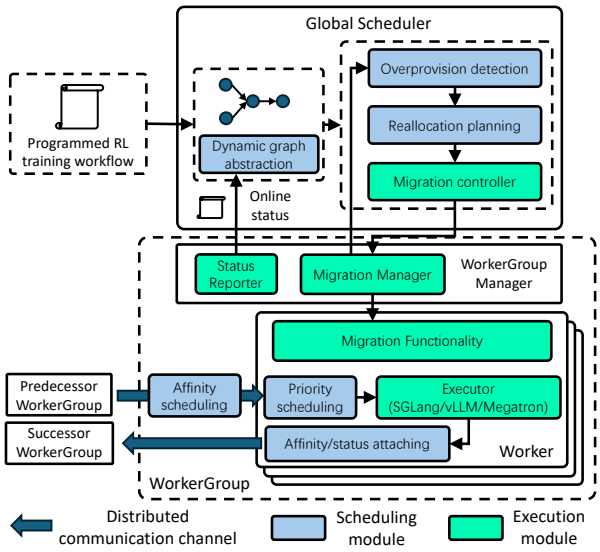

Figure 6: The system architecture of DynaRL.

```python
class HyperNode:
    # static node attributes
    component_type   # dynamic or static

dynamic_schedule(graph: HyperNode[], resource:
 ↪ Resource[])
```

Figure 7: The definition of the dynamic graph.

in real time, and balance resource usage without disrupting the delicate feedback loops in RL training, posing a unique and complex systems challenge that demands a joint understanding of both system-level performance and algorithmic stability. Therefore, beyond an optimization, we envision dynamic scheduling to be a core design principle and challenge for next-generation distributed RL systems.

3 DynaRL Overview

DynaRL is a unified runtime and scheduling system designed to dynamically reallocate resources across heterogeneous RL components, with the goal of maximizing the end-to-end throughput of RL training pipelines whose components' load shifts rapidly over time.

As shown in Figure 6, DynaRL runs as the scheduling plane of a general RL framework, e.g., verl [19] or RLinf [22], which provides the basic infrastructures for composing RL training pipelines and defining diverse components. In such a framework, an RL component (e.g., rollout, tool caller, trainer) is implemented as a group of distributed *Workers* (termed *WorkerGroup*), each of which is a process running on the allocated compute resources (e.g., GPUs). The framework handles the low-level details of assigning Workers to resources, establishing communication channels among Workers, and executing the distributed program, but assumes a static resource allocation throughout training.

DynaRL runs atop the framework also as a WorkerGroup like other components, which contains a *Global Scheduler* and multiple *WorkerGroup Managers* (one per WorkerGroup). Together, they form a feedback-driven control loop. Runtime signals collected from Workers are reported to the Global Scheduler by the WorkerGroup Managers; the Global Scheduler then computes new allocations based on these signals; and the WorkerGroup Managers enact the decisions with minimal disruption to the ongoing training. This design decouples scheduling from the specific implementation of diverse components, allowing DynaRL to continuously adapt to shifting rollout length distributions, changing inference workloads, and evolving training bottlenecks.

In the following sections, we first present the system-level designs and mechanisms that enable dynamic scheduling in DynaRL (§4), and then describe the core scheduling algorithm that drives resource reallocation (§5).

4 DynaRL System Design

Fundamentally, dynamic scheduling can be viewed as online resource migration across components. A component experiencing resource underutilization can release part of its allocated resources (usually by scaling down) to other components that are bottlenecked (by scaling up).

However, the intricate dependencies and stateful nature of RL training pipelines pose systematic challenges to resource migration at *abstraction, resource, and data levels*: (1) **Abstraction level**, how to effectively capture both static structure and runtime variability of RL pipelines, enabling the scheduler to reason about component dependencies and performance dynamics? (2) **Resource level**, how to safely enact resource migration at runtime without disrupting training correctness, when delicate stateful components such as a distributed trainer with cumulated gradients and optimizer states are involved? (3) **Data level**, how to enable efficient data flows for dynamic and interactive components (e.g., multi-turn rollout) under complex dependencies and caching effects?

To address these, the key design of DynaRL is to *transform*

complex, heterogeneous RL pipelines into a single, controllable runtime object that enables fine-grained, low-overhead rescaling and rebalancing:

- A dynamic hypergraph abstraction that captures both structure and runtime signals.
- Unified interfaces for safe online resource migration and context-aware data routing.

Together, they allow DynaRL to perform predictive, low-overhead, and component-agnostic scheduling with minimal disruption to ongoing training.

4.1 The Dynamic HyperGraph Abstraction

To capture both static structure and runtime variability, DynaRL models the RL pipeline as a continuously-updated dynamic hypergraph, i.e., a special graph where a node (termed HyperNode) contains a set of homogeneous nodes, and an edge (termed HyperEdge) can connect multiple HyperNodes beyond the traditional one-to-one connection in common graphs. As shown in Figure 7, a HyperNode represents the WorkerGroup of a logical component (e.g., rollout, trainer) along with a set of homogeneous nodes that represent its active Worker instances. Each HyperNode maintains both static metadata (e.g., component type, interruptibility, dependency constraints) and runtime metrics collected from its corresponding WorkerGroup, including resource utilization, queue pressure, and per-worker throughput.

HyperEdges encode dataflow between Workers/nodes and their relevant context information, including a data processing task's progress and affinity with Workers, i.e., which Workers it might prefer or require to run on. This allows tracking the readiness of dependent components and pipeline backpressure, enabling the scheduler to detect emerging bottlenecks and rebalance resources proactively. Also, the recorded context information can facilitate data redistribution after migration, allowing the scheduler to reason not only about component-level bottlenecks, but also about the structural and temporal dynamics of data processing task propagation.

The unified dynamic graph serves as a single, continuously-updated control surface between the scheduler and the runtime system. Downstream, it gathers fine-grained signals such as GPU load, rollout generation speed, and training throughput from each worker. Upstream, it exposes a consistent abstraction that allows the scheduling policy to reason over heterogeneous components without entanglement with component-specific details. By decoupling policy from implementation, the dynamic graph provides the foundation for predictive, low-overhead adaptations such as resizing component parallelism, reallocating GPUs, or throttling request generation, and a principled representation that captures both the structural and temporal dynamics needed for robust online scheduling.

```python
# The unified migration interface
class MigrationManager:
    def migrate(dest_resources)
    def interrupt()

# Migration strategy interfaces
class RebootMigration:
    def shutdown()
    def restart(dest_resources)
class WorkloadMigration:
    def data_collect()
    def data_distribute()
    def suspend()
class p2pMigration:
    def create()
    def state_switch()
    def suspend()
```

Figure 8: The unified interface of resource migration.

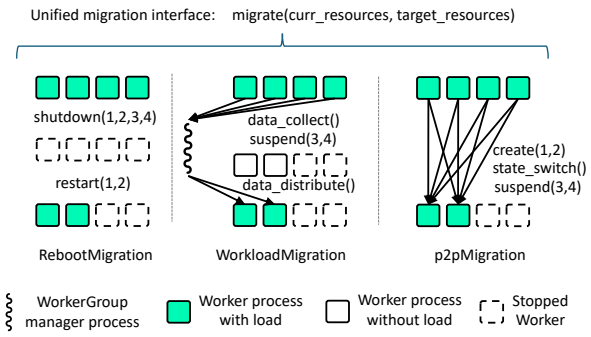

Figure 9: Three types of migration with unified interface.

4.2 Resource Migration

Resource migration is the core mechanism that enables resource rebalancing among components. However, the diverse characteristics of RL components lead to widely varying migration procedures, particularly for stateful components that maintain inter-Worker states or have complex communication patterns. For example, inference engines such as SGLang and vLLM are mostly isolated instances that do not have shared states across Workers, allowing safe migration via process suspension. In contrast, training frameworks such as Megatron-LM maintain tightly coupled states across Workers, e.g., distributed model parameters and optimizer buffers that require synchronization points to be reached before migration.

To accommodate this diversity while maintaining a clean separation between scheduling policy and component-specific details, DynaRL defines a unified migration interface as in Figure 8 that abstracts the resource migration process. The key for safe migration is to identify *interruptible points* in the component's execution flow where migration can occur

without violating correctness. Thus, the interface follows an *interrupt-schedule-migrate* pattern akin to cooperative multitasking in operating systems: (1) The manager process of a WorkerGroup signals the scheduler when it reaches an interruptible point via `interrupt()`. (2) The scheduler determines if a rebalancing is required, (if required) checks for other interruptible components, computes a new resource allocation for all the interruptible components, and instructs the manager to execute `migrate(dest_resources)` with the target resources. (3) The manager performs the migration based on its component-specific migration strategy.

Specifically, certain components (such as the inference engine) are designed to be always interruptible. The `interruptible` attribute in the HyperNode is then set to `always`, allowing the scheduler to trigger migration at any time rather than waiting for specific interruptible points.

Migration Strategy. We identify three fundamental migration strategies that cover a wide range of RL components based on the WorkerGroup statefulness and migration performance, as illustrated in Figure 9. The first is `RebootMigration`, which simply shuts down previous Workers on the source resources, preserves the necessary states, and restarts them on the target resources with the preserved states. This is a generic approach that can work for almost all components, albeit with potentially high overhead. Thus, it is more suitable for lightweight components with negligible restart overhead.

The second is `WorkloadMigration`, which suspends the Workers running on resources to be released, collects their pending and ongoing data processing tasks, and redistributes them to the remaining Workers on the retained resources. This approach is used by stateless components such as inference engines (e.g., SGLang, vLLM) with suspension capability that offload their occupied hardware resources on suspension, allowing safe migration without process restarts.

The third is `p2pMigration`, which launches new Workers on the target resources while keeping the old Workers active. State transfer (e.g., model parameters and optimizer buffers) is performed via planned peer-to-peer communication paths between old and new Workers, after which the old Workers are shut down or suspended. Stateful components such as Megatron-LM leverage this decentralized approach, enabling rapid migration within roughly one second for most cases.

The `p2pMigration` strategy follows a *create-before-destroy* pattern to guarantee atomicity: new Workers are fully initialized and receive complete state transfers before old Workers are suspended or torn down. Specifically, a distributed barrier is enforced before `state_switch()` is invoked. All new-rank Workers must acknowledge full receipt of model parameters, optimizer states, and gradient buffers before the system proceeds. If any transfer fails (e.g., due to a network partition or hardware fault on the destination), the migration is aborted: the newly created Workers are discarded, and the old Workers remain active with their original state intact, effectively rolling back to the previous allocation. This ensures there is no window in which both old and new Workers are partially active for training, and the global training state remains consistent throughout the migration. Only after all new ranks have confirmed readiness does the system atomically switch the active set, tear down the old Workers, and resume training on the new allocation.

```
class DataRouter:
    # HyperEdge
    # affinity: required, preferred, noneed
    def attach_affinity(output, affinity)
    # status: steps, etc
    def attach_status(output, status)
    # requests scheduling
    def distribute_data(data)
    def priority_schedule(data)
```

Figure 10: The interface of the local data router.

Additionally, to handle potential anomalies such as Worker hangs or infinite loops during execution, each Worker in DynaRL runs a background daemon that serves as a heartbeat monitor to receive scheduling commands. Once an anomaly is detected, the scheduler can invoke `RebootMigration` to forcefully shut down the unresponsive previous Workers and restart them on healthy resources.

DynaRL supports all three migration strategies through the unified interface, allowing each WorkerGroup to implement its own migration logic based on its component properties. The interface is shown in Figure 8. We implement the three migration strategies for common RL components including rollout, train, and tool caller as detailed in §6, demonstrating its versatility and generalizability.

4.3 Context-Aware Data Routing

RL training features tightly coupled interactions among components, modeled as HyperEdges in DynaRL. Each HyperEdge aggregates data flowing from one WorkerGroup to another. Efficiently routing these data across and within Workers is essential for end-to-end throughput. For example, in multi-turn rollout, requests belonging to the same episode of interactions may benefit from being processed on the same Worker to leverage the inference engine's KV cache and reduce re-prefilling.

To this end, DynaRL introduces context-aware data routing to realize efficient data flows. The core enabler of this mechanism is a local data router that runs within each WorkerGroup (as a thread or a coroutine), which extracts Worker-specific context and attaches it to outgoing data. Before a Worker forwards data to its successor WorkerGroup, the local router annotates each data item with: (1) affinity infor-

mation indicating where the data was last processed and whether it prefers, requires, or need not use the same Worker (`attach_affinity`); and (2) status metadata, such as sequence IDs that track how many steps the data has progressed across Workers (`attach_status`). The interface is extensible and allows additional metadata to be attached as needed.

With these annotations, the local router governs both inter-Worker data distribution and intra-Worker data ordering. As WorkerGroups communicate through distributed communication channels provided by RL frameworks, the router's `distribute_data` function intercepts outgoing queues to route data to appropriate destination Workers based on affinity constraints. On the receiving side, each Worker invokes `priority_schedule` to decide the execution order of incoming data, enabling fine-grained control under dynamic workloads, particularly in rollout-heavy stages. For example, the SGLang Worker in DynaRL implements a custom priority scheduling policy through this interface to optimize multi-turn interactions (§5).

This context-aware data routing layer allows the system to adapt to the dynamic nature of RL training while preserving efficient data flow across distributed components.

5 DynaRL Scheduling

The goal of DynaRL's scheduling algorithm is to maximize end-to-end RL throughput by dynamically reallocating resources among heterogeneous components, including rollout, inference, and model training, whose resource-performance characteristics diverge substantially over time.

The key idea behind our scheduling policy is to use resource overprovisioning as the primary scheduling signal. A component is considered overprovisioned when (1) allocating additional resources yields only marginal improvements in step-level or end-to-end throughput, and (2) removing a modest amount of resources does not noticeably degrade its performance. Once overprovisioning is detected, DynaRL safely reclaims these underutilized resources and migrates them to the component that currently limits the pipeline, thereby improving overall throughput.

To reason about where overprovision is likely to occur and where reclaimed resources can be most effectively used, DynaRL distinguishes between two types of components—**static** and **dynamic** components. Static components have throughput that scales positively with additional devices (e.g., actor or critic training with abundant input examples), so extra resources directly translate into higher throughput. In contrast, dynamic components exhibit a concave resource-performance curve whose marginal benefit naturally changes as the workload evolves (e.g., rollout whose active sequence count shrinks as trajectories complete), making them prone to entering an overprovisioned regime where additional resources provide little incremental gain.

This design naturally leads to a three-level scheduling framework: *WorkerGroup*-level scheduling on how much resource to allocate across components/WorkerGroups, *Worker*-level scheduling that decides how to balance workload and scale up / down across Workers in one WorkerGroup, and *data*-level scheduling on the distribution and priority of request data for a specific component.

5.1 Online Migration Scheduling

Consider a system with a set of components $\mathcal{C} = \mathcal{C}_S \cup \mathcal{C}_D$, where $\mathcal{C}_S$ is the set of static components and $\mathcal{C}_D$ is the set of dynamic components. The system has a fixed pool of R_{total} homogeneous resources (e.g., GPUs).

- Let $R_i(t)$ be the number of resources allocated to component C_i at time t, with $\sum_{C_i \in \mathcal{C}} R_i(t) \leq R_{\text{total}}$.
- Each component C_i has a throughput function $T_i(R_i)$, which measures its ideal processing rate (e.g., samples per second) when allocated R_i resources.
- For a static component $C_S \in \mathcal{C}_S$, $T_S(R_S)$ is approximately linear: $T_S(R_S) \approx \alpha_S R_S$.
- For a dynamic component $C_D \in \mathcal{C}_D$, $T_D(R_D)$ is a concave function. It has an overprovision point R_D^{oa} where the marginal throughput gain diminishes significantly: $\frac{\partial T_D}{\partial R_D} \ll \alpha_S$ for $R_D > R_D^{\text{oa}}$.

The goal of the scheduler is to find a resource allocation $\mathcal{R} = (R_1, R_2, ...)$ at any given time that maximizes the end-to-end throughput of the pipeline. Since the pipeline is synchronous, the overall throughput is the minimum of the throughputs of its constituent stages (if we ignore the small asynchrony in a pipeline). So the objective of the scheduling algorithm is:

$$\max_{\mathcal{R}} \min_{C_i \in \mathcal{C}} T_i(R_i) \quad \text{s.t.} \quad \sum_{C_i \in \mathcal{C}} R_i \leq R_{\text{total}}. \tag{1}$$

Algorithm 1 describes the procedure of inter- and intra-worker-group resource scheduling. Our algorithm operates in a control loop, continuously monitoring the system and triggering a reallocation when inefficiencies are detected. It consists of two main phases: (1) Overprovision Detection, and (2) Reallocation Planning.

5.1.1 Phase 1: Overprovision Detection

The trigger for rescheduling is the detection of an overprovisioned dynamic component. We implement overprovision detection directly on top of the dynamic hypergraph: for each dynamic component/HyperNode C_D, DynaRL aggregates the per-node utilization reported in its `nodes` field and computes a utilization signal. For rollout components, a practical metric is the average ratio of active Key-Value (KV) cache size to its maximum capacity across all its engines. Formally, for a component with R_D engines,

Algorithm 1: Dynamic Resource Scheduler

8 migrate$(\mathcal{R}, \mathcal{R}_{\text{new}})$;
9 **Function** `DetectOverprovision(`$\mathcal{C}_D, U_{low}, T, \theta$`)`**:**
10 **foreach** $C_D \in \mathcal{C}_D$ **do**
11 low_count $\leftarrow 0$;
12 **foreach** *worker* $\in C_D.workers$ **do**
13 $U_{\text{avg}} \leftarrow$ avg_utilization(worker, T);
14 **if** $U_{avg} < U_{low}$ **then**
15 low_count $\leftarrow$ low_count $+ 1$;
16 **if** $low_count/|C_D.workers| > \theta$ **then**
17 **return** C_D;
18 **return** *None*;
19 **Function** `PlanReallocation(`$C_{opv}, \mathcal{R}, \textbf{metrics}$`)`**:**
20 $\{\Delta R^{(1)}, \ldots, \Delta R^{(K)}\} \leftarrow$ GenerateCandidates$(C_{\text{opv}}, \mathcal{R}, \textbf{metrics})$;
21 best $\leftarrow \varnothing$;
22 $\tau_{\text{best}} \leftarrow -\infty$;
23 **for** $k \leftarrow 1$ **to** K **do**
24 $R^{(k)}_{\text{opv}} \leftarrow \mathcal{R}[C_{\text{opv}}] - \Delta R^{(k)}$;
25 $T^{(k)}_{\text{opv}} \leftarrow$ PredictThroughput$(C_{\text{opv}}, R^{(k)}_{\text{opv}}, \textbf{metrics})$;
26 $(\text{alloc}^{(k)}, \tau^{(k)}) \leftarrow$ SearchAllocation$(\Delta R^{(k)}, C_{\text{opv}}, R^{(k)}_{\text{opv}}, T^{(k)}_{\text{opv}}, \mathcal{C}, \mathcal{R}, \textbf{metrics})$;
27 **if** $\tau^{(k)} > \tau_{best}$ **then**
28 $\tau_{\text{best}} \leftarrow \tau^{(k)}$;
29 best $\leftarrow (R^{(k)}_{\text{opv}}, \text{alloc}^{(k)})$;
30 $\mathcal{R}_{\text{new}} \leftarrow \mathcal{R}$;
31 $\mathcal{R}_{\text{new}}[C_{\text{opv}}] \leftarrow \text{best}.R_{\text{opv}}$;
32 **foreach** $C_j \in best.alloc$ **do**
33 $\mathcal{R}_{\text{new}}[C_j] \leftarrow \mathcal{R}[C_j] + \text{best.alloc}[C_j]$;
34 **return** $\mathcal{R}_{new}$;

$$U_D(t) = \frac{1}{R_D} \sum_{j=1}^{R_D} \frac{\text{KV_cache_used}_j(t)}{\text{KV_cache_capacity}_j}.$$

C_D is considered overprovisioned if $U_D(t) < U_{\text{low}}$ for a sustained period T. This indicates that most engines are underutilized. To avoid reacting to transient fluctuations, we employ a persistent condition: rescheduling is triggered only if the utilization of more than θ (e.g., 80%) of C_D's engines is below U_{low} for a continuous duration of T seconds.

In practice, U_{low} can be derived as the p-th (e.g., 20th) percentile of historical utilization data for C_D, while T and θ are hyperparameters that balance responsiveness and stability. Once C_D satisfies this overprovision predicate, the scheduler marks it as a candidate donor in the dynamic graph and proceeds to Phase 2 to plan how many resources to reclaim and where to reallocate them.

5.1.2 Phase 2: Reallocation Planning

Once a dynamic component C_D is identified as overprovisioned, the planner considers multiple resource-reduction candidates. For each candidate, the planner forecasts both the local impact on C_D and the global throughput improvement achievable by reallocating the released resources. The scheduler then selects the candidate with the highest predicted performance improvement.

1. **Generate candidate reductions**. We construct a discrete set of reduced allocation candidates $\Delta R_D^{(1)}, \cdots, \Delta R_D^{(K)}$ (line 20). They represent feasible and stable scaling levels suggested by recent utilization and throughput trends.

2. **Predict component performance**. For every allocation $R_D^{(k)}$, the planner predicts the resulting throughput $T_D^{(k)}$ using a lightweight, continuously updated performance model (line 25). This estimation provides a conservative bound on the potential performance degradation introduced by releasing $\Delta R^{(k)}$. Concretely, the throughput predictor is a statistical regression model. Before training begins, a short profiling stage measures per-component latency and throughput across representative batch sizes and sequence lengths, establishing an initial baseline model that avoids cold-start inaccuracy. During execution, the system continuously collects real-time runtime metrics (observed throughput, queue depth, batch composition) and uses them to dynamically recalibrate the model via online regression updates, ensuring predictions remain accurate as workload characteristics evolve over training.

3. **Evaluate global reallocation benefit**. For each candidate adjustment $\Delta R^{(k)}$, the planner estimates how the system would benefit from redistributing the freed resources. It allocates these resources based on each component's observed throughput characteristics and request-queue dynamics, producing a predicted end-to-end throughput $\tau^{(k)}$ for the candidate configuration (line 26).

4. **Select optimal plan**. Finally, the scheduler selects the candidate that offers the highest predicted system throughput (line 27 - 29):

$$k^* = \arg\max_k \tau^{(k)}.$$

Using the migration interface, the dynamic component is migrated to the resulting new allocation set $R'_D = R_D^{(k^*)}$, while the released resources are assigned to C_{S^*}.

This multi-candidate approach enables the scheduler to make informed trade-offs: aggressively reducing resources allocated to C_D may free more resources for other components but risks making C_D the new bottleneck. By evaluating multiple options, we ensure the reallocation maximizes throughput.

This design also keeps the reallocation behavior stable over time. Migrations are bound to interruptible points (§4.2) and thus occur at the natural batch-level divider of the RL pipeline rather than on every transient signal. Within each decision, the sustained-window predicate in Phase 1 smooths out short-lived queue spikes, and Phase 2 only commits to a new allocation when the continuously-recalibrated throughput predictor reports a strict improvement over the current one, so noise-level imbalances do not flip the decision. The migration itself rebalances in-flight requests across the new worker set as part of the procedure (e.g., `data_collect`/`data_distribute` in `WorkloadMigration`), so the new allocation lands at its predicted operating point without a queue-pressure rebound. Our sensitivity study (§7.5) further confirms that this stability holds across a wide range of scheduling parameters, so the scheduler does not rely on subtle parameter tuning.

This `PlanReallocation` step maintains low overhead as the cluster scales. It evaluates $O(K)$ candidate reductions (K is typically 3–10) across $O(|C|)$ components ($|C|$ is typically 3–7 in RL pipelines). The scheduling complexity is thus $O(K \times |C|)$, independent of the total GPU count. Furthermore, since per-Worker metrics are aggregated at the WorkerGroup Manager level, the global scheduler only processes $O(|C|)$ summaries rather than $O(N_{\text{GPU}})$ individual signals, allowing scheduling to complete within 200 ms even at 128 GPUs.

5.2 Request Data Scheduling

Algorithm 2: Priority-Aware Request Scheduler

Input: Request queue Q, batch size limit B

Function `SelectBatch(`Q`)`**:**
- $\mathcal{S} \leftarrow \varnothing$;
- **foreach** $r \in Q$ **do**
  - $(k_r, m_r) \leftarrow \text{extract_priority}(r)$;
- $Q_{sorted} \leftarrow \text{sort}(Q, \text{key}=(k_r, m_r))$;
- **foreach** $r \in Q_{sorted}$ **do**
  - **if** $|\mathcal{S}| < B$ **then**
    - $\mathcal{S} \leftarrow \mathcal{S} \cup \{r\}$;
- **return** $\mathcal{S}$;

While request scheduling has been extensively studied in online serving systems, it remains largely overlooked in training pipelines. In agentic RL, a single high-level task unfolds into a multi-turn interaction between the model and external tools. Each request re-enters the rollout component multiple times, and the system must maintain and reuse state across these turns (e.g., KV cache). If the scheduler ignores this structure and simply treats each turn as an independent request, it can easily waste GPU cycles by repeatedly recomputing KV cache and inflate end-to-end episode latency by letting short, late-stage turns wait behind many first turns.

To understand how multi-turn structure affects workload characteristics, we examine the response-length distribution across tool-call rounds in a ReAct-style agent, and observe two clear patterns: (1) the first response (round 0) is substantially longer than subsequent ones, and (2) average token generation decreases monotonically as the request approaches completion. In other words, early turns are long and compute-heavy, whereas later turns are short and relatively cheap.

These observations motivate a priority-based scheduling policy in which a request's priority is its tool-call count, i.e., the number of completed tool invocations so far. Intuitively, always giving higher priority to requests with more completed tool calls has two key benefits. First, it increases the likelihood of KV-cache reuse: when a new turn arrives shortly after the previous one, prioritizing that request over fresh, long first-turn prompts prevents the cached state from being evicted and avoids expensive re-prefilling. Second, it accelerates the completion of late-stage episodes, significantly reducing mean job completion time by flushing short, near-finished turns out of the system instead of waiting behind long initial turns.

Furthermore, while longer early turns are not a universal rule for all LLM interactions, they are a strong characteristic driven by task designs and agentic frameworks (e.g., ReAct [28], Plan-and-Solve [24]) where the first turn handles a complex prompt and generates a full plan, making it the most compute-intensive. Later turns are typically short observation-evaluation steps. Even for workloads where later turns are not shorter, the priority scheduler degrades gracefully to near-FIFO behavior while still preserving KV-cache reuse benefits.

Algorithm 2 implements this idea. For each request r in the queue, the scheduler extracts a priority key (k_r, m_r), where k_r is the number of completed tool calls (i.e., the current round index), and m_r is the length of the prefix of this request in the prefix-tree-based KV cache commonly used in LLM inference engines. The latter serves as a tie-breaker: among requests in the same round, those with longer prefixes are more likely to reuse more cache and thus have higher priority. The scheduler then sorts the queue by this key and selects the top-B requests to form the next batch. Compared to FIFO, this multi-turn–aware, tool-call-count-based policy explicitly exploits the response-length skew across rounds to improve both KV-cache efficiency and end-to-end agentic RL performance.

6 Implementation

DynaRL is implemented in 7K lines of Python code atop RLinf [22], an open-source RL framework that is flexible enough to support various resource partitioning modes (it supports both physical partitioning and time-sharing). Among them, 2K lines are for the Global Scheduler, 4K lines for

the migration manager and migration strategy implemented for different RL components (currently rollout, tool agent, trainer, inference, reward are supported), and an additional 1K lines for the HyperGraph extraction, data routing, and other auxiliary components.

HyperGraph Extraction. DynaRL automatically builds the HyperGraph from RLinf programs using lightweight static analysis plus minimal runtime hooks, without requiring manual annotations. On the static side, we parse the Python source of the training pipeline and components using the standard `ast` module that exposes the abstract syntax tree of the program. We identify component classes by their inheritance from RLinf's `WorkerGroup` base and registration APIs (e.g., rollout, trainer, tool agent), and instantiate a corresponding `HyperNode` for each logical component. We then traverse all call sites to the framework's inter-worker communication primitives (e.g., channel put/get). Each such call yields a `HyperEdge` between two `HyperNodes`, and we populate their `predecessors` and `successors` fields accordingly, forming the static skeleton of the hypergraph.

At runtime, WorkerGroup Managers register their concrete workers as `Node` entries under the corresponding `HyperNode`, and periodically update fields such as `allocated_resources` and `utilization` from monitoring signals. Similarly, the framework's communication hooks update the associated `HyperEdge.progress` and affinity metadata as dataflow events occur. This combination of Python AST analysis for structure and low-overhead runtime updates for state yields a continuously maintained HyperGraph that accurately reflects component interactions and is directly consumable by the global scheduler and data router.

Migration Strategy. DynaRL instantiates the three migration mechanisms in Figure 9 according to each component's statefulness and performance sensitivity. For stateless or weakly stateful components such as rollout, tool agents, inference, and reward models, we adopt `WorkloadMigration` to redistribute the request data upon resource migration.

For distributed trainers like Megatron-LM, DynaRL implements `p2pMigration` to transfer two kinds of state: model parameters and optimizer states. Given the old and new parallelism configurations (e.g., data-, tensor-, and pipeline-parallel degrees), the migration manager computes a rank-mapping and resharding plan that determines which source ranks send which parameter and optimizer shards to which destination ranks. The new trainer processes are launched on the target GPUs and participate in a series of peer-to-peer transfers following this plan until all state is materialized under the new sharding. Afterward, DynaRL reconstructs all communication groups (e.g., NCCL process groups for data/tensor/pipeline parallelism) to match the new topology and only then tears down the old ranks. This design allows large, stateful training jobs to change their parallelism layout with sub-second to few-second pauses, making frequent elastic rescaling practical in multi-component RL pipelines.

All remaining components fall back to `RebootMigration`, which simply shuts down workers on the old resources and relaunches them on the new ones with reloaded states.

7 Evaluation

We evaluate DynaRL on comprehensive workloads including math-reasoning RL and multi-turn agentic RL with LLMs of different sizes ranging from 1.5B to 32B on real-world datasets. The experiment results are summarized below:

- For math-reasoning RL, DynaRL consistently outperforms state-of-the-art RL systems (e.g., verl, RLinf) by 1.27×–1.98× on a variety of math-reasoning RL training configurations under different cluster scales.
- For agentic RL, DynaRL achieves 1.06×–1.53× higher throughput than RLinf. With priority-aware request scheduling for multi-turn interactions, DynaRL further improves performance to 1.27×–1.64×.
- The scheduling plan can be generated within 200 ms, and DynaRL applies each reallocation plan within 0.5–5 seconds, incurring less than 1% overhead.

7.1 Experiment Setup

Testbed. We deploy DynaRL on an H100 cluster with 16 nodes and 128 GPUs. Each node has 8 NVIDIA H100-80GB GPUs, and 2 Intel Xeon Platinum 8558@2.1 GHz CPUs with 48 cores and 2TB memory. Intra-node communication utilizes NVLink, while inter-node communication uses 8 Mellanox ConnectX-7 RDMA NICs per node, each providing 400 Gbps bandwidth with RoCEv2.

Baselines. For math-reasoning RL, we compare DynaRL against verl [19] v0.5 and RLinf [22], the state-of-the-art open-source RLHF systems. We choose SGLang [32] as their rollout engine and Megatron-LM [20] as their training backend. To further demonstrate the broader scheduling space of DynaRL, we also compare it against RLHFuse [33], which performs fusion in rollout and inference phases. Since RLHFuse lacks a publicly available artifact, we implemented its core fusion logic within RLinf using the same rollout engine and training backend to ensure a fair comparison. For multi-turn agentic LLM, we compare with RLinf, as verl only supports FSDP [31] for this experiment, which is much slower than the Megatron-LM backend.

Metrics. For the end-to-end experiments, we use RLHF throughput (tokens/sec) as the performance metric following verl [19], which is defined as dividing the total number of tokens in prompts and responses in a global batch by one RLHF iteration time. For multi-turn agentic RL, we use number of processed requests per second (abbreviated as requests per

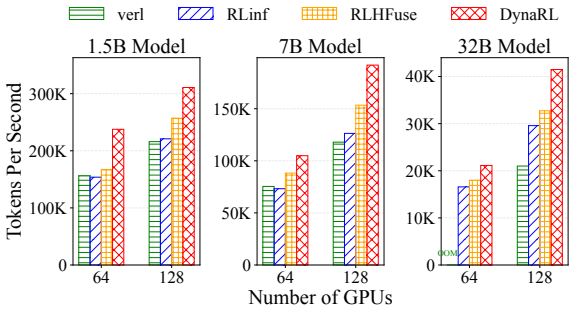

Figure 11: End-to-end throughput of math reasoning RL under different cluster scale and model size settings.

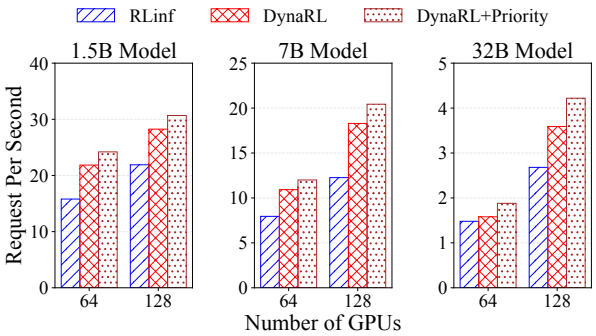

Figure 12: End-to-end throughput of multi-turn agentic RL under different cluster scale and model size settings.

second). All reported performance numbers are averaged over 10 training iterations after warm-up.

Datasets. For math-reasoning RL, we use the AReaL-boba-Data dataset [26]. This dataset integrates multiple standard datasets including DeepScaleR [12], Open-Reasoner-Zero [9], Light-R1 [25], DAPO [30], NuminaMath [14] (AoPS/Olympiad subsets), and ZebraLogic [11]. Overly simple problems are filtered out to ensure dataset quality and effectiveness. For multi-turn agentic RL, we use the rstar2-agent dataset [18], which includes tasks from the DAPO training set, problems from the AoPS forums via OpenMathReasoning [13] and Project Euler [3].

Configuration. For both math-reasoning and multi-turn agentic RL experiments, we use a rollout batch size of 512, group size of 16, and sequence length of 28,672. The trainer tensor-parallel (TP) sizes are 2, 4, and 8 for the 1.5B, 7B, and 32B models, respectively; the corresponding rollout TP sizes are 1, 2 and 4. These configurations remain unchanged as we scale to larger GPU counts.

7.2 End-to-End Experiments

Math-reasoning RL. Math-reasoning RL comprises three stages, i.e., rollout, inference, and training. Existing systems such as verl and RLinf follow a static, sequential execution pattern, dedicating all resources to one stage at a time. Figure 11 compares throughput under baseline's static scheduling and DynaRL 's dynamic scheduling across three model sizes (1.5B, 7B, and 32B) and two GPU scales (64 and 128). As shown, DynaRL consistently improves throughput, with larger gains on larger models.

For the 64 GPU experiments, verl and RLinf exhibit similar performance for 1.5B and 7B models, while DynaRL yields 1.43×–1.55× speedups. Because with static scheduling, rollout eventually runs at low utilization, whereas DynaRL detects overprovisioned components and reallocates their unused capacity to other components. For the 32B model, verl fails due to OOM, and DynaRL achieves a moderate 1.27× speedup over RLinf. The speedup is smaller due to a more constrained scheduling space: with TP size 8, train parallelism can scale when at least 8 idle GPUs are available.

With 128 GPUs, improvements for 1.5B and 7B models stabilize around 1.40×–1.52×. The 32B model, however, benefits significantly more, reaching 1.98× over verl and 1.40× over RLinf, as the larger cluster provides greater flexibility and a wider scheduling space.

Compared to RLHFuse, DynaRL achieves 1.21×–1.42× higher throughput. RLHFuse fuses only the rollout and inference stages, but in practice inference is typically much less time-consuming than rollout, especially at long response lengths, leaving training resources idle as it cannot be fused with other stages. In contrast, DynaRL dynamically schedules resources across all three stages, rollout, inference, and training, jointly, enabling it to better handle diverse components with heterogeneous execution characteristics.

Multi-turn agentic RL. Figure 12 presents the results for multi-turn agentic RL. We compare RLinf with two variants of DynaRL: dynamic allocation alone and dynamic allocation combined with the priority-aware request scheduling policy.

On 64 GPUs, dynamic allocation alone yields 1.06×–1.38× improvement, smaller than in single-turn math reasoning. This highlights the additional scheduling complexity introduced by multi-turn interactions, where rollout becomes more unpredictable. With priority-aware request scheduling, DynaRL achieves 1.51×–1.53× speedups on the 1.5B and 7B models over RLinf. The gains on the 32B model are also smaller (1.27×) due to constrained scheduling space.

When scaling from 64 to 128 GPUs, DynaRL with priority-aware scheduling is 1.40×, 1.64×, 1.58× faster than RLinf on 1.5B, 7B, 32B models, respectively. The benefit of priority-aware scheduling diminishes slightly for the 1.5B and 7B models (from 15% to 11% for 1.5B, and from 14% to 11% for 7B). In contrast, the 32B model experiences increased gains (from 21% to 24%). This divergence stems from KV-cache sufficiency. That is, on 128 GPUs, smaller models can maintain more request prefixes in cache without eviction, reducing the marginal benefit of request-level prioritization.

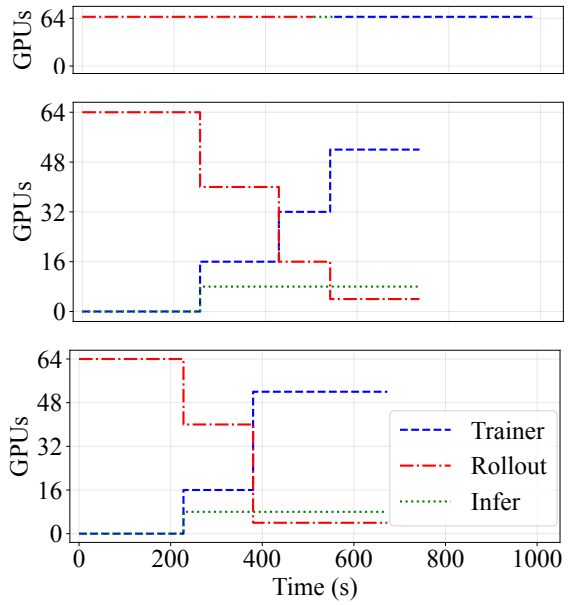

Figure 13: GPU allocation timelines for the three execution modes. From top to bottom: (1) static mode, where all GPUs are assigned to one component at a time; (2) dynamic mode without priority-aware request scheduling, which reallocates resources reactively based on component utilization; and (3) dynamic mode with priority-aware request scheduling, which further prioritizes requests with more completed tool calls. Each plot shows how Trainer, Rollout, and Inference components acquire and release GPUs over time.

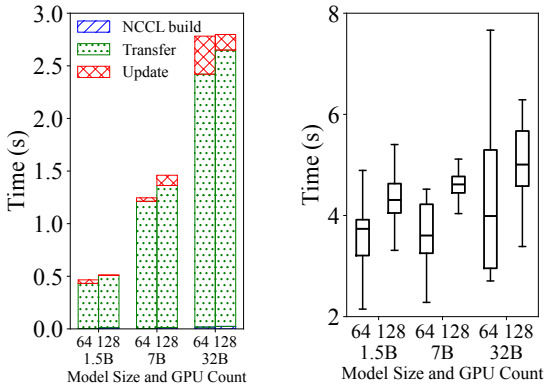
For the 32B model, however, KV-cache pressure remains high, and priority-aware scheduling continues to play a significant role, yielding larger improvements.

7.3 Breakdown of Online Scheduling

Figure 13 illustrates how DynaRL allocates 64 GPUs across rollout, inference, and trainer in the 7B math-reasoning RL experiment. In the top panel, the static configuration fully serializes the three phases, assigning the entire cluster to one component at a time.

The middle panel shows how dynamic allocation reshapes the execution timeline by reallocating GPUs at runtime. At the beginning of the iteration, neither inference nor trainer receives resources because no corresponding requests are yet available. As rollout proceeds, its effective parallelism naturally declines as fewer requests remain. The scheduler detects this underutilization and gradually reallocates GPUs to inference and trainer. This overlap shortens the critical path, i.e., downstream stages start earlier and run concurrently with the tail of rollout, eliminating large idle windows and exposing intra-iteration parallelism that static allocation cannot



(a) Trainer. (b) Rollout.

Figure 14: Trainer and rollout migration cost.

exploit. Inference is consistently assigned fewer GPUs than trainer because it performs only forward passes and maintains no external state (e.g., gradients or optimizer slots), thus requiring substantially less compute for the same number of tokens. Since inference scales adequately with a small GPU budget, DynaRL assigns it a stable initial allocation to avoid unnecessary reallocation overhead.

The bottom panel shows that incorporating priority-aware request scheduling further accelerates resource transitions. By prioritizing rollout requests with more completed tool calls, the system reduces straggler effects and frees GPUs earlier. Consequently, both inference and trainer reach their target allocations sooner and at larger scale. For example, trainer scales to 32 GPUs around 420s under vanilla dynamic allocation, but reaches 52 GPUs by roughly 380s with priority-aware scheduling. Toward the end of the iteration, rollout and inference operate with minimal resources to process long-tail requests, while trainer receives most of the cluster to accelerate training. This demonstrates that fine-grained, request-level scheduling is essential for fully exploiting temporal variability in RL workloads.

7.4 Overhead Analysis

Trainer migration overhead. Figure 14a reports the trainer migration cost across different model sizes. The total migration time grows primarily with model scale, increasing from sub-millisecond ranges for 1.5B to several seconds for 32B, yet still contributes less than 0.5% to end-to-end latency even for the 32B model on 128 GPUs. In contrast, the GPU count has negligible impact. This behavior reflects the design of our trainer migration mechanism, i.e., model states are transferred through fully distributed peer-to-peer communication, allowing the migration cost to mainly scale with the size of the model. As a result, trainer replicas can be rebalanced even

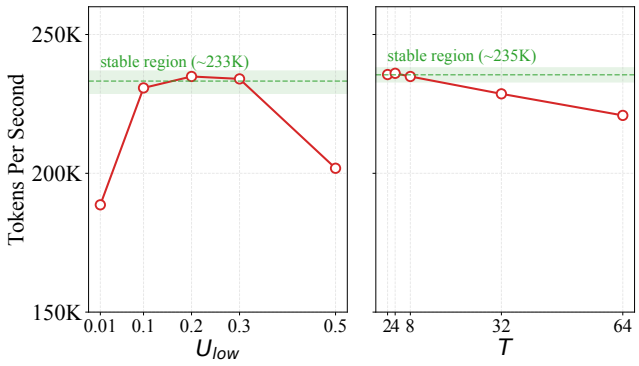


Figure 15: Throughput stationarity of DynaRL under varying scheduling parameters U_{low} (left) and T (right). Shaded bands mark the stable operating regions.

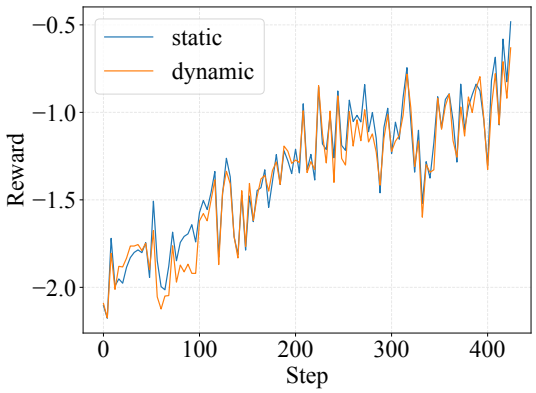

Figure 16: Reward curve of static placement and dynamic scheduling.

on large clusters without incurring significant coordination or communication group rebuild overheads.

Rollout migration overhead. Figure 14b shows rollout migration costs across different model and cluster sizes, averaged over 10 training iterations. Unlike train migration, rollout migration exhibits sensitivity to both model scale and GPU count, as larger rollout groups require more workers to synchronize and transfer running states. Nonetheless, the overall variance remains modest. Migration consistently completes within a few seconds even for the 32B model on 128 GPUs. This small and predictable overhead ensures that migration decisions triggered by dynamic scheduling do not dominate the end-to-end training time. The results confirm that DynaRL 's reallocation mechanism maintains low control-plane overheads and can support frequent, fine-grained resource adjustments during RL training.

Scheduling overhead. We measure the scheduling time during both the reasoning and agentic RL tasks. We find that all scheduling decisions can be made within 200 milliseconds, which is negligible compared to the end-to-end training time. During a training iteration, the total overhead of the scheduling is below 0.5%.

7.5 Parameter Sensitivity

We study the performance sensitivity of DynaRL with respect to its scheduling parameters: the rebalancing threshold U_{low}, which controls how aggressively work is redistributed across stages, and the scheduling window T, which controls how frequently the scheduler reacts to load imbalance. We sweep $U_{low} \in \{0.01, 0.1, 0.2, 0.3, 0.5\}$ with T fixed, and $T \in \{2, 4, 8, 32, 64\}$ with U_{low} fixed, and measure end-to-end token throughput on the 1.5B math-reasoning workload.

Figure 15 shows that DynaRL is largely insensitive to both parameters across more than an order of magnitude. For U_{low}, throughput remains within $\sim$1.5% of its peak (233K tokens/s) over the whole interval $U_{low} \in [0.1, 0.3]$. Performance only degrades at the extremes: an overly small $U_{low} = 0.01$ triggers excessive rebalancing and drops throughput to 188.65K tokens/s ($\downarrow$ 19.7%), while an overly large $U_{low} = 0.5$ suppresses useful rebalancing and yields 201.82K tokens/s ($\downarrow$ 14.1%). For T, throughput stays within 0.5% of peak over $T \in [2, 8]$ (mean 235.5K tokens/s) and degrades only mildly at $T = 32$ ($\downarrow$ 3.1%) and $T = 64$ ($\downarrow$ 6.4%), where the scheduler reacts too slowly to transient imbalance. These results indicate that the stable operating region for DynaRL spans a wide plateau in both dimensions, so practitioners can pick parameters from a broad range without precise per-workload tuning.

7.6 Correctness Verification

Guaranteeing algorithm convergence is a fundamental requirement of DynaRL. To achieve this, all supported migrations strictly preserve the underlying RL semantics by leveraging the interruptible points defined in Section 4.2. During the rollout and inference phases, migrations are executed at the query level; this alters the physical GPU assignment but leaves the execution logic unaffected. During training phases, migrations meticulously preserve model parameters and optimizer states while holding RL hyperparameters (e.g., micro-batch and global batch sizes) constant. For instance, when adjusting the number of GPUs under data parallelism, DynaRL reconfigures how micro-batches are distributed across devices without altering the global batch size. This ensures that the training logic remains intact, providing strict mathematical consistency throughout the migration process.

To empirically validate this consistency, Figure 16 plots the step-wise reward curves for a 1.5B-parameter model on 64 GPUs on a mathematical reasoning task, corresponding to the experiment in Figure 11. As illustrated, DynaRL's dynamic scheduling closely tracks the convergence trajectory of the static placement baseline. This confirms that our dynamic migrations introduce no adverse effects on the RL learning process.

8 Related Works

Reinforcement Learning Frameworks. Existing RL training frameworks for large-scale alignment generally follow static system designs, which can be categorized into task-colocated (e.g., verl [19] and DeepSpeed-Chat [29]) and task-separated (e.g., Slime [34] and OpenRLHF [8]) execution modes. More recently, frameworks with automated scheduling have been introduced. RLHFuse [33], for instance, performs fusion in rollout and inference phases, effectively mitigating long-tail generation bottlenecks and improving end-to-end throughput. Some recent works use async RL algorithms and co-design the infrastructure to alleviate the long-tail issue. AReal [4] introduces an asynchronous model update algorithm for task-separated systems to increase training throughput. Kimi-k1.5 [21] introduces partial rollouts to optimize the handling of complex reasoning trajectories. In contrast to these static or partially optimized designs, DynaRL enables joint dynamic scheduling across rollout, inference, and training phases, allowing the runtime to switch between colocated and separated execution modes based on live workload patterns. Furthermore, while prior systems focus primarily on single-turn reasoning RL pipelines, DynaRL extends dynamic scheduling to agentic RL, where multi-turn environment interaction worsens the impact of long-tail in rollout.

Cluster-Level Deep Learning Schedulers. Beyond RL-specific frameworks, a rich line of systems work has explored dynamic resource management for deep learning clusters. Optimus [16], Gandiva [27], and Tiresias [5] perform introspective GPU scheduling across many concurrent training jobs, adjusting placement and GPU allocations based on job-level progress signals. Traditional cluster managers such as Borg [23], Kubernetes, and their autoscaling extensions similarly treat each training workload as a black box when reallocating resources. These systems operate primarily at the job or container granularity and lack visibility into the internal structure of RL pipelines. In contrast, DynaRL performs fine-grained, intra-job scheduling across rollout, inference, and training components using a dynamic hypergraph abstraction, enabling resource rebalancing that is aware of cross-component dependencies and multi-turn interaction structure inside a single RL workload.

9 Conclusion

Modern RL workloads for reasoning and agentic systems exhibit substantial dynamicity, making static resource allocations highly inefficient. This paper presented DynaRL, the first RL system that makes dynamic scheduling a first-class capability. DynaRL introduces a unified runtime and abstraction that can observe how different RL components behave over time and automatically shift resources to where they are most needed. We demonstrate that DynaRL consistently improves end-to-end throughput while maintaining low online scheduling overhead across diverse RL workloads. In the future, we envision that dynamic resource management will become an essential component of RL systems, enabling more efficient and scalable training through complex interactions.

Abstract

Agentic Reinforcement Learning (RL) trains LLMs through multi-turn interactions with environments, producing workloads that mix compute-bound prefill, bandwidth-bound decoding, CPU-heavy environment execution, and bursty reward evaluation. Existing systems either colocate all stages on a single GPU cluster or decouple them only at a coarse granularity, overlooking hardware heterogeneity and incurring substantial synchronization overhead across stages.

We present ROLLART, a system for multi-task agentic RL on disaggregated infrastructure. ROLLART maps each pipeline stage to best-fit hardware, routing prefill-heavy tasks to compute-optimized GPUs, decode-heavy tasks to bandwidth-optimized GPUs, and environments to CPU clusters. It decouples rollout at the trajectory level, allowing generation, environment interaction, and reward scoring to proceed independently, so that slow or failed environments never block the others. ROLLART offloads stateless reward computation to serverless infrastructure and overlaps rollout with training via staleness-bounded asynchronous weight synchronization. Our results demonstrate that ROLLART effectively improves training throughput and achieves 1.31–2.05× training time reduction compared to various RL systems. We also evaluated ROLLART by training a hundreds-of-billions-parameter MoE model for Qoder product on an Alibaba cluster with above 3,000 GPUs, demonstrating its stability and scalability.

1 Introduction

Reinforcement Learning (RL) is advancing Large Language Models (LLMs) beyond single-turn reasoning toward autonomous, long-horizon decision-making [4, 7, 36]. In this paradigm, known as *agentic RL*, an LLM interacts with external environments for tool use [16, 58], web navigation [22, 24, 50], and computer control [28, 30, 33] over multiple turns, learning to solve tasks through trial and error.

The agentic RL training pipeline operates as an iterative cycle of three stages: *rollout*, *reward*, and *training*. Unlike standard RL post-training with single-turn responses, during rollout, the agent generates actions and receives environment observations over multiple turns until a termination condition is met, producing a *long, multi-turn trajectory*. Each trajectory is then evaluated in the reward stage, using rule-based scripts [13, 19], code sandboxes, or separate LLM judges [49, 68] to assign scalar reward signals. The training stage consumes scored trajectories to update the agent's weights, which are synchronized back to the rollout workers for the next iteration.

As research labs scale agentic RL to larger models and harder tasks [8, 54], a fundamental resource-heterogeneity problem emerges *across and within* these stages. Within rollout alone, LLM generation alternates between compute-bound prefill and bandwidth-bound decoding whose ratio depends on the task: on cost-equivalent hardware, compute-optimized H800 GPUs cut prefill-heavy rollout time to 0.53× that of bandwidth-optimized H20 GPUs, while H20s cut decode-heavy rollout time to 0.49×–0.79× of H800s (§3). Concurrently, environments are *stateful*, *CPU-bound* processes whose latency is heavy-tailed due to host contention, large variance in interaction turns, and environment failures. Reward workers are *stateless* and exhibit persistently low utilization—dropping to as little as 7.4% on dedicated GPUs—yet require elastic scaling when trajectories complete. Finally, the training stage demands high-end GPUs with fast interconnects. No single hardware type satisfies all stages.

A natural solution is to *disaggregate* the pipeline and route each stage to best-fit hardware. Yet, existing systems fall short. *Monolithic* frameworks such as veRL [46, 47], slime [70], and rLLM [53] co-locate all stages on a single GPU cluster and ignore heterogeneity entirely. *Partially disaggregated* systems such as AWorld [63] and DeepSWE [31] offload environments to Kubernetes [55] but still colocate the resource-heavy rollout and training stages. Even state-of-the-art asynchronous systems address only a subset of these heterogeneity dimensions: StreamRL [67], AsyncFlow [15], and SeamlessFlow [56] split training from rollout but treat rollout as a monolith, overlooking prefill/decode divergence *within* a task. AReaL [10] introduces unbounded-staleness asynchrony between training and generation, yet still batches environment interaction and couples reward to generation GPUs. Laminar [45] schedules trajectories individually but does not exploit within-rollout hardware affinity or offload stateless reward. As a result, no existing system jointly addresses prefill/decode heterogeneity

[*]Wei Gao, Yuheng Zhao, Tianyuan Wu, Shaopan Xiong, and Weixun Wang contributed equally to this work.

within generation, long-tail environment stragglers, stateless reward underutilization, and cross-cluster bandwidth variability at production scale (§3).

To address these challenges, we present ROLLART, a distributed system that maximizes throughput for multi-task agentic RL on disaggregated infrastructure. The design of ROLLART is driven by four requirements derived from empirical workload characterization (§3):

- **R1 Hardware-affinity workload mapping:** each pipeline stage, as well as sub-stages within rollout, should be bound to best-fit hardware so that compute-bound workloads land on compute-optimized GPUs and bandwidth-bound workloads on bandwidth-optimized GPUs. Because prefill/decode, CPU-bound, and stateless characteristics are stable per task domain in production workloads (§3 and §8), this binding can be driven by lightweight, domain-level annotations.
- **R2 Trajectory-level asynchronous rollout:** environment interaction, LLM generation, and reward computation should be decoupled at the granularity of trajectories, so that environment stragglers never stall the pipeline.
- **R3 Serverless offloading:** Stateless components, notably reward computation, should be offloaded to serverless infrastructure, eliminating dedicated hot standby GPUs while gaining autoscaling and fault tolerance.
- **R4 Bounded-staleness asynchronous training:** training and rollout should execute concurrently on separate GPUs, overlapping weight synchronization with rollout. An asynchronous bound eliminates resource bubbles while preserving performance.

To meet these requirements, our system combines a declarative programming model with a heterogeneity-aware distributed runtime. At job submission, users declare hardware preferences for each stage through Python decorators. The runtime binds each stage to its best-fit resource pool (**R1**): compute-optimized GPUs for training and prefill-heavy generation tasks, bandwidth-optimized GPUs for decode-heavy generation tasks, CPU clusters for environments, and serverless endpoints for reward. During rollout, the runtime drives each trajectory independently through generation and environment interaction. A slow or failed environment never blocks other trajectories, and reward scoring begins as soon as any trajectory completes (**R2**). Completed trajectories are scored by stateless reward functions on serverless infrastructure, granting elastic autoscaling without dedicated GPU reservations (**R3**). While rollout continues, a separate GPU cluster consumes scored trajectories for training. A bounded-staleness weight synchronization protocol propagates updated weights back to the rollout stage, overlapping training and cross-cluster transfer with ongoing generation to eliminate resource bubbles (**R4**). Finally, cross-cutting optimizations (§6.3) reduce cross-stage data-movement cost, add resilience to environment failures, and support optional prefill-decoding disaggregation within rollout.

Table 1: Taxonomy of Adopted Agentic Environments.

Environment	Task Domain	Modality	#Turns
SWE-bench [23]	SWE	Text	30–50
WebShop [61]	Web	Text	5–30
FrozenLake [9]	Game	Text, Visual	20–100
GEM-math [3]	Math+Tool Use	Text	< 5
GEM-game [3]	Game	Text	1

We have implemented ROLLART in approximately 60k lines of Python code and evaluated it by training Qwen3 models (8B–32B) [2] on a diverse mixture of agentic tasks across disaggregated H800 and H20 GPU clusters. ROLLART achieves 2.05×, 1.35×, and 1.31×, step-time reductions over a strengthened monolithic synchronous baseline, one-off baseline, and AReaL [10], respectively, and delivers 2.65–4.58× throughput over the synchronous baseline. Offloading reward to a serverless cloud raises reward-GPU utilization from 6% to 88% and halves per-step rollout time. We further quantify the overheads introduced by disaggregation, including cross-cluster weight synchronization via Mooncake [38], serverless reward I/O, and trajectory transfer, and show that they are outweighed by the resulting throughput gains (§7). To validate scalability and stability in a production setting, we have deployed ROLLART to train a hundreds-of-billions-parameter Mixture-of-Experts (MoE) model for Qoder [39] product on a cluster of over 3,000 GPUs. This deployment runs continuously for one week, confirming ROLLART's ability to sustain high throughput and robust fault tolerance at scale.

2 Background

2.1 Agentic RL Training

The Training Pipeline. Multi-task agentic RL training follows an iterative loop with three stages. The first stage, **rollout**, collects experience: an agent LLM (actor) interacts with parallel *environments* to generate training data. Unlike standard LLM inference, rollout is *multi-turn* and *stateful* [8, 54]. At each turn, the agent observes a state, emits an action token sequence, and submits it to the environment. The environment executes the action (e.g., running code or clicking a link) and returns feedback. The loop repeats until termination, producing a sequence of state-action pairs, i.e., a *trajectory*. After rollout, the **reward stage** evaluates trajectory quality via a *reward worker*, producing a scalar reward signal. Reward computation ranges from lightweight rule-based checks [19] to computationally expensive model-based judgments (e.g., LLM-as-a-Judge [49, 68]). Finally, the **training stage** consumes trajectories and rewards to update model weights with RL algorithms (e.g., PPO [40], GRPO [44]). To attain optimal training performance [10], production RL pipelines often adopt *synchronous* training, which enforces strict weight synchronization between rollout and training at every step.

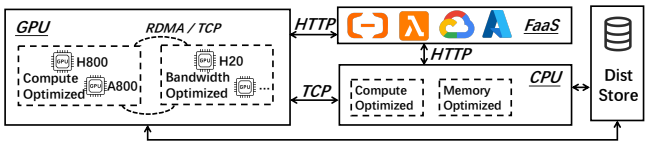

Figure 1: Disaggregated infrastructure for agentic RL.

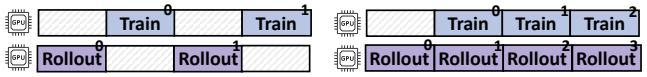

Figure 2: Synchronous vs. asynchronous training.

Environment Heterogeneity. A key challenge in agentic RL is environment diversity, which determines the system compute profile. As summarized in Table 1, agentic tasks vary widely in modality and interaction frequency. Complex reasoning tasks such as `SWE-bench` [23] (software engineering), `FrozenLake` [9] (visual games), and `WebShop` [61] (eCommerce) require long interaction horizons (up to 30–100 turns). Frequent interactions force the agent to repeatedly process growing context histories, making these workloads prefill-heavy and compute intensive. In contrast, tasks like `GEM-Math` and `GEM-Game` [3] may involve fewer turns (up to five) but require longer chains of thought per action. These workloads are decoding-heavy, shifting the bottleneck from compute to memory bandwidth. This variance requires infrastructure that adapts to each task's rollout profile.

2.2 Disaggregated Cluster Infrastructure

The Case for Disaggregation. The extreme heterogeneity of agentic RL workloads, ranging from compute-intensive training to stateful environment simulation (§2.1), renders monolithic architectures inefficient. Consequently, agentic RL training must transition to a *disaggregated infrastructure* that decouples these demand-conflicting computation stages into specialized resource pools. As shown in Figure 1, in a typical disaggregated infrastructure, *training clusters* utilize high-end, compute-optimized GPUs (e.g., NVIDIA H800) to sustain high throughput; *inference clusters* leverage bandwidth-optimized hardware (e.g., H20) to serve memory-bound decoding; *CPU clusters* provide elastic capacity for diverse, containerized runtime environments orchestrated by Kubernetes [55]; and *serverless infrastructure* handles bursty, stateless workloads like reward evaluation. These pools are interconnected through standard network fabrics, relying on distributed storage for persistent logging and fault tolerance.

Sync. vs. Async. Training. While disaggregation resolves resource mismatches, it introduces non-trivial orchestration challenges to the training paradigm that dictates the trade-off between system throughput and algorithmic consistency.

1) Synchronous Training: This paradigm enforces strict consistency by blocking rollout until it receives the latest model weights from the training cluster. In disaggregated settings, this causes substantial "dependency bubbles" (Figure 2-Left), where expensive GPUs sit *idle* during high-latency weight synchronization and straggler-bound environment steps (§3).

2) Asynchronous Training: To mitigate these bubbles, systems can adopt *asynchronous* paradigms (e.g., one-off RL training [32] in Figure 2-Right). Rollout and training then run *in parallel*: training consumes trajectories from slightly older policies (e.g., one iteration stale in one-off training), while rollout continuously produces new data. This design masks synchronization latency and straggler effects inherent to disaggregation, trading some policy staleness for higher hardware utilization and throughput.

Table 2: NVIDIA GPU specifications.

Hardware Specification	H20	H800
TFLOPS	148	989.5
HBM capacity	96GB	80GB
HBM bandwidth	4TB/s	3.35TB/s
NVLink bandwidth	900GB/s	400GB/s
Normalized Cost [69]	1.00	2.85

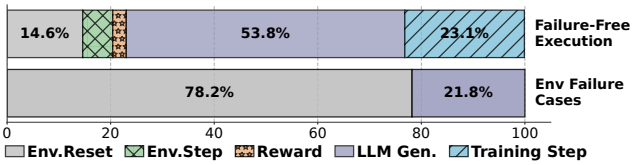

Figure 3: Breakdown of a training step: successful runs (top, avg=365.7s) versus execution with environment failures (bottom, avg=513.3s).

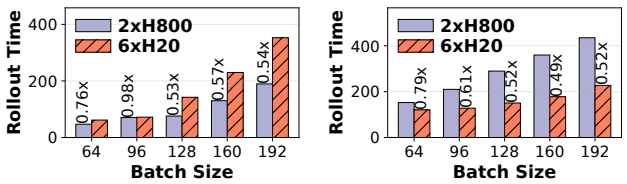
3 Characterization and Requirements

To motivate the design of RollArt, we conduct a comprehensive workload characterization of multi-task agentic RL training. Based on these empirical observations, we derive four critical system requirements that RollArt must satisfy: within-generation hardware affinity mapping (**R1**), trajectory-level asynchrony (**R2**), serverless reward offloading (**R3**), and bounded-staleness asynchronous training (**R4**).

3.1 Stage Computation

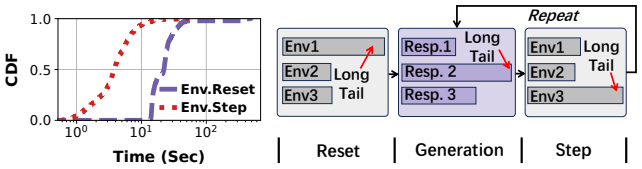
Training Step Latency Breakdown. We first profile the end-to-end latency of a standard training iteration to identify the dominant cost components. We train Qwen3-8B/32K on 32 H800 GPUs using the `SWE-bench` environment (batch size 128), where the agent LLM interacts with a containerized sandbox for software engineering tasks. The interaction involves two core operations: `env.reset` for environment initialization via Docker image pulling and container launching, and `env.step` for agent's action execution.

Figure 3 breaks down the latency of five *successful* iterations against five iterations containing *environment failures*.



(a) `FrozenLake` [Prefill-Heavy]. (b) `GEM-Math` [Decode-Heavy].

Figure 4: End-to-end rollout time (seconds) of different tasks on H20 and H800 GPUs across varying batch sizes.



(a) Env Time Distribution. (b) Batched Env Interaction.

Figure 5: The analysis of environment interaction: (a) Cumulative distribution function of time (log-scaled) taken for environment initialization (`env.reset`) and environment step (`env.step`). (b) Illustration of how long-tail environments affect multi-turn rollouts under batched env interaction.

Even on the success path, the average iteration time is 366 seconds, with LLM generation accounting for only 54%. The rest is split across training (23%), environment initialization (15%), and other overheads, a mixed profile that invalidates the common assumption of overwhelming generation dominance [12,18]. When environment timeouts occur, the average time spikes to 513 seconds and `env.reset` alone consumes 78% of rollout time, shifting the bottleneck entirely from GPU computation to environment overhead. Our production data indicates these failures are not rare corner cases, occurring approximately once every ten iterations (§8). Our empirical study therefore reveals that, in agentic RL, the system must handle four heterogeneous workloads, including generation, training, environment, and reward, rather than optimizing for the generation dominant regime reported by prior systems.

Divergent Hardware Affinities in Generation. Modern GPUs expose different trade-offs between compute capability, memory capacity, and cost (Table 2). While recent RL systems [15,56,67] advocate physically decoupling generation from training, assigning rollout to cost-effective, bandwidth-optimized GPUs and training to compute-optimized GPUs, our characterization reveals that *this static assignment is insufficient for agentic workloads*. LLM generation comprises two distinct phases with opposing resource demands: the compute-bound prefill phase and the memory-bandwidth-bound decoding phase. In environments with a few interaction turns but long chains of thought per action, most of the runtime is spent in decoding (decoding-heavy); conversely, in environments with many turns, the prefill phase dominates and demands high compute throughput (prefill-heavy). In our production clusters, agentic RL tasks exhibit a clear *bimodal distribution*, featuring either a small number of interaction turns (< 5) or a large number (> 10).

To quantify this divergence, we run a prefill-heavy task (`FrozenLake`) and a decoding-heavy task (`GEM-Math`) using Qwen3-8B/32K for ten iterations with prefix caching enabled. For a cost-equivalent comparison, we execute the workloads on two distinct hardware configurations: one with six H20 GPUs and the other with two H800 GPUs. As shown in Figure 4a, the compute-heavy H800 outperforms the H20 on `FrozenLake`, reducing end-to-end rollout time to as low as 0.53×. Conversely, for `GEM-Math` (Figure 4b), the H20's higher memory bandwidth accelerates decoding, reducing rollout time to 0.49×–0.79× of the H800. These results invalidate the assumption that generation is uniformly bandwidth-bound. Instead, maximizing throughput requires dynamically mapping tasks to their best-fit hardware.

R1: Generation is not uniformly bandwidth-bound; the system must bind each task to a best-fit GPU class rather than committing rollout to a single GPU type.

Heavy-Tailed Environment Execution. Since each training step collects a batch of trajectories, it runs hundreds to thousands of environments *simultaneously*, at which scale strong resource isolation becomes essential: without it, concurrent disk I/O exhausts shared quotas and triggers cascading failures. We therefore employ Kubernetes clusters to manage and isolate each containerized environment.

A substantial body of prior work [12, 18, 67] has analyzed the long-tail behavior of LLM generation. In agentic RL, environment interactions introduce additional sources of long-tail execution patterns. Figure 5a illustrates the latency distributions of `env.reset` and `env.step`, both exhibiting pronounced long tails. The long-tail delay of `env.reset` can reach hundreds of seconds in production, mainly due to (1) network contention, where concurrent Docker image pulls saturate network links, and (2) compute and I/O contention on host nodes, where launching containers consumes substantial CPU and disk resources. The cumulative `env.step` time per trajectory also varies widely, driven by the large variance in interaction turns and per-step overhead.

These long-tail trajectories act as stragglers that delay end-to-end rollout latency. Since LLM engines execute requests in batches, it is natural to batch environment interactions with the agent LLM as well. Figure 5b illustrates this pattern: fast environments must wait for the slowest one before the next generation step can proceed. Our profiling (Figure 3) indicates that batched environment interaction increases rollout time by up to 21.3% compared to ideal execution, an overhead that compounds as environment failure rates increase. Trace analysis on our production deployment (§8) confirms that such long-tail conditions are not rare throughout training, and would significantly penalize any batched execution scheme.

Table 3: Transmission overhead from the training cluster to the inference cluster over TCP and RDMA.

Model	Size (GB)	TCP (s)	RDMA (s)	Speedup
Qwen3-8B	15.26	6.911	5.466	1.264×
Qwen3-14B	27.51	14.437	5.817	2.482×
Qwen3-32B	61.02	29.649	9.442	3.140×

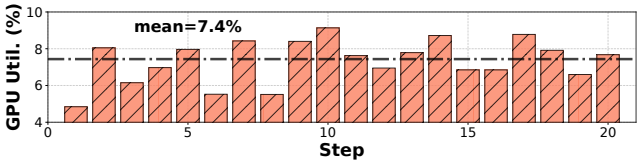


Figure 6: Inefficient resource usage when dedicating local GPUs for reward computation.

R2: Environment execution, including `env.reset` and `env.step`, is prone to extreme long-tail latency. The system must manage environment execution at trajectory granularity rather than batch granularity, so that slow or failed environments do not stall the pipeline.

Stateless Reward Computation. The reward stage follows rollout, and most reward computations can be implemented as *stateless functions*. For lightweight *rule- and code-based rewards*, they have small, bursty resource demand, making them a natural fit for elastic serverless execution that can scale to zero between steps. The *LLM-based reward computation*, on the other hand, demands intensive GPUs: colocating them with rollout contends with generation for GPU memory, KV-cache capacity, and scheduling slots, degrading both stages under concurrent demand. A common workaround is to reserve separate GPUs for the reward LLM: in our Qwen3-8B/32K `SWE-bench` run with batch size 128, we allocate four H800 GPUs to a dedicated 7B reward LLM and 28 H800 GPUs to rollouts, but the reward GPUs achieve only 7.4% average utilization across steps (Figure 6). Since the reward LLM's parameters remain fixed during training, it can be treated as a stateless function, and serverless deployment [11, 64, 65] simultaneously avoids rollout contention and reclaims the idle GPU budget wasted by dedicated reservations.

R3: Reward workers are stateless, bursty, and persistently underutilized; colocating them with rollout contends for GPU memory under concurrent generation, making elastic serverless deployment the better fit.

3.2 Inter-Stage Communication

Beyond computation, inter-stage communication plays a critical role in agentic RL training, comprising two distinct types: stability-critical, small-packet *trajectory transfer* and bandwidth-intensive, large-volume *weight update*.

Stability-Critical Trajectory Transfer. Trajectory and observation payloads are orders of magnitude smaller than the multi-GB weight transfers: a single agent-environment exchange typically carries kilobytes to a few megabytes of tokenized state and action data, yet each rollout issues hundreds to thousands of such exchanges per trajectory. Consequently, cumulative latency, rather than bandwidth, determines end-to-end interaction cost. In practice, environment interaction should therefore prioritize *network stability* over *network bandwidth*, and asynchronous execution between environment interaction and LLM generation prevents network latency from becoming the rollout bottleneck.

Bandwidth-Intensive Weight Update. During training, the agent LLM periodically updates its weights, which must then be synchronized with the rollout stage. This weight synchronization is the dominant source of inter-stage communication overhead. We measure the end-to-end transmission cost of synchronizing model parameters between the training and inference clusters using Mooncake [38] over TCP (200 Gbps Ethernet) and RDMA (400 Gbps InfiniBand), and report the results in Table 3. RDMA provides higher bandwidth and lower communication overhead than TCP. In *synchronous* RL training, the rollout stage can only proceed after the latest agent LLM weights have been synchronized. As a result, the substantial cost of weight transmission over low-bandwidth links increases end-to-end training time and diminishes the speedup of disaggregated training (Figure 2-Left).

In asynchronous training (Figure 2-Right), the training and rollout stages execute in parallel on separate GPUs. Although this introduces data staleness, many prior works [18, 29] empirically observe that asynchronous training can preserve model quality under a staleness bound. Given the dominant rollout overhead, asynchronous training can effectively hide both training and weight synchronization costs with rollout, thereby reducing end-to-end training latency.

R4: Training and rollout must execute concurrently on separate GPU clusters with *bounded* staleness for system efficiency and training quality.

4 System Overview

We present RollArt, a distributed system that orchestrates the rollout, reward, and training stages of agentic RL across disaggregated, heterogeneous resource pools. RollArt is implemented in approximately 60k lines of Python code. We first present the system architecture and then walk through one training iteration to illustrate its workflow.

4.1 Architecture

To meet the requirements in §3, RollArt is organized into three layered planes: resource, data, and control, as shown in Figure 7. The *resource plane* decides placement: it tracks heterogeneous hardware pools and binds each role, task, or

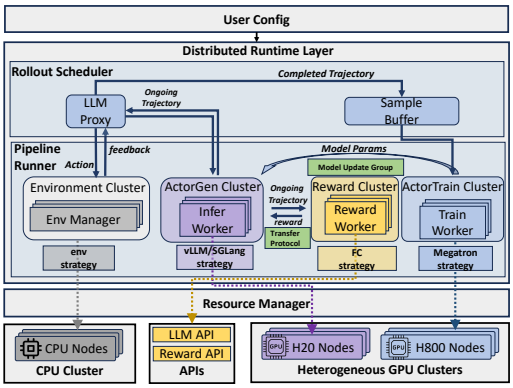

Figure 7: System Architecture of ROLLART.

generation sub-phase to a compatible resource class using hardware-affinity declarations (**R1**). The *data plane* realizes the pipeline through `Worker` and `Cluster` abstractions that encapsulate user-defined execution logic and offload stateless computation to serverless infrastructure (**R3**). The *control plane* coordinates progress: it schedules trajectories independently, dispatches reward computation as trajectories finish, buffers scored samples, and overlaps training with rollout under a bounded-staleness protocol (**R2** & **R4**).

Resource Plane. The resource plane is implemented by the *resource manager* (Figure 7), which monitors the state of disaggregated hardware pools and binds resources to specific `Workers` based on their roles and corresponding hardware affinities (e.g., training to H800 GPUs, rollout to H20 GPUs, environment execution to CPU servers, and reward computation to serverless infrastructure).

Data Plane. The data plane executes the distributed RL job on resources provisioned by the resource plane. It is implemented by the *pipeline runner*, which constructs role-specific `Clusters` for training, generation, environment execution, and reward computation. Each `Cluster` then launches its associated `Workers` and orchestrates their execution over the appropriate backend runtime (e.g., Megatron [48] and vLLM [25]). In this way, the data plane translates user-defined `Worker`/`Cluster` logic into concrete distributed execution.

Control Plane. The control plane coordinates trajectory-level rollout and asynchronous training. It is centered on the *rollout scheduler*, which orchestrates the interaction among environment execution, generation workers, reward workers, and training workers. To decouple these stages, ROLLART introduces two auxiliary components: `LLMProxy`, which mediates generation requests between environment execution and generation `Workers`, and `SampleBuffer`, which buffers completed and scored trajectories for training. Together, these components allow rollout, reward evaluation, and model updates to proceed concurrently, hiding trajectory-level synchronization and weight-update coordination from the user.

4.2 End-to-End Workflow

To illustrate how the three planes interact, we walk through the first asynchronous training iteration in ROLLART. At startup, the resource manager in the resource plane binds heterogeneous GPU, CPU, and serverless resources to the corresponding `Clusters` by allocating and placing their constituent `Workers` according to user-specified hardware affinities. The pipeline runner then materializes the data plane by instantiating the corresponding `Clusters` for training, generation, environment execution, and reward computation, each backed by its assigned `Workers` and execution engine.

Once the pipeline is instantiated, the rollout scheduler in the control plane launches multiple `EnvManager` instances to collect trajectories. Each `EnvManager` alternates between issuing generation requests through the shared `LLMProxy` and applying the returned actions to its environment. Completed trajectories are scored by a reward backend and deposited into the `SampleBuffer`, from which the training `Cluster` consumes batches and updates the model. Rollout, reward evaluation, and training proceed concurrently.

The following sections detail these planes. §5 describes the programming abstractions and mechanisms that configure the resource and data planes. §6 describes the system-managed control plane that drives runtime execution, followed by cross-cutting optimizations that span multiple planes.

5 Programmable Resource and Data Planes

ROLLART provides a declarative programming model that separates user intent from system execution. Users specify execution logic and task-specific mappings for the data plane, as well as hardware preferences for the resource plane, through the `Worker`-level interface. The resource manager interprets the resource-plane declarations to construct concrete bindings over heterogeneous resources, while the pipeline runner materializes the data plane through `Cluster` abstractions.

5.1 `Worker` and `Cluster` Abstractions

The resource and data planes are built around two core abstractions: `Worker` and `Cluster`.

`Worker` Abstraction. A `Worker` is the basic execution unit that spans both the resource and data planes. It encapsulates user-defined computation logic together with method-level declarations, and executes on the hardware provisioned by the resource plane. A `Worker` can be specialized into the roles required across stages, including training, generation, reward, and environment, by subclassing and method annotations.

`Cluster` Abstraction. While `Workers` execute the actual computation logic, managing thousands of `Workers` individually is prohibitive for algorithm developers. To address this, ROLLART introduces the `Cluster` abstraction. A `Cluster`

```python
import rollart.distributed as rdist
from rdist.worker import ActorTrainCls, ActorGenCls,
    RewardCls
from rdist import ResourceManager as RM

# 1. Single Controller Example
class MyActorTrain(ActorTrainCls):
    @rdist.register(mode="execute_all")
    def compute_gradients(self, input_tensor):
        ...

# 2. Define actor_gen on heterogeneous GPUs
# 2.1 heterogeneous GPU allocation.
gen_rm=RM( {"H800": list(range(0, 8))},
           {"H20", list(range(8, 32))})
# 2.2 hardware affinity mapping
class HeteroActorGen(ActorGenCls):
    @rdist.hw_mapping(
    hw_affinity={"FrozenLake": "H800","default": "H20"}
    )
    def generate(self, input_ids:List[int],
                 tag_name:str="default"):
        return self.model.process(prompt)

# 3. Define a serverless reward computation func
class ServerlessRewardWorker(RewardCls):
    @rdist.register_serverless(
        attribute='reward_proxy',
        serverless_url='fc://xxx.xxx')
    def compute_rewards(self, traj: list):
        prompt = f"Evaluate the trajectory:{traj}"
        return ray.get(self.reward_proxy(prompt))
```

Listing 1: Worker-level programming interface of ROLLART.

acts as a proxy and controller for a role-specific `Worker` group. A `Cluster` spawns `Workers`, binds their methods, and manages collective invocation on their behalf. In practice, ROLLART defines four `Clusters`: `ActorTrain`, `ActorGen`, `Reward`, and `Environment`, corresponding to the four RL stages shown in Figure 7. By composing these abstractions, ROLLART maps the agentic RL pipeline onto the disaggregated hardware fabric.

5.2 `Worker` Declarations and Binding

ROLLART exposes three worker-level interfaces through Python decorators, allowing users to implement role-specific computation logic and specify task-specific mappings and hardware preferences under a unified *single-controller* model. The resource manager interprets the resource-related declarations to bind `Workers` to heterogeneous resources.

Decorator-Based Interface. Listing 1 shows the three decorator-based interfaces for `Worker` declarations.

1) Single Controller. Like other industry RL frameworks [46, 70], ROLLART adopts the single controller programming model to streamline pipeline construction. When a `Worker` method is annotated with the `register` decorator and set to `execute_all` mode (Lines 7–8 in Listing 1), the runtime broadcasts inputs and invokes the method across all `Workers` in the corresponding `Cluster`. The runtime also collects the returned results and automatically aggregates them. A typical use case is defining how gradients are computed on each training `Worker` (Line 8 in Listing 1).

2) Hardware-Affinity Mapping. To align workload characteristics with hardware capabilities (**R1**), ROLLART allows users to declare preferred hardware targets for role-specific workers through the `hw_mapping` decorator. By default, training workers (`ActorTrainCls`) are mapped to compute-optimized GPUs (e.g., H800), generation workers (`ActorGenCls`) to bandwidth-optimized GPUs (e.g., H20), environment workers (`EnvironmentCls`) to CPU servers, and reward workers (`RewardCls`) to local GPU servers. Users can override these defaults with finer-grained preferences.

As shown in the `HeteroActorGen` class, a dictionary-based resource specification provisions heterogeneous GPU groups (Lines 13–14), and the `hw_mapping` decorator (Lines 17–19) declares sub-stage affinities. Prefill-heavy `FrozenLake` rollouts are routed to H800 GPUs, while all other tasks default to H20s. At runtime, the rollout scheduler passes the current task's identity (e.g., `FrozenLake`) as the `tag_name` argument (Line 21), allowing the system to route each generation request to the most appropriate hardware.

This declaration is coarse-grained by design: users specify affinity at the task-domain level rather than performing per-request load-balancing. In our production traces, different agentic task domains diverge in computation characteristics (e.g., turn counts and prefill/decode ratios), making domain labels a practical basis for hardware selection (§8). Our evaluation confirms this lightweight annotation captures enough heterogeneity to improve throughput (§7.3). This leaves affinity selection explicit, and §9 discusses how an online profiler could automate or refine these mappings at runtime.

3) Serverless Registration. Reward workers are stateless and exhibit low utilization on dedicated GPUs (**R3**). To address this, ROLLART provides the `register_serverless` decorator (Lines 26–28) to offload reward computation to serverless platforms. With the specified `serverless_url`, the runtime invokes `compute_rewards` (Line 29) as a pure function through the same method-level interface while redirecting execution to an external serverless platform (e.g., Function Compute [1]). This grants the system zero-overhead autoscaling without provisioning costly, hot-standby GPUs.

Resource Binding. The resource manager uses a shared metadata store (e.g., Redis) to maintain a global, real-time view of resource pools, including compute-optimized GPUs (e.g., H800), bandwidth-optimized GPUs (e.g., H20), CPU clusters, and serverless endpoints. `Worker`-level annotations specify hardware affinities and execution targets for individual methods. Upon a `Worker` deployment request, the resource manager interprets these declarations to determine concrete placements and bindings. It first checks the availability of the preferred resource pool and binds the requested `Worker` accordingly. If the preferred hardware is temporarily unavailable, the manager opportunistically falls back to compatible default resources rather than stalling deployment. The resulting binding metadata is recorded for subsequent dispatch, failover, and reconfiguration.

```python
class Cluster:
    def __init__(self, res_manager, worker_cls):
        self._create_worker(worker_cls, res_manager)
        self._bind_worker_method()

    def execute_all(self, method_name, *args, **kwargs):
        result = []
        for worker in self.workers:
            rcall = getattr(worker, method_name)
            result.append(rcall(*args, **kwargs))
        return ray.get(result)

    def hw_mapping(self, hw_affinity, tag_name, *args):
        hw_type = hw_affinity.get(tag_name)
        new_workers = []
        for worker in self.workers:
            if worker.resource_type == hw_type:
                new_workers.append(worker)
        # route requests to new_workers next

    def register_serverless(self, attr, url, *args):
        # define a call_fc to call serverless url
        for worker in self.workers:
            setattr(worker, attr, call_fc)
        # perform execute_all logic next
```

Listing 2: Simplified implementation of `Cluster`.

5.3 `Cluster`-Level Realization

The resource manager realizes the resource plane, while the `Cluster` governs execution in the data plane. We next describe how the default `Cluster` implementation turns `Worker`-level decorators into concrete execution behavior.

`Cluster` Construction and Method Binding. At initialization, `Cluster` assembles a role-specific `Worker` group from the specified `worker_cls` using resources provisioned by the resource manager, and initializes the corresponding backend runtime (e.g., Megatron or vLLM) so that `Worker` methods execute on that backend (Line 3 in Listing 2). Each `Worker` is associated with resource metadata, such as its hardware type, enabling later affinity-aware dispatch. The `_bind_worker_method` function then binds each method of `worker_cls` to the `Cluster` instance, allowing the `Cluster` to act as an invocation proxy (Line 4). For example, if `worker_cls` defines `compute_gradients` (Line 8 in Listing 1), users can directly invoke `Cluster.compute_gradients`.

Realizing `Worker` Declarations. For methods annotated with the `register` decorator, `Cluster` enters the `execute_all` path, which calls the target method on every constituent `Worker` and aggregates results via `ray.get` (Lines 6–11). For methods annotated with `hw_mapping`, `Cluster` inspects the `tag_name` argument, filters for `Workers` whose resource type matches the preferred hardware, and routes the request to those `Workers` (Lines 13–19). For methods annotated with `register_serverless`, `Cluster` replaces the reward proxy attribute (`attr`) with a callable that invokes the registered serverless URL, so reward computation is performed by the serverless backend (Lines 21–25). In all affinity-based paths, if the preferred target is temporarily unavailable, `Cluster` redirects execution to a compatible fallback provided by the resource manager, ensuring forward progress under transient contention.

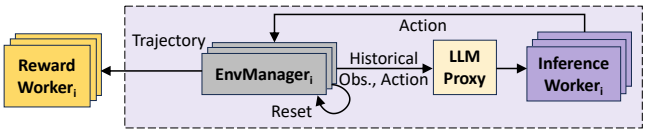

Figure 8: Trajectory-Level Rollout and Reward Overview.

The abstractions and mechanisms above, including `Worker` logic, decorator annotations, resource bindings, and `Cluster`-level realization, constitute what users configure at pipeline setup time. Once the pipeline is materialized, the control plane takes over: it drives trajectory-level rollout, reward evaluation, and asynchronous training without further user intervention, which we explain next.

6 System-Managed Control Plane

ROLLART's control plane is entirely *system-managed*: users specify no coordination logic. In this section, we first describe how the control plane orchestrates trajectory-level rollout, reward, and asynchronous training (§6.1–§6.2), then present cross-cutting optimizations that span the data and control planes to improve end-to-end efficiency (§6.3).

6.1 Trajectory-Level Rollout and Reward

As identified in §3 (**R2**), batched environment interaction forces fast environments to wait for stragglers, inflating end-to-end rollout latency. To eliminate this synchronization barrier, ROLLART adopts a *trajectory-level* design in which each trajectory progresses through generation, environment interaction, and reward computation independently. Figure 8 gives an overview. Three components realize this: `LLMProxy` dispatches requests at per-trajectory granularity, `EnvManager` drives each environment's lifecycle independently, and `Reward Workers` score asynchronously.

`LLMProxy`: Trajectory-Level LLM Generation. As shown in Figure 7, `LLMProxy` sits between `EnvManagers` and inference workers in the control plane. It acts as a gateway that decouples generation clients from the serving instances, dispatching per-trajectory requests across inference workers.

Each inference worker runs a command-driven event loop (Figure 8) that manages an inference engine (e.g., vLLM [25], SGLang [41]). This loop operates continuously in a non-blocking fashion with two components:

1) Step Wise Command Processing. The loop polls for commands dispatched by `LLMProxy`, `ADD` to enqueue requests and `ABORT` to cancel existing ones. When no commands are pending, it advances the engine by executing a decode or prefill step for a batch of requests, keeping GPU utilization high. Because commands are processed between engine steps, adding or aborting a trajectory does not stall ongoing generation.

2) Post-Processing. When the engine finishes a request, the loop immediately invokes a pre-registered callback that post-processes the output and returns the result to the requesting `EnvManager`. This allows each trajectory to proceed to environment interaction as soon as its generation completes, without waiting for stragglers.

`EnvManager`: Trajectory-level Environment Interaction. Each `EnvManager` is a lightweight controller that manages the lifecycle of a single environment to collect trajectories (also depicted in Figure 8). It begins with environment initialization via `reset`, after which it enters an independent event loop that orchestrates the interaction between an environment instance and the shared `LLMProxy` via `step`. During this loop, the `EnvManager` maintains a list of (observation, action) pairs to construct a trajectory. Specifically, it feeds `LLMProxy` with the historical (observation, action) sequence as input to obtain the next action, applies this action to the environment via `step`, and records the resulting observation. Unlike batched environment interaction (Figure 5b), where all environments must synchronize before the next generation step, each `EnvManager` operates on its own timeline, so a slow environment never blocks others.

Overlapping Rollout and Reward. Once a trajectory completes, the runtime dispatches it to a reward worker, which invokes a serverless reward function as a non-blocking task. Because each `EnvManager` yields trajectories independently, reward computation begins as soon as any single trajectory finishes, without waiting for an entire batch. ROLLART launches multiple inference workers, `EnvManagers`, and reward workers so that generation, environment interaction, and reward computation overlap in time, hiding reward latency behind ongoing rollouts and maximizing pipeline throughput. This design avoids colocating reward on the inference cluster, which would force batched computation. Recent RL post-training systems [10, 12, 57, 59, 67] also adopt asynchronous reward computation for this reason. ROLLART further eliminates the underutilization of dedicated reward GPUs (Figure 6) through serverless deployment.

6.2 Asynchronous Training Orchestration

In a disaggregated setup, synchronous training forces rollout workers to idle while model weights are transferred across clusters. This cost grows with model size (§3, **R4**). To hide this overhead, ROLLART overlaps rollout and training: two stages execute concurrently on separate GPU clusters, coordinated through a weight synchronization protocol (Figure 9).

Weight Synchronization Protocol. To propagate model weights to inference workers while preserving the overlap between rollout and training, ROLLART implements a six-step synchronization protocol in each iteration. ① `get_batch`: The runtime invokes a blocking `get_batch` call to retrieve trajectories from the `SampleBuffer`, which buffers scored

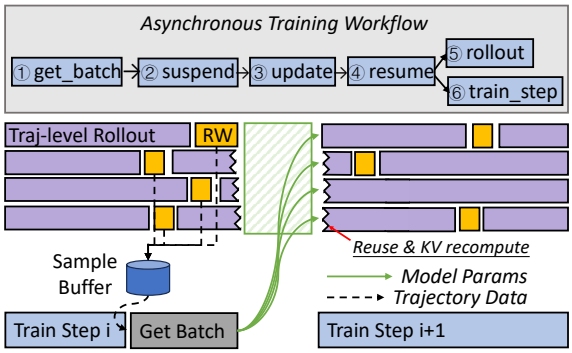

Figure 9: Asynchronous Training Workflow.

trajectories for training (Figure 7). The pipeline waits until a predefined batch size is collected. ② `suspend`: Once the batch is ready, the runtime issues a `suspend` command to the `LLMProxy`, preventing new generation requests from being accepted while preserving in-flight trajectories. ③ `update`: After rollout is suspended, the pipeline fetches the latest LLM weights from the training workers and updates all inference workers. ④ `resume`: Upon completion, a `resume` command is issued to the `LLMProxy`, which then continues pending generation requests. ⑤ `recomp` & `rollout`: To reuse in flight trajectories generated under the previous model version, ROLLART performs KV cache recomputation, rebuilding each trajectory's KV cache under the updated weights so that generation can continue without restarting from scratch. ⑥ `train_step`: In parallel with the resumed rollout, the pipeline executes `train_step` on the batch retrieved in ①, allowing training to overlap with ongoing rollout.

Asynchronous Bound and Buffer Management. The protocol above lets rollout and training proceed concurrently, but trajectories in `SampleBuffer` may come from different model versions. Excessive staleness can increase variance and destabilize training, so ROLLART enforces a per-trajectory *asynchronous bound* α (**R4**). If the current agent LLM is at version n, any buffered trajectory must have been initiated by a version no older than $(n-\alpha)$; trajectories outside this window are aborted. This same version window bounds buffer growth: with E concurrent environments, `SampleBuffer` holds at most $O(\alpha \cdot E)$ pending trajectories across versions. Before `get_batch` forms a training batch, it eagerly evicts stale trajectories, so highly asynchronous or out-of-order completion cannot cause unbounded buffer growth. Our empirical study (§7.2) shows that $\alpha = 1$ balances training speed and stability.[1]

6.3 Cross-Cutting Optimizations

The execution workflow above relies on data movement, hardware-specialized serving, and scheduling mechanisms

[1] Unlike AReaL [10], which bounds staleness only at trajectory start, ROLLART controls trajectory-level staleness in each iteration to prevent long-tail trajectories from spanning multiple model versions.

that span the data and control planes. We describe three optimizations that improve end-to-end efficiency.

Data Movement. ROLLART matches each data path to an appropriate transfer mechanism. The *transfer protocol* streams trajectories and supervision signals between stages as Ray's object references [34]. The exchanged objects are sharded to match each worker's parallelism layout. The *model update group* synchronizes weights between stages. Intra-cluster weight synchronization uses NCCL [35] over NVLink or InfiniBand. The main bottleneck is *cross-cluster* weight updates, which bridge the training cluster and inference cluster over lower-bandwidth Ethernet. ROLLART addresses this with an *asynchronous weight update engine* built on Mooncake [38]: after each training step, updated weights are bucketized (e.g., 1GB) and published to a remote CPU-resident Mooncake store rather than synchronously pushed to remote inference workers. Inference workers then asynchronously fetch the latest weight buckets from the Mooncake store on demand, decoupling weight transfer from ongoing rollouts and avoiding GPU stalls caused by slow cross-cluster communication.

This makes the data movement explicit: training workers write weight buckets once over the lower-bandwidth cross-cluster link, while inference workers pull them over high-bandwidth intra-cluster links. The additional hop through the Mooncake store introduces only minimal overhead, as we quantify in §7.4. While Mooncake adds a pull step, it uses optimized data movement (e.g., zero-copy transfers) and is overlapped with ongoing rollout and weight push. For smaller models, the absolute transfer volume is also lower, limiting the exposed latency. We quantify both the accumulated pull cost and the non-overlapped exposed overhead in §7.4.

Redundant Environment Rollouts. Within the control plane, the trajectory-level design of `LLMProxy` and `EnvManager` enables an optimization we term *redundant environment rollouts*. This allows the system to launch more environments than required for trajectory collection. Once the target number of trajectories has been collected, in-flight trajectories can be terminated. Because rollouts are managed at trajectory granularity, slow or failed environments do not block faster ones, mitigating stragglers (§7.4) and environment failures (§8).

Prefill-Decoding (PD) Disaggregation. Within the data plane, PD disaggregation, which is widely adopted in LLM serving systems [37, 66], refines the `LLMProxy` routing described in §6.1. ROLLART supports PD disaggregation by deploying prefill and decoding workers on compute-optimized and bandwidth-optimized GPUs, respectively, and routing the two phases of each request to the corresponding workers. We evaluate the above optimizations in §7.4.

7 Evaluation

In this section, we present the end-to-end evaluation (§7.2), ablations of the four design requirements(§7.3), cross-cutting optimizations (§7.4), and the system's disaggregation tax (§7.5).

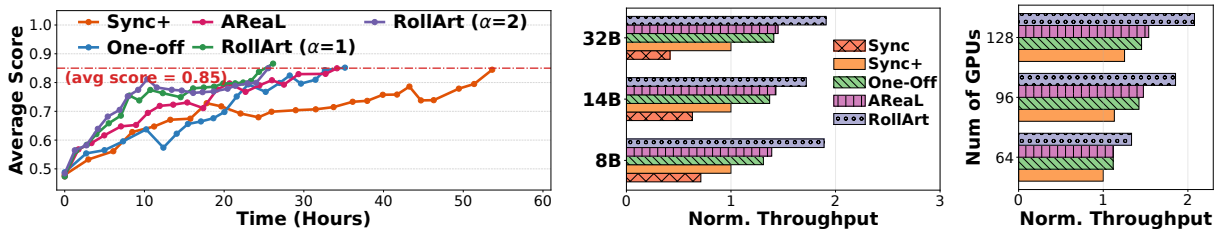
7.1 Evaluation Setup

Models and Tasks. We train Qwen3 [60] models from 8B to 32B on a diverse mix of agentic tasks (Table 1), using a 32k-token maximum context length. Because `SWE-bench` is substantially harder than the other tasks, we train it only on Qwen3-32B. For mathematical tasks, we use Qwen2.5-7B as the reward LLM to validate the reasoning process.

Infrastructure. We deploy ROLLART on a 96-GPU H800 cluster and a 32-GPU H20 cluster. GPU nodes within each cluster are connected by 400 Gbps InfiniBand; cross-cluster communication uses 200 Gbps Ethernet. We use one dedicated CPU cluster for `SWE-bench`, another for the remaining environments, and our internal serverless platform for reward workers. Unless otherwise stated, all experiments use 128 GPUs. We use NCCL [35] v2.26.5 for intra-cluster weight updates and a Mooncake v0.3.7 [38] storage server for cross-cluster communication.

Training Configuration. We train with GRPO [19], a batch size of 512, a group size of 8, and uniform task sampling. For asynchronous training, we reserve 32 H800 GPUs for training and use the remaining H20 and H800 GPUs for rollouts. Rollout tensor-parallelism degrees for Qwen3-8B/14B/32B are 1, 2, and 4, respectively; the corresponding training-side tensor and pipeline parallelism are tuned for throughput. Rollouts run on vLLM 0.8.4 with prefix caching and CUDA graphs enabled, while training runs on Megatron v0.12.2.

Baselines. We compare against four post-training baselines, grouped into sync and async designs. Since no existing open-source system supports our full spectrum of agentic tasks, we implement two sync baselines on top of ROLLART: **Sync**, a standard synchronous RL pipeline, and **Sync+**, which strengthens Sync with async reward computation, async environment interaction, and serverless offloading—techniques that are widely adopted in recent systems [10, 57, 67]. For async baselines, we compare with **One-off** [32] (see Figure 2-Right) and **AReaL**. One-off overlaps rollout and training by consuming trajectories from the previous step, but requires all trajectories in an iteration to finish with stale model weights. Differently, ROLLART with $\alpha = 1$ preempts and resumes ongoing rollouts in the next iteration. We re-implemented AReaL in ROLLART's codebase, adopting AReaL's staleness bound of one, which constrains trajectory-level staleness only at the start rather than at every turn of every trajectory, to ensure fairness. Both One-off and AReaL implementations incorporate the Sync+ optimizations, so they differ from ROLLART mainly in the coordination between training and rollout for staleness control, as well as the lack of hardware affinity routing. **Laminar** [45], another async baseline, repacks long-tail rollouts but does not account for hardware affinity, serverless reward computation, or long-tail environment exe-



(a) Time-to-Score (target 0.85) on Qwen3-32B. (b) Norm. Throughput across LLMs. (c) Scaling Efficiency.

Figure 10: End-to-end results: (a) time-to-score on Qwen3-32B; (b) throughput across LLMs (normalized to Sync+); (c) throughput of Qwen3-14B across H800 GPU counts, normalized to Sync+ on 64 H800 GPUs.

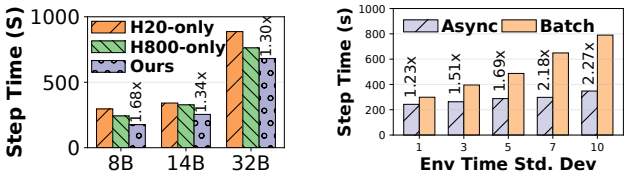
cution, and we provide a quantitative feature-decomposition argument in §7.2 (Throughput Efficiency). We run baselines on 128 H800 GPUs, so ROLLART incurs roughly 83% of the baselines' per-GPU-hour cost.

Metrics. We measure end-to-end latency as the average step time over five iterations, and throughput as the number of prompt and response tokens in a global batch divided by step time [47]. We report the average validation score across tasks.

7.2 End-to-End Evaluation

Model Convergence. We measure validation score every ten iterations on Qwen3-32B, the most network-sensitive model in our setup, and report the time to reach a target score of 0.85 in Figure 10a. The asynchronous configuration with $\alpha = 1$ reduces step time by 2.05×, 1.35×, and 1.31× over Sync+, One-off, and AReaL, respectively. One-off already improves over Sync+ by 1.52× by overlapping rollout and training. AReaL converges faster in the early stage but achieves similar time-to-score performance to the One-off approach because it bounds staleness only at the start of trajectories, collecting more stale long-tail trajectories. ROLLART enforces per-step staleness control within the bound α in §7.3 and promptly aborts stale trajectories. Increasing the bound to $\alpha = 2$ for ROLLART improves initial convergence but slightly worsens later time-to-score relative to $\alpha = 1$, consistent with the throughput–quality tradeoff in §7.3. The results in Figure 10b corroborate the advantages of ROLLART over these baselines across 8B, 14B, and 32B.

Throughput Efficiency. Figure 10b reports throughput efficiency normalized to Sync+; we set $\alpha = 1$ for ROLLART. The results show how throughput improves as the baselines add more overlap and scheduling flexibility. Sync+ first improves throughput by 1.40–2.40× over Sync by adding async reward computation, async environment interaction, and serverless offloading. One-off adds 1.31–1.47× over Sync+ by overlapping rollout and training. AReaL contributes another 1.03–1.06× over One-off. ROLLART then adds 1.22–1.36× over AReaL by layering hardware-affinity mapping on bounded-staleness async training. This ROLLART/AReaL gap is consistent with the hardware-affinity



(a) Rollout Efficiency. (b) Traj.-Level vs. Batch Rollout.

Figure 11: The efficiency of (a) hardware affinity and (b) trajectory-level rollout, where env latency is sampled from a Gaussian distribution with mean $\mu = 10$ s and standard deviation σ varying from 1 to 10 s (x-axis).

contribution measured in isolation in §7.3 (R1, 1.12–1.37× over an H800-only rollout). Overall, ROLLART achieves 2.65–4.58× throughput over Sync.

Laminar [45] is closed source, so we cannot evaluate it directly. Instead, the decomposition above isolates the capabilities that Laminar does not provide. The measured ROLLART/AReaL gap captures the effect of hardware affinity (§7.3, R1). Laminar does not optimize for environment instability, which yields a 1.23–2.27× improvement under environment variability (§7.3, R2), and it lacks serverless reward computation, which can reduce rollout time by up to ∼ 2× (§7.3, R3). Composing these isolated gains lower bounds the gap between ROLLART and Laminar.

Scaling Efficiency. We train Qwen3-14B while sweeping the cluster size from 64 to 128 H800 GPUs. Thus, ROLLART does not support hardware-affinity mapping in this evaluation. We compare the scaling performance of ROLLART under $\alpha = 1$. Figure 10c reports throughput normalized to Sync+ on 64 GPUs. As cluster size increases, Sync+ exhibits diminishing marginal gains, and One-off and AReaL show similar limited scaling performance from 96 to 128 GPUs, whereas ROLLART delivers 1.33–2.08× higher throughput, demonstrating better scaling efficiency.

7.3 Ablations of Design Requirements

We next present ablations of the four design requirements.

R1: Hardware-Affinity Mapping. We evaluate hardware-affinity mapping across LLM sizes on compute-optimized

and bandwidth-optimized GPUs. To isolate routing, we fix training to 32 H800 GPUs and compare three rollout configurations that yield approximately an equal cost: 72 H800 GPUs, 208 H20 GPUs, and an affinity-aware mix of 64 H800 plus 24 H20 GPUs. The mixed configuration routes mathematical and game-oriented agentic tasks to H20 GPUs while keeping prefill-heavy work on H800 GPUs. As shown in Figure 11a, RollArt reduces step time by 1.30–1.68× over H20-only and by 1.12–1.37× over H800-only. H20-only performs worst because many agentic tasks still incur frequent prefill operations, while the mixed configuration adds H20 capacity for decoding-heavy tasks without moving prefill-heavy work off compute-optimized GPUs. Beyond task-level mapping, PD disaggregation extends RollArt's affinity routing from task-level to phase-level placement; we evaluate it as a cross-cutting optimization in §7.4.

R2: Trajectory-Level Asynchrony. Trajectory-level rollout decouples environment interaction across trajectories, so slow turns do not stall an entire batch (§6.1). To isolate this effect, we run Qwen3-8B with a 32k context and inject per-turn environment latency sampled from Gaussian distributions with mean $\mu = 10$ s and standard deviation σ ranging from 1 s to 10 s. This synthetic injection controls latency variance; production-side straggler stacking is reported in §8. Figure 11b compares trajectory-level and batch-level environment interaction using average step time over ten iterations. As σ increases, trajectory-level rollout improves over batch-level interaction from 1.23× to 2.27×, showing that it better absorbs environment variance.

R3: Serverless Offloading. We evaluate serverless offloading against a local-GPU reward setup on a 16-H800 cluster. We run three concurrent mathematical agentic RL jobs with Qwen3-8B/16k as the actor agent and Qwen2.5-7B as the reward LLM. Both serverless and local setups reserve eight GPUs for training. The local setup assigns four remaining GPUs to rollout and the other four to reward, whereas the serverless setup assigns all eight remaining GPUs to rollout and offloads reward computation to an elastic serverless platform. Figure 12 reports GPU utilization and per-step rollout time for a batch size of 84, including asynchronous reward computation. Serverless offloading raises average GPU utilization from 6% to 88% and doubles the local rollout allocation, reducing average rollout time from 158 s to 77 s. Although remote serverless reward calls introduce network I/O, the disaggregation tax measured in §7.5 is small (max 2.1 s, mean 0.01 s per call). Thus, transfer cost does not negate the resource efficiency gains from serverless offloading.

R4: Asynchronous Bound. We quantify the throughput–convergence tradeoff induced by the per-trajectory asynchronous bound α. Figure 13 sweeps α from 1 to 6 and reports average step time across LLMs. Larger bounds reduce staleness-triggered trajectory aborts and lower step time, but the gain quickly plateaus: the best bound differs by LLM

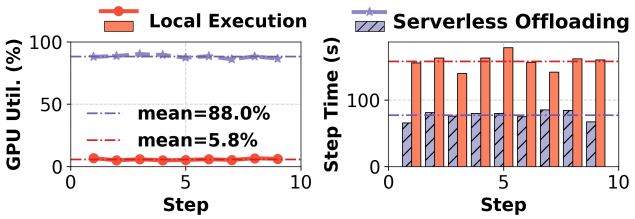


Figure 12: Comparison between dedicating local GPUs and using serverless offloading.

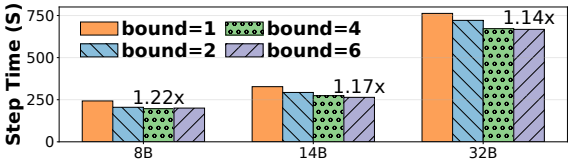

Figure 13: Average step time across LLMs and bounds.

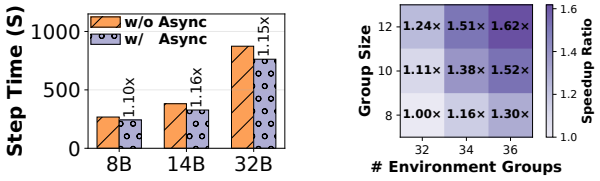
and improves step time by at most 1.22× over $\alpha = 1$. These throughput gains do not necessarily improve time-to-score. Figure 10a shows that $\alpha = 2$ already incurs a measurable late-stage time-to-score regression , and we set $\alpha = 1$ by default.

7.4 Cross-Cutting Optimizations

We evaluate the three cross-cutting optimizations in §6.3.

Asynchronous Weight Transfer. Cross-cluster weight transfer is costly when training and rollout clusters communicate over heterogeneous interconnects. To quantify the benefit of overlap, Figure 14a compares RollArt's asynchronous cross-cluster communication with veRL's NCCL-based scheme, which assumes uniformly high-bandwidth links across servers. Asynchronous communication reduces end-to-end step time by 1.10–1.16× across LLMs. Table 4 decomposes this gain. *Weight Push* is the cost of streaming updated weights from the training cluster to the Mooncake store over the cross-cluster TCP/Ethernet link. *Accumulated Weight Pull* is the total cost of inference workers pulling new weight buckets from Mooncake, while *Exposed Weight Pull* is the residual pull cost not hidden by ongoing rollout. The *Naive (Push + Acc. Pull)* row reports the cost exposed by a synchronous design such as veRL. Asynchronous overlap hides 67–78% of the pull cost, reducing the exposed overhead to at most 9.6 s on 32B versus 38.6–157.0 s without overlap.

Redundant Environment Rollouts. Redundant rollouts exploit GRPO's group structure to mask environment failures



(a) Cross-Cluster Comm. (b) Redundant Env Rollout.

Figure 14: Cross-cutting optimizations: (a) async cross-cluster weight transfer; (b) redundant environment rollouts.

Table 4: Breakdown of ROLLART's asynchronous cross-cluster weight transfer (seconds).

Cost	8B	14B	32B
Naive (Push + Acc. Pull, no overlap)	38.6	84.1	157.0
Weight Push	32.4	67.8	127.3
Accumulated Weight Pull	6.2	16.3	29.7
Exposed Weight Pull (ROLLART)	1.4	5.1	9.6

and stragglers. We run Qwen3-8B/32k on 32 H800 GPUs to vary the number of environment groups and the group size on the `GEM-math` task. Figure 14b reports rollout speedup ratios. Larger groups and more environment groups increase the chance that a fast subset finishes early, sustaining efficiency under straggler conditions. The maximum speedup reaches 1.62×, and increasing either parameter yields a speedup.

PD Disaggregation. PD disaggregation extends hardware-affinity mapping from task-level to phase-level placement. We train Qwen3-32B and Qwen3-30B-A3B models on `SWE` tasks with batch size of 128 and 32k sequence length. We evaluate two configurations: 1P3D and 2P2D where each prefill node uses eight H800 GPUs and each decoding node uses eight H20 GPUs. For the dense model, PD disaggregation achieves relatively modest speedups of 1.03× and 1.05× compared with colocation. For the MoE model, 1P3D and 2P2D achieve 1.11× and 1.21× speedup over colocation, respectively. The performance and optimal configuration[2] of PD disaggregation are workload- and model-dependent. §9 further discusses how to automate these configurations to adapt to workload demands.

7.5 Disaggregation Tax

We next quantify the disaggregation tax along three data paths.

Cross-Cluster Weight Synchronization. Weight transfer is the largest overhead, but the asynchronous data-movement in §7.4 hides most of it. As Table 4 shows, ROLLART exposes 1.4–9.6 s of residual pull cost; without overlap, rollout would block on Push + Accumulated Pull for 38.6–157.0 s.

Env-Interaction I/O. Trajectory-level rollout moves data between the environment and inference clusters at each interaction. Across our evaluation, the maximum transferred volume is 2.7 MB, and the maximum and average per-call transfer overheads are 1.4 s and 0.02 s, respectively. These costs are negligible relative to per-step training time.

Serverless Reward I/O. Remote reward calls transfer trajectory payloads of up to 5.2 MB, with maximum and average per-call overheads of 2.1 s and 0.01 s. The residual disaggregation tax is therefore dominated by cross-cluster weight transfer, which ROLLART overlaps with rollout, so data movement does not erase the end-to-end gains reported in §7.2.

[2]We also evaluated the 3P1D configuration, and both models achieved worst rollout performance, as the single decoding node became a bottleneck.

Table 5: Rollout time (seconds) comparison between colocation and disagg. under different models and configurations.

Model	1P3D	Colocate	2P2D	Colocate
Qwen3-32B	722.7	741.2	701.6	734.9
Qwen3-30B-A3B	294.8	327.4	251.1	305.2

8 ROLLART in Production

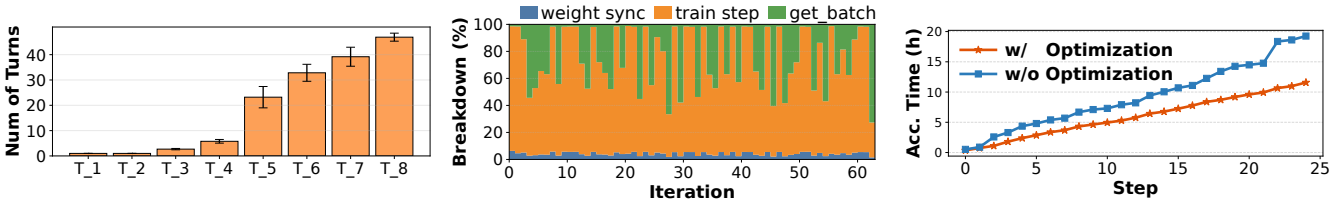
Over the past nine months, thousands of agentic RL jobs have used ROLLART for post-training. We report one large production deployment on more than 3000 GPUs to show how the workload properties in §3 appear in practice and how operators tune ROLLART at scale.

Workload Characterization. We trained a hundreds-of-billions-parameter MoE LLM with ROLLART on in-house mathematical and software-engineering agentic tasks. Prompts and responses reach 12k and 46k tokens, respectively, and the average number of turns per task ranges from 1 to 48 (Figure 15a). This mix exposes both prefill-heavy and decode-heavy behavior. Stragglers persist throughout training: in each step, the maximum response length exceeds 5× the mean and peaks at 9×; the maximum number of environment-interaction turns remains above 40× the mean. These tails explain why production runs need both fast prefill execution and trajectory-level rollout that can absorb slow environments.

The job uses asynchronous training with a 1:5 ratio of training to generation GPUs and an asynchronous bound of one to balance rollout throughput with gradient stability. Still, the longest iteration reaches 1.5 hours (Figure 15b). The bottleneck is the blocking `get_batch` call: after computing log probabilities and gradients, the training stage waits for `SampleBuffer` to collect enough trajectories. This accounts for up to 62% of iteration time as GPU idleness; removing it would ideally reduce training time by 22% (Figure 15b).

Characterization-Driven Optimization. The production trace also shows why coarse-grained characterization is a practical starting point for hardware affinity: task domains are known before training, and their token and turn profiles differ substantially. Using this information, we adjust the training-to-generation resource ratio and tune prefix caching for the MoE architecture. Figure 15c shows that these changes achieve a 1.66× end-to-end speedup over the first 25 steps. Beyond this resource tuning, we apply dedicated optimizations for environment stability and failure recovery.

Optimizing Environment Stability. Across 60 iterations, long environment initialization failures appear in seven iterations. At this scale, Docker-based environments on Kubernetes are sensitive to image-pull failures and network instability during `env.reset`. We therefore use a multi-tiered cache: an internal image registry mirrors external images, and a distributed load-balanced cache between compute nodes and the registry absorbs high-volume requests. During `env.reset`, clients fetch images from cache first. This optimization raises



(a) Average Number of Turns per Task. (b) Step Time Distribution. (c) Accumulated Step Time.

Figure 15: Production-grade agentic RL workload characterization and optimization.

the `env.reset` success rate above 99.99%. It also avoids repeated image-pull retries, keeping over 99.99% of initialization under one minute. After the optimization, no more than ten heavy-tailed initialization events occur among hundreds of thousands of resets; trajectory-level rollout and redundant environments absorb the remaining tails.

System Resilience. RollArt isolates failures across environment, reward, inference, and training workers. Persistent sessions and exponential backoff reduce environment-connection timeouts; Kubernetes manages environment workers, and the serverless platform manages reward workers. If an inference worker fails, RollArt first restarts it on the same GPU; after repeated failure, the worker is removed and its stored trajectories resume on healthy workers. Training-worker failures restart from the latest checkpoint. In a week-long training run, we observed only one failure.

9 Discussion and Related Work

Automating Hardware-Affinity Mapping. RollArt currently requires static, per-task-domain affinity declarations, which is a real limitation when computation profiles shift mid-run. In our production deployment, however, per-domain profiles are stable: turn counts vary widely *across* families but stay bounded *within* each domain across iterations, so coarse `hw_mapping` declarations needed no re-tuning across the week-long 3,000-GPU run. The natural extension is an online profiler integrated with the resource manager: per-domain prefill/decode latency would let RollArt re-route requests when within-domain shifts occur (e.g., a domain alternating between long-observation and long-response prompts) and the same profiling can drive PD-disaggregation ratios (§6.3). Per-iteration optimality is not required: workload profile is dominated by task-domain identity rather than per-step policy variance, so profiling decisions stabilize over a few iterations.

Operational Regime. RollArt targets multi-task agentic RL on heterogeneous, disaggregated infrastructure; it offers limited benefit on homogeneous clusters, where **R1**'s affinity routing collapses to a no-op; on strict on-policy or compute-light RL, where **R4**'s bounded-staleness overlap yields little; and on deployments without elastic compute, where **R3**'s serverless offloading is unrealizable. Trajectory-level rollout (**R2**) and redundant environment rollouts (§7.4) still apply to any agentic RL workload exposed to long-tail environments.

RL Post-Training Systems. Many systems address the systems challenges of RL post-training. Early frameworks [17, 21, 46, 62] adopt appropriate stage and resource mapping to improve utilization. Subsequent systems [5, 6, 10, 15, 18, 27, 43, 45, 67, 68] explore a range of accelerations, including speculative decoding, fusion of pipeline stages, asynchronous or decoupled training to hide latency, and various forms of resource disaggregation. RollArt builds on the disaggregated paradigm and assigns workloads based on hardware affinity.

Resource Disaggregation. Resource disaggregation is adopted in many modern systems to improve utilization [14, 26, 42]. This pattern is prevalent in LLM serving, where systems separate the prefill and decoding phases [20, 37, 38, 51, 52, 66, 69]. Several RL systems apply a similar principle, separating the training and rollout stages across different GPU types [56, 67]. Compared to these approaches, RollArt provides a more general and fine-grained disaggregation model, tailored for the entire lifecycle of multi-task agentic RL.

10 Conclusion

We presented RollArt, a system for multi-task agentic RL training on disaggregated infrastructure. Its design rests on four requirements: hardware-affinity workload mapping (**R1**), trajectory-level asynchronous rollout (**R2**), serverless offloading for stateless reward (**R3**), and bounded-staleness asynchronous training (**R4**). On Qwen3 (8B–32B), RollArt reduces step time by 1.31–2.05× over strengthened synchronous, one-off, and AReaL baselines. A week-long, 3,000-GPU production run training a hundreds-of-billions-parameter MoE model confirms these gains at scale.

Abstract

Reinforcement Learning (RL) has emerged as a critical technique for advancing modern Large Language Models (LLMs), yet existing synchronous RL systems face severe performance bottlenecks. The rollout phase, which dominates end-to-end iteration time, suffers from substantial long-tail latency and poor resource utilization due to inherent workload imbalance. We present SEER, a novel context learning RL system that addresses these challenges through a key observation: requests sharing the same prompt exhibit strong similarities in output lengths and response patterns. Leveraging this insight, SEER introduces three coordinated techniques: (1) divided rollout for dynamic load balancing, (2) context-aware scheduling to mitigate long-tail request delays, and (3) adaptive grouped speculative decoding to accelerate generation. These mechanisms work in concert to markedly reduce long-tail latency and improve resource efficiency during rollout. Evaluations on production-grade RL workloads demonstrate that SEER achieves up to 2.04× end-to-end rollout throughput improvement compared to the state-of-the-art synchronous RL systems, while notably reducing long-tail latency by 72–94%.

1 Introduction

Reinforcement Learning (RL) has become a cornerstone in the development of state-of-the-art Large Language Models (LLMs), enabling significant breakthroughs in complex reasoning and problem-solving capabilities [9, 38, 39]. The iterative RL training process alternates between a *rollout phase* for data generation and a *training phase* for updating model parameters. However, the rollout phase consistently emerges as the dominant bottleneck, consuming approximately 80% of the total iteration time (see Table 1). Therefore, improving the efficiency of the rollout phase represents one of the most pressing challenges in modern LLM development.

The primary challenge in RL rollout arises from severe resource inefficiency driven by the increasing demand for long-generation capabilities, especially in tasks requiring complex chain-of-thought (CoT) reasoning. These workloads create two fundamental bottlenecks. First, long-generation requests exhibit highly **unpredictable and rapidly increasing memory footprints**: a CoT request may begin with only a few hundred megabytes of KVCache usage but expand to tens of gigabytes as decoding progresses. This volatility forces the system to shrink batch sizes dynamically or to preempt running requests; both outcomes reduce hardware efficiency, and preemptions are particularly costly because they trigger expensive re-prefills, ultimately degrading rollout throughput.

Table 1: Time distribution across RL training phases for different workloads. Detailed configurations given in §4.1.

	Rollout	Training	Weight Update
Moonlight [24]	84%	14%	2%
Qwen2-VL-72B [43]	63%	31%	6%
Kimi-K2 [38]	87%	10%	3%

Second, long-generation requests produce a **heavy-tailed distribution of output lengths**, resulting in pronounced load imbalance. Toward the end of a rollout iteration, only a small number of disproportionately long-running requests remain active, leaving most accelerators underutilized. The inefficiency is so severe that attempting to use idle nodes to accelerate these long-tail requests often yields little benefit and can even harm performance due to increased inter-node communication overhead.

To improve hardware utilization, recent works have explored asynchronous rollout systems [5, 10, 11, 29, 33, 51], which overlap the rollout and training phases. While this approach can reduce end-to-end iteration time, it comes at the cost of algorithmic fidelity. By nature, these systems introduce a degree of off-policy learning, as data generated with model parameters from step i may be used to train the model at step $i+1$ or beyond. Furthermore, asynchronous or non-strictly synchronous [8, 53] RL systems often suffer from distributional skew, where faster-to-generate short samples

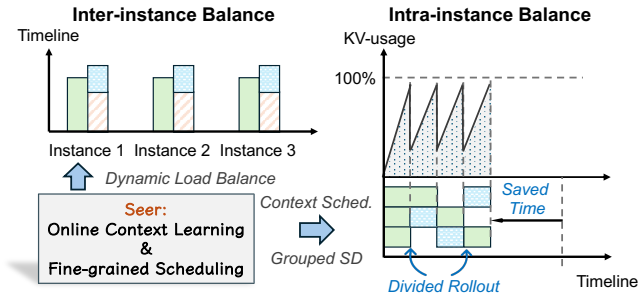
(a) Group-level rollout.



(b) SEER's rollout.

Figure 1: Challenges and SEER's solution for long-generation rollout.

disproportionately populate early training batches [40]. These off-policy effects can diminish final model performance and complicate debugging and reproducibility [49]. Consequently, synchronous (or "on-policy") rollout remains critical in many settings for ensuring methodical evaluation, reproducibility, and strict adherence to the underlying algorithm's assumptions. This paper, therefore, focuses on optimizing the synchronous case, although we note that our techniques can also be adapted to improve asynchronous settings.

Speculative decoding [17] (SD) presents another promising direction for accelerating memory-bound generation, as its parallel verification mechanism can utilize more computational resources to accelerate individual requests. However, conventional SD methods struggle to simultaneously achieve high draft accuracy and low draft overhead in RL settings, where both the request workload and the target model itself evolve dynamically. This motivates the need for adaptive SD techniques tailored to the unique characteristics of RL rollout.

To address these challenges, we introduce SEER, a novel system for synchronous RL rollout that dynamically exploits contextual information within the workload to maximize resource efficiency. SEER is built upon a key observation: Group Relative Policy Optimization (GRPO) [31] and its growing family of variants (DAPO [48], GSPO [50], Dr.GRPO [25], etc.), which have become the dominant paradigm for LLM post-training, generate G (typically 8–16) responses per prompt, and **responses within a group tend to exhibit similar length profiles and recurring local token patterns**, which represent a rich structure that existing schedulers and inference engines leave untapped. For instance, generating an early "probe" response per prompt provides a strong, online estimator of that prompt group's remaining work (i.e., expected output length and KVCache footprint), enabling more informed scheduling decisions than static heuristics. SEER leverages this latent intra-group context to make three key contributions:

1) Divided Rollout with Global KVCache: SEER departs from conventional group-level scheduling, where all requests within a prompt group are treated as a single, inseparable unit. This traditional approach causes pronounced inter-instance and intra-instance load imbalance. As illustrated in Figure 1, SEER instead performs *Divided Rollout*, splitting each group not only into G independent requests but further into smaller chunks that are scheduled incrementally. This fine-grained decomposition lets the scheduler pack many short requests together early in rollout to fully utilize VRAM, and later, when long requests dominate, adjust concurrency based on KVCache budgets to avoid preemptions. SEER's global scheduler continuously monitors KVCache usage across instances and can migrate a request to a less-loaded worker when its next chunk is scheduled. This migration is efficient because SEER uses a global KVCache pool adapted from Mooncake [30] and shared across all instances, eliminating the cost of prefill recomputation.

2) Context-Aware Scheduling: SEER leverages a *"speculative request"* from each GRPO group to estimate that group's remaining workload—specifically its likely generation length and KVCache footprint. These lightweight online estimates allow SEER to approximate a longest-job-first scheduling policy that pairs long requests with short ones to maintain dense batches throughout rollout. Experiments in §4.5.1 show that this approach significantly reduces the time spent in the long-tail phase by 89%.

3) Adaptive Grouped Speculative Decoding: To leverage speculative decoding for rollout acceleration while overcoming the acceptance rate collapse of traditional SD, SEER introduces a context-learning-based speculative mechanism. SEER deploys a Distributed Grouped Draft Server (DGDS) that maintains a Compressed Suffix Tree [45] (CST) for each group, aggregating token sequences from all requests within the same group. This approach creates a highly accurate, dynamic "draft model" that is inherently synchronized with the target model. Additionally, DGDS introduces a Marginal-Benefit-Aware Adaptive Speculation policy that balances overall throughput with the latency of high-priority requests. Our ablation experiments in §4.5.2 demonstrate the effectiveness of the SD components. Our adaptive grouped speculative decoding outperforms multiple SD strategies, achieving up to 1.3× performance improvement. Compared to vanilla CST-based SD without group context, it increases the mean acceptance length by 0.22.

Beyond RL rollout, the components and design principles

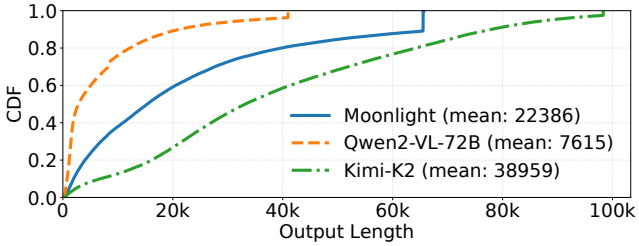


Figure 2: Distribution of output lengths during rollout across three reasoning tasks.

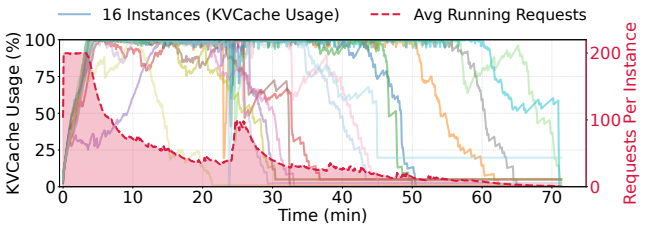
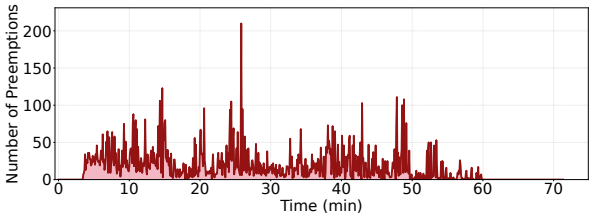


(a) KVCache utilization and average number of running requests across instances.



(b) Request preemption count.

Figure 3: KVCache utilization, number of running requests, and preemption count during a synchronous rollout phase of the Qwen2-VL-72B task. In the early stage of rollout, insufficient KVCache capacity causes frequent request preemptions; in the later stage, a small number of extremely long request groups contribute to a long-tail period that accounts for nearly half of the total rollout time.

of SEER are broadly applicable to other large-scale parallel generation workloads. Divided Rollout addresses KVCache bloat and load imbalance that arise in any high-concurrency, long-form generation serving scenario. Similarly, Context-Aware Scheduling and Adaptive Grouped Speculative Decoding generalize to any multi-sample setting or generation task whose requests exhibit recurring structural similarities.

We have implemented SEER and conducted an extensive evaluation on 256 H800 GPUs across multiple production-grade RL workloads, encompassing models ranging from tens of billions to over one trillion parameters. Our experiments demonstrate that SEER consistently improves end-to-end rollout throughput by 44–104% and cuts long-tail latency by 72–94% relative to a highly optimized synchronous baseline. Through detailed ablations, we isolate the contributions of divided rollout, context-aware scheduling, and adaptive grouped speculative decoding, showing that each component provides substantial and complementary gains. We further compare SEER against state-of-the-art rollout optimization approaches, including a non-strictly synchronous system [53], as well as multiple speculative decoding strategies [17, 22, 28]. We find that SEER achieves the best overall performance while preserving strict on-policy training semantics.

2 Background and Motivation

Reinforcement learning (RL) for LLMs progresses through a repeated iterative loop. In each iteration, the model generates responses for a batch of prompts (rollout), evaluators assign quality scores to those responses (reward computation), these scores are transformed into supervision signals (experience construction), and the model is updated accordingly (training). The updated parameters are then distributed to inference workers to initiate the next iteration (weight update). A series of recent systems aim to accelerate this loop by improving coordination across stages. veRL [34] colocates rollout and training to reduce data movement, RLHFuse [52] overlaps reward computation with experience construction, and Kimi-K2 [38] further optimizes checkpoint conversion and weight distribution. However, Table 1 makes clear that such non-rollout phase optimizations are insufficient: across three representative production workloads, rollout alone occupies 63–87% of total iteration time, overwhelmingly dominating all other stages.

This imbalance is structural and rooted in the nature of training reasoning models. RL increasingly relies on chain-of-thought (CoT) supervision, which encourages models to produce longer and more detailed reasoning traces. As a result, rollout exhibits two defining characteristics: long average output lengths and extremely high variance across requests. Figure 2 shows that generations range from a few hundred tokens to as many as 96k tokens. Long average outputs exert heavy pressure on memory because KVCache consumption scales with request length, while the extreme variance produces severe long-tail effects: a small number of exceptionally long requests monopolize GPU resources near the end of rollout. Figure 3 illustrates how these properties cause substantial resource underutilization and imbalance, motivating the two challenges discussed next.

2.1 Challenge #1: Request Scheduling Dilemma

During the rollout process of long-CoT models, the KVCache memory of requests undergoes dramatic changes, from negligible in the early phase to several gigabytes per request in the final stage. This varying memory consumption creates

a dilemma in concurrency management. If concurrency is not controlled, the increasing request length leads to memory exhaustion, resulting in massive **request preemption**, where the KVCache of some running requests is evicted to allow a few requests to complete inference. This introduces huge overhead for KVCache recomputation. Conversely, if concurrency is controlled to avoid preemption, requests in their early generation phase (with only a few hundred tokens) may occupy the entire memory space for hundreds of seconds, leading to severe **resource underutilization**. Furthermore, this memory footprint is amplified by a factor of G in GRPO-like algorithms, where G responses are generated for each prompt within the same group, further exacerbating the inter-instance imbalance.

To address the inter-instance imbalance caused by group-level scheduling, a concurrent work Roll Flash [26] proposes *prompt replication*, which splits request groups into independent requests for separate scheduling, thereby resolving the amplified imbalance caused by scheduling entire request groups. However, this does not address the dilemma of *intra-instance* concurrent scheduling, and still suffers from uneven request distribution across instances, leading to inter-instance imbalance. The root cause of these issues is treating individual (or groups of) requests as indivisible monolithic units, even though rollout scenarios impose no strict latency constraints on individual requests. This persistent scheduling dilemma motivates our design of *divided rollout* (detailed in §3.2), which schedules requests at the chunk level with little overhead, enabling fine-grained scheduling and dynamic load balancing.

2.2 Challenge #2: Severe Long-tail Effect

The long-tail problem is another critical issue in rollout, widely noted in prior work [8, 11, 53]. As shown in Figure 3a, the long-tail phase can account for nearly 50% of the total rollout time. This phenomenon arises from two factors: (1) In GRPO-like algorithms, requests within the same group tend to have similar lengths. Groups with extremely long average lengths form "monolithic" batches that cause severe load imbalance across instances when scheduling is performed at the group granularity. (2) Under memory constraints, requests may be preempted or delayed, causing extremely long requests to be blocked and further exacerbating tail latency.

To mitigate the long-tail effect, recent works [5, 10, 11, 33, 51] have proposed *asynchronous RL*. Unlike synchronous methods, where all training experiences must originate from the current policy iteration, asynchronous methods allow training on stale rollout data from previous policy iterations, introducing *off-policyness*. Other works [8, 53], while nominally maintaining synchrony, allow deferring a portion of requests to subsequent iterations, thereby sacrificing iteration-level consistency compared to strict synchronous RL systems. Although asynchronous or non-strictly synchronous RL can reduce the long-tail impact, many RL practitioners still prefer synchronous training to achieve the best convergence and maintain reward stability.

Speculative decoding (SD) [2, 6, 14, 17–20, 22, 28] offers a promising approach to accelerate the long-tail phase while preserving synchronous RL training guarantees. SD consists of two stages: *Draft* and *Verification*. In the draft stage, a lightweight mechanism proposes candidate tokens, which are then verified in parallel by the target model in the verification stage. Since parallel verification of n tokens by the LLM is faster than serial generation of n tokens due to reduced memory access, SD can improve the generation speed for individual requests. Draft tokens can be produced by a smaller auxiliary model [17–20], which offer high acceptance rates but incur significant draft overhead, or by retrieval-based methods such as n-gram matching, which look up a request's recent tokens in its own generation history and extend the longest match. SuffixDecoding [14, 28] optimizes n-gram matching with a Compressed Suffix Tree (CST), a space-efficient suffix index that supports longest-match lookup and draft-token generation in linear time. However, when only the request's own history serves as the reference corpus, the acceptance rate remains low. RL rollout scenarios further exacerbate these limitations: batch sizes fluctuate dramatically, and the target LLM undergoes continuous updates, causing rapid "model drift". Existing SD strategies suffer from either high draft overhead or low draft token accuracy, resulting in marginal or even negative performance gains in rollout scenarios.

2.3 Opportunity: Shared Contextual Information in Group Sampling

In LLM reinforcement learning practice, the most widely adopted algorithm is Group Relative Policy Optimization (GRPO) [31]. GRPO performs group-based preference optimization by sampling G candidate responses for each prompt, computing rewards for these responses, and then normalizing the rewards *within* the group to obtain advantages. Several recent works [25, 48, 50] refine GRPO to improve generalization, but they all preserve the core principle of generating multiple responses for the same prompt. Other efforts, such as BroRL [12] and Knapsack RL [21], even scale G to 512 or more to enhance exploration. As a result, GRPO and its variants establish *group sampling* as a dominant training paradigm, in which each prompt is associated with a set of responses generated by the same policy.

This group sampling paradigm naturally introduces strong and stable contextual signals during rollout. Since all responses in a group are conditioned on the same prompt and produced by the same model, they exhibit notable similarity in semantics, structural templates, and generation length. However, existing RL systems typically treat each prompt group as a monolithic unit during rollout, overlooking the potential to externalize and exploit such intra-group similarity

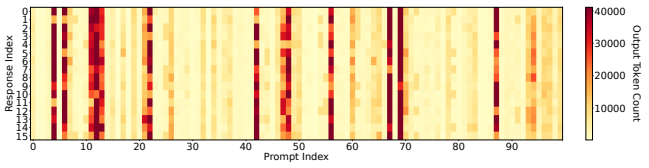


Figure 4: Length correlation within response groups. Each column represents a prompt group in the GRPO rollout, and each cell corresponds to an individual response. The color intensity indicates output length.

Table 2: Mean acceptance length in n-gram speculative decoding with grouped pattern references under different draft strategies. Linear generates one draft sequence per step, while multi-path generates multiple candidate sequences with top-k branching. Values represent mean acceptance length (including bonus token).

Ref. Count	**Linear**	**Multi-Path (k=2)**	**Multi-Path (k=4)**
$n = 0$ (baseline)	1.70	1.77	1.85
$n = 1$	2.04	2.14	2.25
$n = 5$	2.32	2.44	2.59
$n = 15$	2.53	2.69	2.85

as **shared contextual information**. Our statistical analysis shows that this shared context is sufficiently rich to support both scheduling and inference optimizations.

First, at the *length* level, responses within the same group have highly correlated generation lengths. Prior work [3,7,51] has shown that response length is predictable from prompt and model characteristics. Our measurements on real RL workloads, summarized in Figure 4, further confirm that most prompt groups in GRPO rollout exhibit strong length correlation. We observe that responses within the same group tend to have similar lengths, forming visually consistent columns. This length context can be obtained cheaply via speculative sampling and used to inform global scheduling policies, such as approximate longest-first scheduling, which prioritizes groups likely to produce very long responses. Such length- and memory-aware scheduling is a promising direction for mitigating the long-tail effect while respecting device memory constraints.

Second, at the *pattern* level, grouped responses share recurring semantic and syntactic structures that can be exploited to accelerate inference. Instead of relying solely on each request's own history, we can aggregate previously generated tokens from other responses in the same group into a shared pattern dictionary (e.g., via compressed suffix trees) and use it as an n-gram reference for speculative decoding. To quantify this opportunity, we sample 20 prompt groups from a Qwen2-VL-72B task and simulate n-gram speculative decoding under different draft strategies. Table 2 reports the mean acceptance length (including bonus tokens) for varying numbers of grouped references n and different drafting modes. Compared to the self-referencing baseline with no grouped references ($n = 0$), incorporating even a small number of intra-group references (e.g., $n = 1$ or $n = 5$) consistently increases the mean acceptance length, and using more references (e.g., $n = 15$) together with multi-path drafting yields the largest gains. In the later stage of rollout, speculative decoding with full grouped pattern references can improve the number of accepted draft tokens by up to 119% compared to a baseline that only uses per-request history.

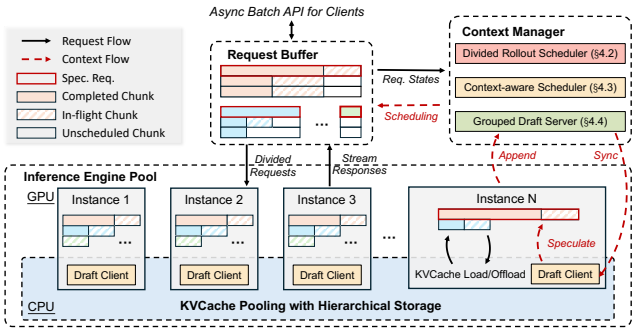

Figure 5: The overview of SEER.

In summary, group sampling in GRPO-like algorithms provides rich shared contextual information, both in terms of length correlation and pattern similarity, that is currently underutilized by existing RL systems. Our statistical data indicates that this contextual signal can be harnessed to enable length- and memory-aware scheduling and grouped speculative decoding, offering a promising opportunity to mitigate long-tail inefficiency and improve rollout throughput in synchronous LLM RL training.

3 Design of SEER

3.1 Overview

SEER is a synchronous, colocated RL system designed to substantially reduce rollout long-tail latency and improve overall system throughput without compromising algorithmic fidelity. The broader pipeline remains standard: training uses Megatron [35] for distributed optimization, rollout uses vLLM [16] for generation, reward computation is handled by an independent server that runs in parallel with generation, and Moonshot Checkpoint Engine [1] ensures rapid movement of updated model weights. SEER's contributions therefore layer onto a conventional architecture without imposing additional integration overhead.

Within rollout, as motivated by the workload analysis in §2.3, SEER introduces a unifying idea that drives its three innovations: *Online Context Learning*. SEER continuously learns the intra-group shared properties and uses them to

guide scheduling and decoding. Length similarities become signals for estimating whether upcoming generations are likely to be long-running; pattern similarities reveal opportunities to construct group-level draft predictions that accelerate decoding without a separate draft model. In addition to these optimizations, SEER also incorporates efficient memory management, load balancing, and asynchronous reward computation.

To support this context-driven approach at scale, the rollout subsystem is organized into three tightly connected components as illustrated in Figure 5. An `Inference Engine Pool` hosts multiple model-serving instances backed by a distributed KVCache pool, enabling KVCache migration across nodes without recomputation. A `Request Buffer` provides a global view of all pending and in-progress rollout work, allowing the system to coordinate concurrency precisely. Atop these components, a logically centralized `Context Manager` maintains group-level contextual views and drives scheduling and draft generation decisions.

On this foundation, SEER introduces three techniques that address the underlying challenges of long-CoT rollout. Divided Rollout (§3.2) resolves the concurrency–memory dilemma by breaking each request into smaller schedulable units and enabling fine-grained placement across instances. Context-Aware Scheduling (§3.3) then leverages learned length context to approximate a longest-first policy that reduces tail latency. Finally, Adaptive Grouped Speculative Decoding (§3.4) exploits shared token-pattern structure to build speculative decoding at the group level and dynamically adjusts draft lengths to maximize throughput. Despite these performance enhancements, SEER maintains logical consistency across all stages of the synchronous RL pipeline, thereby achieving an algorithmically lossless reinforcement learning process.

3.2 Divided Rollout

As illustrated in Figure 1, conventional group-level request scheduling mechanisms lead to severe load imbalance both within and across inference instances. Divided Rollout addresses this core tension by rethinking what constitutes a schedulable unit. Rather than binding any request group to a single execution slot, SEER not only decomposes it into individual requests but further divides each request into a sequence of generation chunks, each representing a bounded segment of progress. A request that would previously monopolize an instance for thousands of tokens becomes a pipeline of shorter units that can be interleaved and redistributed as the system's load evolves. This change in granularity enables continuous rebalancing: after each chunk completes, the next chunk can be scheduled on whichever instance currently has the most available memory and compute.

However, Divided Rollout poses significant challenges to the KVCache system. When requests are rescheduled at the chunk level, all KVCache will be recomputed, and this overhead can even negate the benefits of load balancing. Although existing inference frameworks [4, 41] support offloading request KVCache to DRAM within instances, the dynamic load balancing scheduling policy may reschedule requests to other instances, leading to cache misses. Therefore, Divided Rollout requires a globally shared, high-capacity cache system to support chunk-level request scheduling with minimal overhead.

To address this challenge, SEER builds upon Mooncake [30] to construct a globally shared KVCache pool distributed across inference nodes. The KVCache of all active requests is stored in a hierarchical global storage spanning DRAM and SSD, with RDMA enabling rapid KVCache transfer between nodes. From the perspective of the upper-level scheduling system, request chunk scheduling can be treated as stateless, eliminating the need to consider KVCache distribution. To further improve cache utilization and reduce the migration overhead, SEER layers a cache-aware policy on top of this pool. Using the number of in-flight requests as a load signal, the scheduler routes each incoming request to the node holding the longest matching cache prefix as long as the load remains balanced across instances. Once the spread of in-flight counts exceeds an imbalance threshold, the scheduler switches to a load-first decision and dispatches the request to the least-loaded node. Whenever this load-driven placement leaves a cache-affinity gap larger than a configurable margin such as 512 tokens, the chosen node proactively pulls the missing KVCache from the best-affinity node so that the corresponding prefix is not recomputed. The pool itself further exploits the predictable access pattern of a rollout iteration. Rather than relying solely on LRU, the KVCache of a request is released the moment that request finishes, which maximizes the DRAM capacity available to active requests.

What distinguishes Divided Rollout from prior offloading or preemption-based approaches is that cache movement is no longer a reactive measure taken only when memory pressure becomes intolerable. Instead, since chunk-level work units have well-defined memory footprints, the scheduler can proactively place and move them to optimize global system balance rather than merely avoiding out-of-memory events. This shift from reactive eviction to proactive, mobility-aware scheduling is the key novelty that allows SEER to resolve the concurrency–memory dilemma that has long constrained synchronous RL rollout. Compared with live migration systems for online serving (e.g., Llumnix [37]), it offers greater scheduling flexibility due to the absence of strict per-request latency constraints.

3.3 Context-Aware Scheduling

Long-CoT rollout inevitably runs into memory limits, which means some requests must wait. When the scheduler cannot anticipate which requests will run long, these delays occur

arbitrarily, creating unnecessary congestion in the tail. As shown in §2.3, requests within the same GRPO group tend to exhibit similar output lengths. SEER leverages this structure to predict which requests are likely to be long-running and schedules them more intelligently. The goal is to approximate a longest-first scheduling (LFS) policy (known to reduce tail latency) without needing to know true output lengths in advance.

SEER's key idea is to designate one request per group as a **speculative request**. This request serves as an online probe: by observing how quickly it completes during generation, SEER can infer the approximate length of the other requests in the group. To surface these signals early, speculative requests are placed in a high-priority path and scheduled according to a shortest-first strategy (SFS). Because short requests complete quickly while long ones linger, this "length filtering" step exposes potential long-tail groups early in the rollout, giving SEER time to react before those long generations dominate system resources.

Specifically, the scheduling process unfolds in three conceptual phases. First, speculative requests are executed promptly so that length information can be gathered with minimal delay. Second, the Context Manager maintains and continually updates an estimated output length for each group. This estimate is simply the maximum generation length observed among completed requests in the group, an approach that naturally converges toward the true length as more information becomes available. For groups in which no request has finished yet, SEER conservatively assumes they may be long-tail cases and initializes their estimate to the upper bound on generation length. Third, with group-level length estimates in place, the scheduler shifts to an approximate LFS policy: groups predicted to be long are prioritized so that their requests begin making progress early, rather than being deferred until system load is already high. The detailed scheduling algorithm is provided in §A.1.

SEER also incorporates safeguards to mitigate inaccuracies in early predictions. It occasionally schedules requests from underserved groups to avoid starvation and updates group length estimates conservatively to reflect the longest sample observed so far. These mechanisms ensure stability even when speculative signals are noisy. As shown later in §4.5.1, this context-aware scheduling policy approaches the performance of an oracle LFS scheduler that has perfect knowledge of request lengths.

3.4 Adaptive Grouped Speculative Decoding

To further improve resource utilization during the rollout phase, especially in the long-tail stage, SEER implements Adaptive Grouped Speculative Decoding, which **adaptively** adjusts draft lengths based on computational intensity and exploits the **grouped** pattern context (as analyzed in Table 2) to enhance acceptance rates.

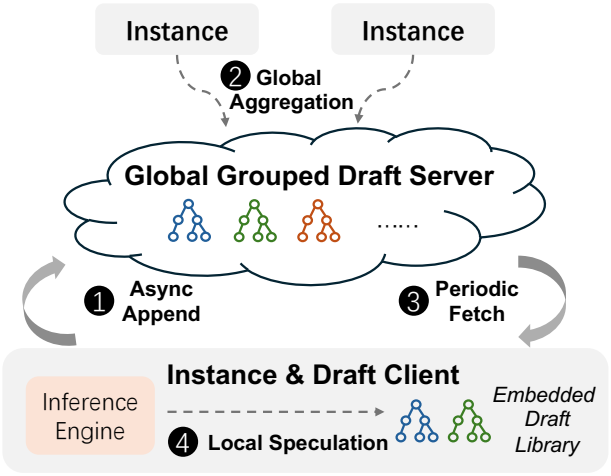

Figure 6: The distributed grouped draft server.

3.4.1 Challenges of Speculative Decoding in Rollout

Speculative decoding (SD) benefits from underutilized computational resources when batch sizes are small, enabling faster parallel verification compared to serial generation. However, rollout scenarios feature dynamically varying batch sizes that start large and rapidly decrease as long requests dominate. Fixed-length SD methods often incur excessive draft or verification overhead, degrading overall throughput. We now model SD throughput [17] in the rollout scenario to identify the key factors affecting performance. Let α denote the acceptance rate, where $\alpha = E(\beta)$ and β is the acceptance probability at each position. Let γ represent the number of draft tokens predicted by the draft model per step, B denote the current batch size, $D(B,\gamma)$ represent the forward time of the draft model, and $T(B,\gamma)$ represent the forward time of the target model.

The expected number of tokens generated per request in each forward is $\frac{1-\alpha^{\gamma+1}}{1-\alpha}$. The expected time for SD to generate one token per request is:

$$T_{SD} = \frac{(1-\alpha)(D(B,\gamma)+T(B,\gamma))}{1-\alpha^{\gamma+1}}$$

SD provides a benefit when T_{SD} is less than the forward time of the target model $T(B,1)$.

When B is small, $D(B,\gamma)+T(B,\gamma)$ is approximately equal to $T(B,1)$, making SD clearly beneficial. However, when B is large, $D(B,\gamma)$ becomes non-negligible and $T(B,\gamma)$ increases rapidly with γ as the target model becomes compute-bound, potentially resulting in negative gains from SD. In rollout scenarios, B dynamically varies and can range from 1 to several hundred. Conventional static SD strategies with fixed draft lengths suffer from either underutilization of computational resources with small γ or excessive verification overhead with

large γ, resulting in marginal or even negative performance gains. Furthermore, to optimize SD performance, the draft system should minimize $D(B,\gamma)$ while maximizing α. In rollout scenarios dominated by large batches, conventional SD methods suffer from either high $D(B,\gamma)$ (e.g., using a separate draft model) or low α (e.g., naive n-gram methods). Therefore, an efficient draft system specifically tailored to the characteristics of rollout workloads is required.

3.4.2 Adaptive Speculation with Disaggregated Architecture

SEER introduces the Distributed Grouped Draft Server (DGDS), a disaggregated SD framework specifically designed for rollout scenarios. As illustrated in Figure 6, DGDS aggregates response pattern context across requests and instances through an independent draft server, which asynchronously distributes the context to the embedded draft client within each inference instance. As shown in Table 2, multi-reference and multi-path n-gram methods can significantly improve the acceptance rate; however, a naive implementation incurs prohibitive overhead. To address this, DGDS employs a distributed draft service and adopts an asynchronously updated Compressed Suffix Tree (CST) to minimize speculative decoding latency $D(B,\gamma)$ on the critical path. The detailed workflow is provided in §A.2. Compared with prior CST implementations [28, 41], DGDS is optimized for rollout scenarios with support for highly concurrent access and dynamic updates. Its distributed architecture enables cross-instance context sharing, substantially improving both the efficiency and acceptance rate of speculative decoding.

To ensure that SD consistently provides positive gains throughout the rollout process, it is necessary to dynamically adjust γ based on the current batch size according to the throughput model. Furthermore, as described in §3.3, requests are classified into high-priority and low-priority categories. High-priority speculative requests are used to probe the length distribution of requests within the same group and should complete faster, thus requiring higher draft budgets. However, acceptance rates decrease rapidly with increasing draft length, making overly disparate budget allocations between high-priority and low-priority requests wasteful. To address this challenge, we propose a **Marginal-Benefit-Aware (MBA) Adaptive Speculation** policy inspired by classical utility maximization and marginal-utility scheduling principles widely used in resource allocation systems [15], which dynamically balances overall throughput with the latency of high-priority requests.

Algorithm 1 presents the MBA strategy. Using offline-profiled T_{SD} models and online-collected acceptance rates and batch sizes, the algorithm determines draft lengths (γ_h, γ_l) for high-priority and low-priority requests. The algorithm is invoked periodically during rollout, as request characteristics remain relatively stable over short time intervals. Given

Algorithm 1 Marginal-Benefit-Aware Adaptive Speculation

Require: High-priority and low-priority batch sizes B_h and B_l; per-position acceptance probabilities $\beta[1], \beta[2], \ldots$; maximum token budget per request $\gamma_{\max}$; priority factor $\lambda \in [1, \infty)$ (e.g., $\lambda = 2$).
Ensure: Draft token counts γ_h and γ_l.

$B \leftarrow B_h + B_l$
$\gamma^* \leftarrow \arg\min_\gamma T_{SD}(B,\gamma)$ ▷ optimal draft length for batch size B
$\Gamma^* \leftarrow \gamma^* \cdot B$ ▷ total token budget
if $\Gamma^* < B_h$ **then**
  return $(\gamma_h = 0, \gamma_l = 0)$ ▷ disable speculation
▷ Allocate budget based on marginal benefit
$\gamma_h \leftarrow 1, \gamma_l \leftarrow 0, \mathit{remaining} \leftarrow \Gamma^* - B_h$
while $\mathit{remaining} > 0$ **do**
  $\mathit{benefit}_h \leftarrow B_h \cdot (\beta[\gamma_h] - \beta[\gamma_h + 1])$
  $\mathit{benefit}_l \leftarrow B_l \cdot (\beta[\gamma_l] - \beta[\gamma_l + 1])$
  if $\mathit{benefit}_h > \lambda \cdot \mathit{benefit}_l$ **and** $\gamma_h < \gamma_{\max}$ **and** $\mathit{remaining} \geq B_h$ **then**
    $\gamma_h \leftarrow \gamma_h + 1$ ▷ allocate to high-priority
    $\mathit{remaining} \leftarrow \mathit{remaining} - B_h$
  else if $B_l > 0$ **and** $\gamma_l < \gamma_{\max}$ **and** $\mathit{remaining} \geq B_l$ **then**
    $\gamma_l \leftarrow \gamma_l + 1$ ▷ allocate to low-priority
    $\mathit{remaining} \leftarrow \mathit{remaining} - B_l$
  else
    break ▷ cannot allocate further
return (γ_h, γ_l)

the draft lengths, the embedded draft client in DGDS generates the corresponding number of draft tokens based on the grouped CSTs for each request. The basic single-path speculation algorithm follows SuffixDecoding [28], where each candidate path is assigned a confidence score computed from suffix probabilities. Building on this foundation, SEER uses these scores to filter low-probability candidates and is capable of returning multiple candidate paths via a beam search that retains the top-k highest-scoring branches at each fork.

For long-tail requests, adaptive grouped speculative decoding offers two particular advantages. First, during the long-tail stage, concurrency is minimal, allowing larger draft lengths to increase the number of accepted tokens per request. SEER also implements multi-path speculative decoding to further improve the acceptance length in the long-tail stage. Second, as more requests in the same group complete over time, the CST aggregates richer contextual information. As demonstrated in Table 2, this enables long-tail requests to achieve substantially longer acceptance lengths.

4 Evaluation

In this section, we evaluate SEER's performance advantages during the rollout phase, particularly in improving throughput and reducing tail latency (§4.2). In the ablation study (§4.3), we provide a detailed analysis of how each technique in SEER contributes to improving end-to-end performance. In §4.4, we compare SEER against non-strictly synchronous RL in

Table 3: Model configurations and RL workload characteristics.

Metric	Moonlight	Qwen2-VL-72B	Kimi-K2
Model Size	32 GB	146 GB	1 TB
Total GPUs	32	128	256
GPUs per Instance	1	8	32
Reqs per Iter	3200	9600	6400
Group Size	8	16	8

Avg. Gen. Length	22386	7615	38959

both rollout performance and training quality, demonstrating that SEER achieves lossless acceleration. Finally, we present extended studies (§4.5) on scheduling, speculative decoding, and the global KVCache pool to demonstrate the effectiveness of our techniques.

4.1 Setup

Testbed. Our experimental infrastructure consists of 32 high-performance compute nodes, each equipped with 8×H800 GPUs, 224 CPU cores, 2TB DRAM, and 4TB NVMe storage, providing sufficient hardware support for the global KVCache pool and distributed grouped draft server. For deployment, we adopt a strategy that balances task performance with resource efficiency by configuring different numbers of GPUs and parallelization strategies to serve models based on their size and architecture.

Models and Workloads. To validate the generalizability of SEER's design, we evaluate three models with diverse sizes and output characteristics: Moonlight [24], Qwen2-VL-72B [43], and Kimi-K2 [38]. All models are trained as **reasoning models** with chain-of-thought capabilities, where Moonlight and Kimi-K2 are trained on mathematical datasets, while Qwen2-VL-72B is trained on language-vision-mixed reasoning tasks using the LLM-as-a-Judge [36] reward model. Their configurations and RL workload characteristics are shown in Table 3. We employ Qwen2-VL-72B with tensor parallelism (TP8) and Kimi-K2 with data parallelism (DP32) and expert parallelism (EP32).

Settings. We use the GRPO [31] algorithm in our experiments. The group size (i.e., the number of requests per prompt) follows RL training conventions unless otherwise specified: we use a smaller group size (8) for mathematical problems and a larger group size (16) for open-ended tasks with LLM-as-a-Judge evaluation. For SEER's SD hyperparameters described in §3.4.2, we set $\gamma_{max} = 8$ and $\lambda = 2$.

Baselines. We evaluate SEER against a set of strong and representative baselines that capture the best available techniques for synchronous rollout scheduling, skewness mitigation, and speculative decoding.

(1) *veRL* [34]: veRL is a state-of-the-art synchronous RL system that supports efficient colocation of training and rollout. It provides a well-engineered baseline for measuring SEER's end-to-end improvements because it already incorporates optimized model execution pipelines and a production-grade rollout subsystem.

(2) *StreamRL-Oracle*: Although StreamRL [51] is designed as a disaggregated asynchronous RL framework, its proposed Skewness-Aware Scheduling directly targets the same long-tail latency issues that appear in synchronous rollout. StreamRL's scheduling relies on a small auxiliary model that predicts prompt lengths and uses those predictions to perform bucketing and LFS-style scheduling. To ensure a **fair and stringent comparison**, we evaluate against StreamRL-Oracle, which uses the ground-truth prompt lengths obtained from veRL's rollout traces rather than model predictions. This removes the confounding effects of prediction errors and reflects the best-case performance achievable by the StreamRL scheduling approach.

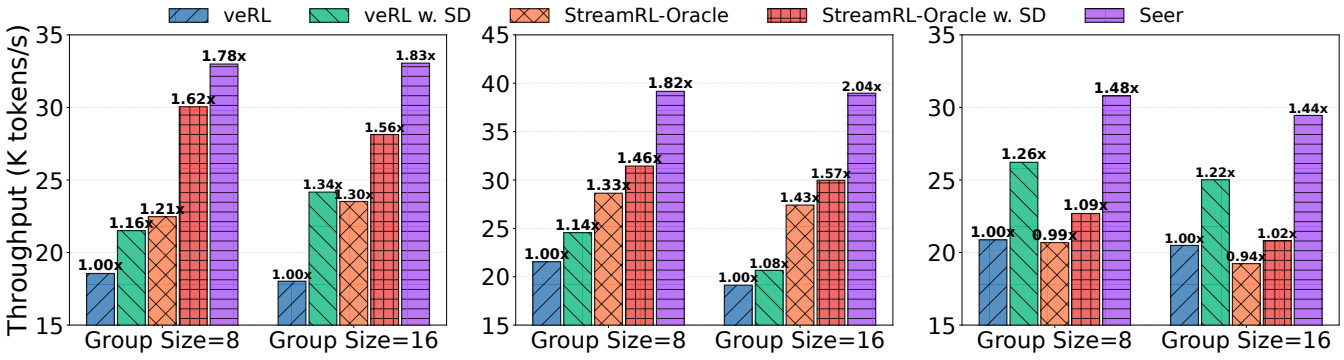
(3) *Vanilla Speculative Decoding (SD)*: To benchmark against modern decoding accelerators, we implement strong speculative decoding baselines tailored to each model family. For Moonlight, we use SuffixDecoding [28] with a maximum draft length of $\gamma_{max} = 16$. For Qwen2-VL-72B, we adopt a dedicated Qwen2-7B-VL draft model with $\gamma_{max} = 3$. For Kimi-K2, we apply Multi-Token Prediction (MTP) [22] with $\gamma_{max} = 1$. Each of these SD methods is integrated into both veRL and StreamRL-Oracle pipelines, enabling direct comparisons across scheduling regimes and decoding strategies.

To isolate the effect of scheduling and speculative mechanisms, all baselines (including SEER) use a unified in-house implementation of vLLM [16] as the inference engine. This ensures that differences in performance arise solely from the scheduling and decoding techniques under evaluation, not from underlying infrastructure discrepancies.

Metrics. For the end-to-end experiments, we measure the average rollout throughput across 5 iterations, which is defined as the average number of output tokens generated per second in each rollout iteration.

4.2 End-to-End Performance

In our end-to-end experiments, we conduct three RL tasks based on the aforementioned models, with workload configurations detailed in Table 3. We provide a comprehensive comparison of SEER's end-to-end performance against different baselines in §4.2.1. To validate SEER's effectiveness



(a) Moonlight (b) Qwen2-VL-72B (c) Kimi-K2

Figure 7: End-to-end rollout throughput of RL systems across different tasks and group sizes.

in mitigating tail latency, we analyze the tail latency phenomenon in our experiments and compare the tail latency between SEER and the baseline system veRL in §4.2.2.

4.2.1 Rollout Throughput

We compare the throughput performance of SEER against state-of-the-art baselines across different workloads and group sizes, as shown in Figure 7. Despite significant variations in model size and workload characteristics across different RL tasks, SEER consistently achieves substantial speedups across all tasks, with throughput improvements ranging from 44% to 104% over veRL.

SEER also outperforms StreamRL-Oracle and multiple SD strategies. StreamRL sets buckets with smaller concurrency for long-request groups to minimize latency. However, it still treats each request group as an atomic, non-preemptible unit and cannot dynamically adjust instance loads at runtime. Consequently, its performance is heavily dependent on the accuracy of the preset bucketing algorithm. When encountering out-of-distribution workloads such as Kimi-K2, StreamRL-Oracle even underperforms veRL, which uses a simple round-robin scheduling strategy. For vanilla SD methods, although we have implemented adaptive draft length, these SD methods still suffer from either excessive overhead or low average acceptance length, resulting in inferior performance compared to our adaptive grouped speculative decoding. A detailed comparison is provided in §4.5.2.

Across different workloads, SEER achieves greater performance improvements on memory-constrained tasks (Moonlight and Qwen2-VL-72B), where SEER's divided rollout mitigates load imbalance and context-aware scheduling reduces long request delays. Furthermore, as the group size increases, the load imbalance caused by veRL's group-level scheduling becomes more severe, leading to throughput degradation. In contrast, SEER addresses the monolithic request group problem through divided rollout and dynamic load balancing, and leverages group context to optimize both scheduling and speculative decoding. As a result, when the group size increases from 8 to 16, SEER achieves an average performance improvement of 5%.

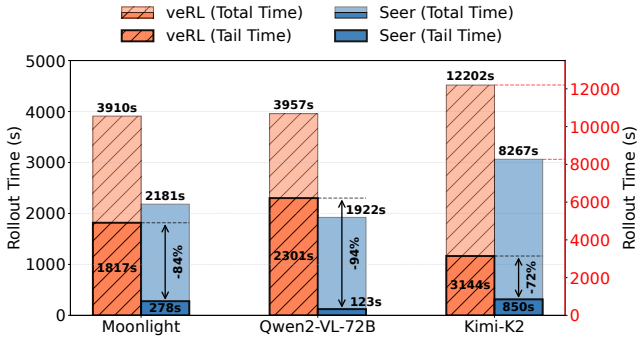


Figure 8: Tail time and total time of three RL tasks.

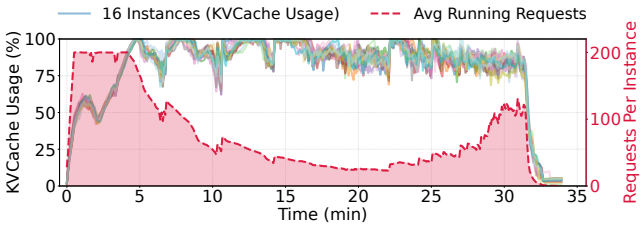

Figure 9: KVCache utilization and average running requests with SEER during a rollout iteration of the Qwen2-VL-72B task.

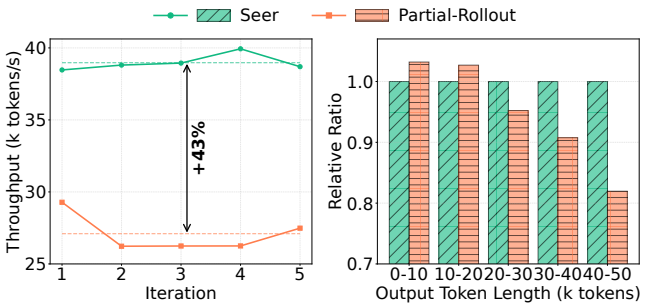
4.2.2 Long-Tail Time

To analyze SEER's performance advantages, we examine tail latency in the rollout process. We define **tail requests** as the last 10% of requests to complete in a synchronous system rollout, and **tail time** as the time spent **solely** processing these tail requests. Figure 8 shows the tail time and total rollout

Table 4: Performance improvement breakdown across three RL tasks. Context Sched. denotes context-aware scheduling (§3.3), and Grouped SD denotes adaptive grouped speculative decoding (§3.4).

Method	Moonlight	Qwen2-VL-72B	Kimi-K2
Baseline	1.00	1.00	1.00
+ Divided Rollout	1.41×	1.42×	1.16×
+ Context Sched.	1.47×	1.56×	1.27×
+ Grouped SD	1.90×	2.04×	1.53×



(a) Rollout throughput. (b) Output length distribution.

Figure 10: Rollout experiments comparing SEER and Partial Rollout on the Qwen2-VL-72B workload.

completion time, averaged across all iterations. The results demonstrate severe tail latency for memory-constrained tasks like Moonlight and Qwen2-VL-72B, where the last 10% of requests consume up to 50% of total time.

The tail latency problem stems from two primary causes. First, request queuing and preemption lead to delayed scheduling of long-output requests. Second, monolithic request groups result in load imbalance across instances. We provide quantitative evidence using the Qwen2-VL-72B task on veRL, shown in Figure 3. In this rollout iteration, a total of 13,686 preemption events occurred. The last 5% of completed requests have an average length in the top 15th percentile, yet their average execution start time is at 42% of the total time. The load imbalance across instances is even more pronounced: the completion time difference between the earliest and latest instances accounts for 70% of the total time, with each instance idle for an average of 1,580 seconds, representing 37% of the total time. These scheduling and load imbalances result in severe tail latency and throughput degradation.

By leveraging online context learning and fine-grained request scheduling, SEER significantly reduces tail latency by 72% to 94%, thereby substantially improving system throughput. Figure 9 illustrates the impact of these techniques, showing that SEER substantially reduces the tail phase duration compared to the baseline shown in Figure 3a.

4.3 Improvement Breakdown

We present a systematic ablation study to quantify the contribution of each optimization component to SEER's overall performance. Table 4 demonstrates the cumulative end-to-end speedup obtained by incrementally integrating each major optimization component, where each set of experiments is executed on the 5th rollout iteration.

First, SEER's divided rollout mechanism enables dynamic, fine-grained load balancing across instances, mitigating tail latency caused by inter-instance load imbalance and reducing preemption overhead within instances due to varying KV-Cache memory consumption. This optimization yields significant improvements for memory-constrained tasks, achieving up to 42% throughput improvement. Building upon divided rollout, context-aware scheduling leverages learned intra-group length distributions to guide scheduling, providing up to 14% additional throughput improvement. To further address the computational underutilization inherent in tail requests, SEER incorporates adaptive grouped speculative decoding, which contributes an additional 26–48% performance improvement over the scheduling optimizations alone.

4.4 Comparison with Non-Strictly Synchronous RL

Some RL training systems [8, 39, 53] employ non-strictly synchronous RL, which defers or reschedules long-tail requests to subsequent iterations. While non-strictly synchronous RL can improve resource utilization, it introduces some degree of inconsistency with synchronous training algorithms. Partial Rollout [39, 53] is a popular non-strictly synchronous method that over-issues requests during rollout and terminates the rollout phase once a predetermined number of requests are completed, with remaining requests executed with high priority in the next rollout iteration. In this section, we compare SEER against Partial Rollout. Following the experimental setup from APRIL [53], which applies Partial Rollout, each rollout iteration issues 2× the original number of requests and terminates once the original number of request groups have fully completed.

4.4.1 Rollout Performance

We first compare SEER and Partial Rollout on the Qwen2-VL-72B workload over five rollout iterations. As shown in Figure 10a, SEER achieves 43% higher average throughput than Partial Rollout. This advantage stems from two factors. First, in memory-constrained long-CoT scenarios, Partial Rollout's doubling of request volume exacerbates preemption issues, preventing it from fully leveraging its higher degree of parallelism. Second, SEER's adaptive grouped speculative decoding further enhances throughput for long-generation requests. Additionally, Figure 10b shows the output length

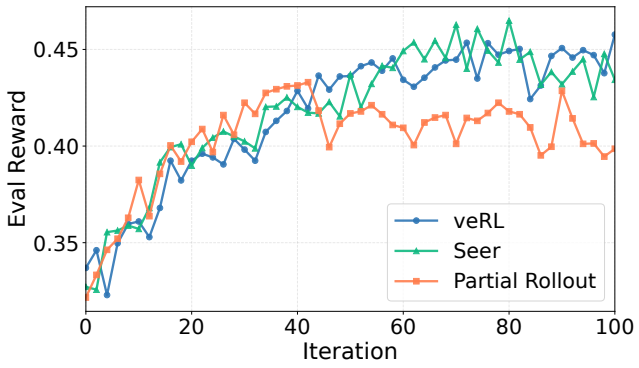


Figure 11: Reward curves of end-to-end RL training.

distributions of SEER and Partial Rollout. Compared to the synchronous method, Partial Rollout generates a significantly lower proportion of requests with longer output lengths. This bias may negatively impact RL training and degrade model performance, as we examine in detail in §4.4.2.

4.4.2 End-to-End Reward

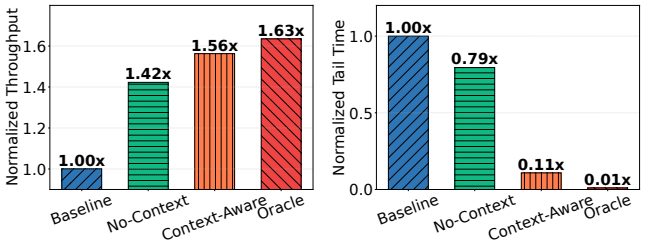
As stated in §3.1, SEER is designed to be algorithmically lossless with respect to strictly synchronous RL. To validate this property and compare the training quality of strictly and non-strictly synchronous RL, we evaluate three systems end-to-end: veRL as the strictly synchronous ground truth, SEER, and Partial Rollout. All three systems train Moonlight for 100 iterations under identical hyperparameters and data, and we evaluate checkpoints every two iterations on a fixed prompt set sampled with a shared random seed.

Figure 11 reports the resulting reward curves. The curves of veRL and SEER track each other closely throughout the run, indicating that SEER preserves the training quality of synchronous RL while delivering substantial performance gains. Partial Rollout, by contrast, falls measurably behind both synchronous baselines after roughly 50 iterations and stays below them thereafter. We attribute this divergence to Partial Rollout's bias against long-output requests, which skews the on-policy training data toward shorter trajectories. While recent work has explored algorithmic remedies such as bounding staleness [5, 10, 26] or adjusting the training objective via importance sampling and modified clipping [5, 26, 29], synchronous RL remains necessary in many scenarios due to its algorithmic stability.

4.5 Extended Studies

4.5.1 Context-Aware Scheduling

To validate the effectiveness of length context, we conduct an ablation study by varying the length information available to SEER's scheduler, as shown in Figure 12. Specifically, we compare: (1) No-Context, which applies only divided rollout



(a) Normalized throughput. (b) Normalized tail latency.

Figure 12: Impact of length context on improving throughput and reducing tail latency (defined in §4.2.2). No-Context applies only divided rollout without using length context to guide scheduling. Oracle obtains all output lengths in advance and applies the LFS strategy.

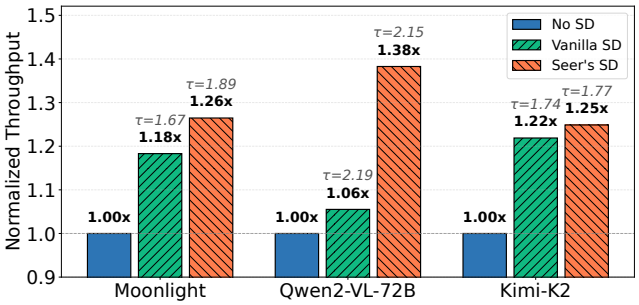


Figure 13: Normalized throughput and mean acceptance length (τ) of SD strategies across three tasks.

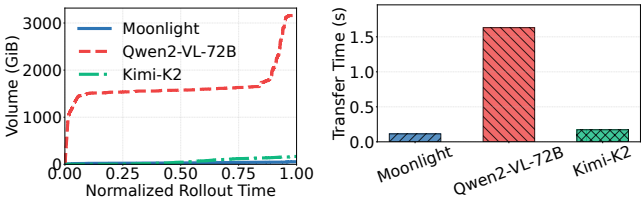
without using length context to guide scheduling, and (2) Oracle, which obtains the actual output lengths of all requests in advance and replays the rollout iteration using these precise lengths to guide scheduling.

While divided rollout significantly improves throughput through dynamic load balancing, the tail latency problem persists, with tail latency reduced by only 21% compared to the baseline. In contrast, context-aware scheduling leverages length prediction information from speculative requests to implement approximate longest-first scheduling, substantially reducing tail latency by 89% compared to the baseline. Compared to Oracle, context-aware scheduling achieves 96% of its throughput performance. This demonstrates that despite some performance degradation from prediction errors, context-aware scheduling still provides substantial benefits.

4.5.2 Adaptive Grouped Speculative Decoding

As discussed in §3.4, the benefits of speculative decoding during rollout depend on multiple factors including batch size, draft model overhead, and draft accuracy. We conduct ablation experiments on different SD strategies based on a single rollout iteration executed on veRL. As shown in Figure 13, SEER's adaptive grouped SD consistently outperforms



(a) Cumulative KVCache migration volume.

(b) Per-node time spent on KVCache migration.

Figure 14: Quantitative analysis of the overhead introduced by the Mooncake-based global KVCache pool used in divided rollout.

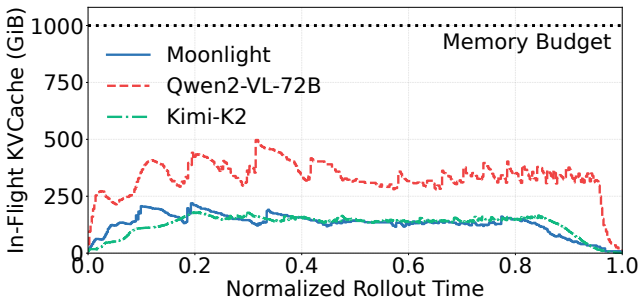


Figure 15: Peak KVCache storage footprint across nodes for in-flight requests during a rollout iteration, reported for the most loaded node in the rollout. Memory budget denotes the DRAM capacity allocated per node for KVCache storage.

vanilla SD in throughput across all tasks, achieving up to 1.3× speedup. Furthermore, by leveraging group context, our approach improves the mean acceptance length by 0.22 compared to the CST-based SD method [28], and exceeds MTP's performance. While vanilla SD with a small draft model achieves slightly higher mean acceptance length than our adaptive grouped SD, its excessive draft model overhead results in the lowest overall throughput gain.

4.5.3 Global KVCache Pool

SEER adopts the Mooncake global KVCache pool to share KVCache across inference nodes and thereby eliminate the re-prefill cost that divided rollout would otherwise introduce. We now quantify the migration traffic and storage occupancy of this pool to assess its impact on system performance. As described in §3.2, SEER layers a cache-aware policy on top of the global KVCache pool to improve cache locality. In the experiments reported below, the scheduler declares load imbalance whenever the spread of in-flight requests across instances exceeds 32, and triggers a KVCache migration whenever the cache hit length gap between the chosen node and the best-affinity node exceeds 512 tokens.

Figure 14a reports both the frequency and the cumulative volume of KVCache migrations observed during a full rollout iteration. The cache-aware scheduling policy keeps migrations sparse throughout the rollout. Even for Qwen2-VL-72B, which carries the largest per-token KVCache among the evaluated workloads, the total migration volume reaches only about 3 TB. This volume is negligible relative to the 8×400 Gbps RDMA fabric provisioned on each node. Figure 14b further reports that the average per-node time spent on KVCache transfer remains below 0.1% of the corresponding rollout duration, and these transfers can be overlapped with GPU computation. Taken together, the migration cost of the global KVCache pool has no measurable impact on end-to-end performance.

Another concern is the storage capacity of the global KVCache pool. Should the pool be unable to hold the KVCache of all active requests, the resulting cache misses would force divided requests to re-prefill and degrade end-to-end performance. Figure 15 reports the aggregate KVCache footprint of in-flight requests, namely requests that have been scheduled but not yet completed. The measurement is taken at the granularity of an 8-GPU node and aggregated over the most loaded node across the rollout cluster. Even under the heaviest load observed in our workloads, the footprint never exceeds half of the allocated DRAM budget. This headroom indicates that the request-aware eviction policy keeps the working set of all active requests resident within the global pool, so capacity-induced cache misses do not arise in practice.

5 Related Work

RL Frameworks for LLM Post-Training. Numerous open-source RL frameworks [13, 32, 34, 42, 44, 47, 54] have been proposed to achieve both efficiency and usability, providing robust infrastructure support for both research and production RL workloads. OpenRLHF [13] and veRL [34] seamlessly integrate training and inference engines, supporting various parallelism strategies to improve RL training efficiency. ROLL [44] targets large-scale RL training optimization, enabling flexible resource allocation and heterogeneous task scheduling. Slime [54] balances high performance with flexibility, supporting highly customizable data generation pipelines. These works primarily focus on overall RL training workflow orchestration, while the long-tail problem in the rollout phase remains unaddressed. SEER complements these frameworks by providing a system-level optimization for the rollout phase, which can be integrated into existing RL frameworks to further enhance their performance.

On-Policy RL Optimization. Some efforts have been made to optimize the RL workflow at both the system and algorithmic levels. RealHF [27] dynamically reallocates model parameters and memory budgets to optimize utilization. RLHFuse [52] proposes stage fusion to overlap reward and experience computation with the rollout long tail, thereby improving resource utilization. RLBoost [46] utilizes preemptible fragmented GPU resources to accelerate rollout at low cost.

Nevertheless, these approaches do not adequately address the long-tail latency problem. For the long-tail problem, speculative decoding [2, 6, 14, 17–20, 22, 28] is regarded as an effective optimization technique. However, these methods suffer from either high draft overhead or low accuracy in RL rollout scenarios due to dynamically changing batch sizes and continuously evolving target LLM weights. RhymeRL [11] and SPEC-RL [23] propose utilizing historical sequences generated from previous RL iterations as references to accelerate decoding. However, in most state-of-the-art model rollout scenarios, different iterations sample different data to improve generalization, leaving no historical sequences to reuse. SEER systematically elevates online group-level context as a first-class citizen in RL rollout optimization, eliminating the reliance on repeated sequences across iterations. Meanwhile, it employs an adaptive speculation policy atop a disaggregated architecture, achieving higher acceptance rates while maintaining low draft overhead.

Off-Policy RL Optimization. Recently, many works [5, 8, 10, 11, 26, 29, 33, 51, 53] have proposed RL workflows that do not maintain complete logical synchronization, trading a degree of off-policy behavior for improved RL efficiency. StreamRL [51], Areal [5], RhymeRL [11], and Laminar [33] propose asynchronous training approaches to improve resource utilization. In asynchronous RL, training and rollout are completely decoupled: rollout workers continuously generate new outputs without waiting, while training workers update the model whenever a batch of samples is collected. Other works relax the synchronization constraints of synchronous RL to achieve speedup, referred to as non-strictly synchronous RL. Partial Rollout [39, 53] defers long-tail requests to continue execution in the next rollout iteration. RollPacker [8] proposes tail batching, which schedules long-tail requests into a few designated long iterations, effectively reducing GPU idle time. While these techniques improve RL efficiency, the off-policyness inherent in these algorithms introduces risks of instability and accuracy degradation, limiting their applicability in research and production environments where algorithmic fidelity is critical. SEER significantly reduces rollout tail latency through fine-grained scheduling within the rollout phase, while maintaining consistency with on-policy algorithms.

6 Conclusion

In this paper, we present SEER, a synchronous RL system that accelerates the rollout process through online context learning. With divided rollout, a fine-grained and dynamically load-balanced scheduling approach, SEER leverages the similarity among requests within the same group in GRPO-like algorithms to achieve efficient scheduling and speculative decoding, while strictly maintaining consistency with on-policy RL algorithms. Experimental results demonstrate that SEER achieves up to 2.04× throughput improvement and up to 94% reduction in long-tail latency compared to the current state-of-the-art RL framework. Beyond RL rollout, SEER's design principles constitute a system-level optimization paradigm for grouped inference that generalizes to other large-scale parallel LLM generation scenarios.

A Implementation Details of SEER

A.1 Context-Aware Scheduling Algorithm

Algorithm 2 presents the context-aware scheduling workflow built on top of divided rollout. The algorithm is invoked continuously by SEER's global scheduler, each time returning a scheduling decision $(r^\star, i^\star)$ that assigns the selected request $r^\star$ to an inference instance $i^\star$, until all requests are completed.

Algorithm 2 Context-Aware Scheduling based on Divided Rollout

Require: Active requests $\mathcal{R} = \{r_{g,i}\}$ grouped by prompt g; group-level length estimates $\{\widehat{L}_g\}$; inference instances I with KV-usage telemetry.
Ensure: A scheduling decision $(r^\star, i^\star)$ with $r^\star \in \mathcal{R}$ and $i^\star \in I$.

for all $r_{g,i} \in \mathcal{R}$ **do**
  if $r_{g,i}$ is finished **then**
    $\widehat{L}_g \leftarrow \textsc{UpdateEstimate}(\widehat{L}_g, L_{g,i})$
    remove $r_{g,i}$ from $\mathcal{R}$
  else if $r_{g,i}$ is the group's speculative request **then**
    keep in high-priority queue Q_{spec}
  else
    add to low-priority candidate set C_{rest}
$r^\star \leftarrow$ **None**
if $\neg\textsc{IsEmpty}(\mathsf{Q}_{\text{spec}})$ **then**
  $r^\star \leftarrow \textsc{PickSFS}(\mathsf{Q}_{\text{spec}})$ ▷ smallest generated length first
else if $\neg\textsc{IsEmpty}(\mathsf{C}_{\text{rest}})$ **then**
  $r^\star \leftarrow \textsc{PickLFS}(\mathsf{C}_{\text{rest}})$ ▷ largest $\widehat{L}_g$ first
else
  return `all requests are finished`
$r^\star.\mathit{max_tokens} \leftarrow \min\big(\mathit{chunk_size}, r^\star.\mathit{ori_max_tokens} - r^\star.\mathit{generated_tokens}\big)$
$i^\star \leftarrow \textsc{SelectInstance}(I, r^\star.\mathit{max_chunk_tokens}, \text{KV-usage})$
if $i^\star \neq$ **None then**
  return $(r^\star, i^\star)$
return `no available instance for this cycle`

A.2 Workflow of Distributed Grouped Draft Server

To minimize speculative decoding latency in the critical path, Distributed Grouped Draft Server (DGDS) adopts asynchronous updates and employs a distributed master-worker architecture for global sharing of grouped context, as illustrated in Figure 6. The system operates through four key steps, with core APIs listed in Table 5 and Table 6:

1) Asynchronous Append: Each inference instance runs an independent process to handle output tokens. When newly generated tokens are produced, the instance invokes the `update_cst` API to send them to DGDS, identified by `group_id`. To reduce communication overhead, each request batches a fixed number of tokens before sending updates, which has negligible impact on draft token quality.

2) Global Aggregation: DGDS aggregates token updates from requests belonging to the same group. To prevent cross-request interference, DGDS isolates updates by `request_id`, mapping each new token only to the corresponding local path in the CST.

3) Periodic Fetch: Each inference instance embeds a draft client as a library component that periodically synchronizes the latest CST from DGDS. The client registers active request groups via `register_group` and then periodically invokes `fetch_cst` to retrieve the latest CSTs for these groups. To reduce communication overhead, the client supports incremental synchronization based on local cache states.

4) Local Speculation: Inference instances perform speculation based on their local CSTs by invoking the `batch_speculate` API. The local CSTs aggregate paths from all requests within the same group, enabling instances to share contextual statistics and obtain higher-quality draft tokens.

Table 5: Grouped draft server API.

Operation	Description	Parameters
`update_cst`	Append generated tokens from a specific request to the compressed suffix tree	`const string& group_id, int request_id, int prev_token_count, const vector<int>& new_tokens`
`fetch_cst`	Fetch incremental draft contexts of request groups based on their current cache states (if have)	`const vector<string>& group_ids, const vector<DraftCacheInfo>& draft_cache_infos`

Table 6: Draft client API.

Operation	Description	Parameters
`register_group`	Register a new request group for draft fetching with TTL	`const string& group_id, int ttl_seconds`
`batch_speculate`	Generate speculative tokens for multiple requests via zero-copy memory access: reads input token patterns and writes predicted tokens directly to inference engine memory buffers	`const vector<string>& group_ids, const vector<size_t>& buffer_offsets, void* pattern_buffer_ptr, void* output_buffer_ptr, const vector<SpeculationArgs>& speculation_args`
SpeculationArgs: `max_spec_tokens` (int), `pattern_lookup_max` (int), `pattern_lookup_min` (int), `top_k` (int)		

Harvesting Sub-Microsecond CXL Memory Stalls with LITESWITCH

Abstract

Compute Express Link (CXL) offers a practical path to scale memory capacity and bandwidth available to a single host. However, CXL memory incurs sub-microsecond latency that is typically 3× or more compared to local memory, exacerbating memory-induced CPU stalls and degrading application performance. This paper presents LITESWITCH, a lightweight hardware-software co-design that opportunistically harvests otherwise idle cycles caused by CXL memory accesses. LITESWITCH introduces: (1) a hardware mechanism that precisely identifies a CXL-induced memory stall and exposes it to software with near-perfect accuracy and minimal overhead; (2) an ultra-fast software path that switches to another ready thread for harvesting in under 20 nanoseconds, an order of magnitude faster than conventional context switches. Together, these mechanisms enable efficient harvesting of sub-µs-scale memory stalls (> 200 nanoseconds), without requiring changes to the application. The evaluation demonstrates that with a sufficient number of available threads per core, LITESWITCH recovers up to 80% of the performance lost due to CXL access latency, enabling the adoption of CXL memory without prohibitive slowdowns.

1 Introduction

Compute Express Link (CXL) has emerged as a promising technology to scale memory capacity and bandwidth at the server/rack levels beyond DDR limitations [48]. CXL is being evaluated in four concrete use cases: (1) capacity expansion via tiered or pooled memory, where CXL-attached DRAM/SSD extends host DRAM for memory-hungry services at lower TCO (total cost of ownership) [6, 10, 25, 33, 44, 63, 64, 66]; (2) utilization improvement by pooling across servers memory [44] and PCIe devices (NICs, SSDs) [67] over CXL; (3) bandwidth scaling by interleaving host DRAM and CXL memory to aggregate DDR and PCIe channels [30]; and (4) pod-level shared memory for distributed systems to reduce messaging overhead [31, 52].

However, these benefits come at a performance cost, as accessing CXL-attached memory incurs much higher latency compared to local DRAM. Measured CXL memory devices report load latencies of 214-394 ns (nanoseconds), compared to 81-117 ns for DRAM [48], while pooled CXL deployments can reach up to 1 µs (microsecond) depending on topology, device type, and multi-tenant interference [10, 44, 67]. This higher latency exacerbates memory-induced CPU stalls (i.e., backend stalls) that already dominate execution time even on systems with only local memory. Empirically, many memory-intensive and cloud-scale workloads spend the majority (20-80%) of their cycles stalled on memory [21, 37, 50]. Under the same synchronous, blocking load/store interface, CXL's higher latency therefore prolongs each stall by hundreds of nanoseconds, amplifying an already significant inefficiency.

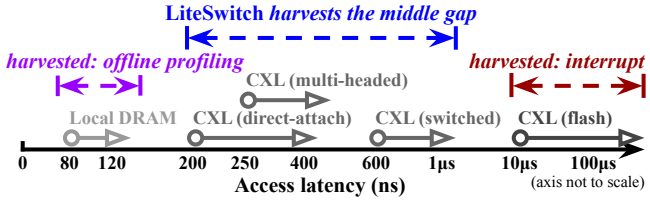

Figure 1: Illustration of CXL memory latency and the scope of prior work. CXL expands memory access latency from roughly 200 ns with direct-attach CXL memory to tens of µs with flash-backed CXL memory. Prior work harvests memory-induced CPU stall cycles near local DRAM latencies and at flash-scale latencies, leaving a substantial sub-µs "middle gap" that LITESWITCH targets.

This problem can be mitigated if the system could still do useful work while a thread is blocked waiting for memory access: a mechanism termed *stall cycles harvesting*. Simultaneous multithreading (SMT) mitigates memory stall cycles by interleaving two independent hardware threads on a shared core: when one thread stalls, the other can continue issuing instructions. However, SMT's concurrency is inherently limited: two hardware threads already saturate most cores' backends without incurring excessive intra-core contention [23, 42, 59]. Under long CXL stalls, both hardware threads can easily stall simultaneously. Moreover, even when only one thread is stalling, SMT cannot 'un-stall' that thread, thus the core falls back to lower utilization achievable by a single thread.

Software-based approaches instead 'un-stall' a blocked thread in place when stall happens and invoke a software routine to run another ready context (termed a scavenger) [50, 65]. MSH [50] relies on offline profiling to identify likely stall sites, while SkyByte [65] targets much higher (tens of µs) CXL-SSD latencies by using interrupts to preempt the blocked thread and then leveraging kernel-level scheduling. However, these designs face three fundamental obstacles when harvesting sub-µs CXL memory stalls (§3). **(1) Detection**. Software lacks advance knowledge (i.e., at compile

time) of when a CXL stall occurs or how long it will last. Because CXL latency is highly variable and topology-dependent, offline profiling is unreliable in dynamic, multi-tenant environments. **(2) Delivery**. Traditional interrupt delivery is a costly hardware path that must drain the CPU's speculative and out-of-order state and establish a precise architectural state, incurring sub-µs overhead that easily consumes the entire harvestable window. **(3) Scheduling**. Although user-level scheduling makes choosing the next runnable context cheap, switching between contexts remains expensive even in optimized runtimes [22, 36], where saving and restoring CPU's extended SIMD/FP state (`xstate`) alone costs tens to hundreds of nanoseconds.

This paper makes four key observations and insights to guide the design for efficiently harvesting CXL memory stalls:

- *Any memory access targeting a CXL memory device can be meaningfully harvested*, given the naturally large gap between local DRAM and CXL latencies (3× or more). This uniform treatment simplifies stall detection into two hardware operations already on the memory request path: a cache lookup (whether in L1/L2/LLC) and a routing decision (whether it targets a CXL memory device), achieving near-perfect accuracy with negligible extra overhead.
- *Harvesting should occur within the same address space*. This insight enables the possibility that stalls can be delivered to software via lightweight branching (i.e., control-flow jumps) than expensive interrupts.
- *Any regular worker thread can act as a scavenger during harvesting*, rather than dedicating separate best-effort threads. This enables simplified scavenger selection logic and avoids paying context switch cost twice per stall.
- *Usage of CPU extended state (`xstate`) is uncommon in most code*, thus saving and restoring `xstate` can be skipped safely when it is not actively used in a context.

This paper presents LITESWITCH, a lightweight hardware-software co-design that opportunistically harvests sub-µs CXL memory stall cycles, without requiring changes to the application. On the hardware side, LITESWITCH proposes *Location-Dependent Memory Branching* (LDMB, §4.1), a simple and novel CPU mechanism that detects stall conditions *online and per-access* based on existing cache lookup and routing operations. Then, LDMB un-stalls the CPU hardware thread and delivers the notification to software via a direct *control-flow jump*. LDMB revives the classic architectural idea of cache-miss-triggered software handling, which was previously shown to support low-overhead memory-performance monitoring and software-driven memory optimizations [28].

On the software side, LDMB's control jump invokes the *Bundled Handoff* handler (§4.2), where a small set of user threads from the same user process (a "bundle") is multiplexed on each hardware thread for fast scavenger selection and handoff, without interfering with the process's regular scheduler. This design is further optimized by `xstate`-*Aware Context Switch* (§4.3) that safely skips unnecessary saving and restoring of SIMD/FP state (`xstate`), reducing context switch overhead to under *20 ns* for non-compute-dense applications.

The observations and insights that guided LITESWITCH's design are grounded in measurements on a real CXL hardware tiering system in Intel Flat Memory Mode [6, 66]. However, a physical LDMB prototype is not implemented mainly because FPGAs cannot accurately model modern CPU's memory hierarchy. Instead, LITESWITCH uses emulation (§5.1) to reproduce realistic CXL memory stall behaviors and provide a software interface for running unmodified applications.

Together, LITESWITCH is a mechanism that can efficiently harvest memory stalls longer than 200 ns, making it effective even on the fastest, locally-attached CXL memory devices (Figure 1). The evaluation (§6) shows that LITESWITCH reduces performance slowdowns by up to 80% (multiplicatively) relative to the setup with 200-ns CXL access latency across diverse workloads. Crucially, LITESWITCH produces consistently low slowdowns even under more complex CXL configurations with higher latency and greater variability, highlighting its potential to enable practical adoption of CXL memory. The artifact of LITESWITCH is open-sourced [45].

LITESWITCH makes the following contributions:

- A characterization of unique challenges, observations, and insights for efficient harvesting of CXL memory stalls.
- A hardware proposal of LDMB for online, per-access stall detection and branch-based delivery that achieves near-perfect accuracy with negligible extra overhead.
- An ultra-lightweight software handler path that enables instant scavenger selection and minimal context switch overhead, without interfering with high-level scheduling policies or compromising correctness.
- A prototype emulation that runs unmodified applications to faithfully evaluate LITESWITCH, with comprehensive results showing it significantly reduces slowdowns.

2 Background and Motivation

CXL is a high-speed interconnect over the PCIe fabric that lets CPUs, accelerators, and device-attached memory participate in a unified memory space [17]. This paper focuses on the key use case of memory expansion via the `CXL.mem` protocol (Type-3 devices), which exposes device-attached memory to the CPU via load/store semantics.

The heterogeneity of CXL memory. As illustrated in Figure 1, CXL-attached memory spans a wide latency spectrum that is largely determined by device type and topology. Its inherent heterogeneity is shaped by device characteristics, CXL memory controller complexity, and topology. Recent measurements on production CXL memory expanders report load-to-use latencies of roughly 214–271 ns for locally attached, ASIC-based devices, only modestly higher than NUMA DRAM, while a single CXL switch or remote NUMA hop can push average latency toward 600 ns and beyond in

multi-hop fabrics [48]. At the other extreme, CXL-attached flash devices incur tens or hundreds of µs when requests miss DRAM caches and access NAND, though DRAM-cache hits can be served in sub-µs time [47, 64, 65].

To mitigate the monetary cost and latency overheads of CXL switching, emerging *multi-headed* CXL devices expose multiple host links into a single DRAM-backed pool, enabling rack-scale shared memory without an external CXL switch; these devices are an appealing solution for multi-host memory sharing [10, 27, 31, 35, 67].

Availability and use cases of CXL memory. CXL memory is available through a growing hardware ecosystem and is being explored in several concrete use cases. 25+ vendors ship CXL-capable CPUs, memory, switches, and controllers [15]. Recent systems (e.g. Intel Xeon 6 and AMD 5th Gen EPYC) provide 64 CXL lanes per socket [1, 2], for an aggregate 200–240 GB/s of bandwidth per direction (each lane provides 3.12–3.75 GB/s in each direction). In late 2025, Microsoft Azure launched the industry's first deployment of CXL-attached memory (in private preview) on its M-series VMs that leverages Intel Xeon 6 in Flat Memory Mode to support multi-terabyte in-memory workloads such as SAP HANA [33]. PNNL's Crete project employs a large pool of CXL-attached coherent memory alongside local DRAM to enable scientific and AI workloads to operate on datasets far larger and more shared than is possible on traditional HPC architectures [55]. At SC'25, XConn demonstrated a CXL memory pool shared across two NVIDIA H100 servers, achieving up to 6.5× higher throughput than RDMA for LLM inference and drastically reducing time-to-first-token [57].

2.1 CXL Exacerbates Memory Stalls

Memory-induced CPU stalls are already a major inefficiency on DRAM-only systems. Empirical studies show that many memory-intensive and cloud-scale workloads spend a large fraction of their total cycles stalled on memory: 25-31% for in-memory key-value and analytics workloads such as Masstree and Sphinx [50], around 50% in warehouse-scale web and storage services [37], and up to 80% in classic scale-out workloads such as OLTP, social networking, and data-serving [21].

CXL's higher access latency materially worsens this inefficiency. Studies on real CXL tiering and pooling systems confirm application-visible slowdowns relative to DRAM-only systems: Memstrata observes performance degradation of up to 34% even with hardware-managed tiering under moderate interference [66], and Pond reports that 21% of evaluated workloads experience $>$ 25% slowdown on an 8-socket, multi-tenant CXL fabric [44].

2.2 Stall Harvesting Meets CXL Memory

With the heterogeneity of CXL memory, the synchronous load/store interface meets far more variable and longer-latency access paths, yielding a unique profile: stalls are *hundreds of nanoseconds with much higher latency variability.*

On the high-latency end, SkyByte [65] targets stalls in CXL-SSDs that are tens of µs. When a request misses the device's internal DRAM cache and thus falls through NAND, the device raises an interrupt to 'un-stall' the thread; the OS kernel then schedules and switches context. This path has µs-scale overhead that is appropriate for misses in CXL-SSDs, but too costly to pay per event for sub-µs CXL memory stalls.

Offline profiling-based stall site identification can eliminate this cost altogether, but it assumes predictable stall locations. While this holds in some systems with only local DRAM [50], CXL introduces substantially greater variability: a memory page may reside on a direct-attach device, a multi-headed device, or behind a switch. Moreover, multi-tenant interference, which is common in CXL memory expansion use cases, further exacerbates unpredictability.

As a result, there is a substantial gap from $\sim$ 200 ns to $\sim$ 1 µs (Figure 1), in which stalls are common and harmful, yet existing solutions fall short. This gap calls for a harvesting mechanism that identifies stalls accurately and promptly in dynamic conditions and is ultra-lightweight in stall delivery and context switching.

3 Problem Statement and Challenges

The goal of LITESWITCH is to *efficiently* and *transparently* harvest CPU stall cycles on the order of *hundreds of nanoseconds* induced by CXL memory access, *without application changes*. LITESWITCH targets a harvestable budget of **200 ns** per stall, representative of CXL access latency for the simple memory extension use case, while more complex configurations such as pooling typically exhibit even longer stalls.

The general problem of stall harvesting decomposes into three steps: **detection**, **delivery**, and **scheduling**. Stall detection refers to the timely and accurate identification of stall conditions long enough to harvest. Stall delivery then 'unstalls' the hardware thread and invokes a software handler, with low overhead. Finally, the stall handler rapidly selects and switches to a ready scavenger thread. For harvesting to be worthwhile, the combined overhead of the three steps must be well below the 200-ns budget.

***Detection:* CXL memory latency is more unpredictable and variable than local DRAM.** The detection task's goal is to decide, early in the memory access path, whether a request will incur a high latency so that harvesting can begin in time. As discussed, offline profiling based methods assume predictable memory behavior. CXL adds layers of variability on top of an already opaque memory hierarchy: memory pages can move transparently between L1/L2/LLC, local DRAM, direct-attach CXL devices, and locations deeper into the CXL fabric. For example, in Intel Flat Memory Mode, a memory load can take anywhere from 1 ns (L1 cache hit)

to $\sim$ 300 ns (local DRAM miss) [66], and software cannot know at compile time what latency the load will exhibit.

This motivates a *runtime hardware hint* that indicates, with sufficient lead time, that a request is on the high latency path. For example, a load reaching the memory controller has already missed the cache and is a candidate for harvesting; more informative hints (e.g., queueing delay) are available deeper in the path (e.g., at the device-side CXL controller), but observing them at that point delays detection and thus reduces the harvestable window. The design questions are: which hint yields high accuracy, and where along the access path should it originate from to balance timeliness and accuracy?

***Delivery:* the load/store interface lacks a lightweight mechanism to 'un-stall' a hardware thread.** After a stall hint is raised, the hardware thread must be notified and control needs to be transferred to a software handler quickly. The closest mechanism today is hardware interrupt, but it is too costly for harvesting cycles in a sub-µs window. To deliver an interrupt safely, the CPU must squash speculative and out-of-order state and establish a precise architectural state before redirecting control. This path can cost hundreds of ns even when no privilege transition is needed (e.g., Intel User Interrupts allow direct user-space delivery of interrupts) [8,26]. An interrupt delivery costs around 600 ns in LITESWITCH's measurements, far exceeding the harvesting budget. Therefore, a hardware primitive that delivers a stall notification directly to a user-space handler, but at a much lower cost, is desired.

***Scheduling:* full context switching is too heavy for sub-µs stalls.** After delivery, the software handler must choose a scavenger thread and switch to it with minimal overhead, without violating critical scheduling properties (e.g., fairness and responsiveness) and without application changes. Existing user-level, µs-scale scheduling designs have significantly optimized the logic for selecting the next runnable thread [22,32,36], but context switches still remain costly [46]. A full context switch saves and restores large architectural state, including general registers, extended SIMD/FP state, and ancillary metadata that could read and write KiBs of data, taking up to $\sim$ 300 ns in LITESWITCH's experiments. Naively, through register liveness analysis, CPU state can be saved selectively because only a subset is actually live at any given context [50], but stalls are inherently arbitrary (i.e., any memory access could end up stalling). As a result, such analysis would either require costly online inspection or be infeasible to perform comprehensively offline. These costs necessitate a lightweight software handoff mechanism.

4 Design

Three principles guided the design of LITESWITCH: (1) while hardware changes are deemed necessary, LITESWITCH must incrementally build on existing hardware capabilities rather than introducing new ones; that is, the hardware mechanisms needed to support LITESWITCH should be trivially feasible on a real ISA platform; (2) unmodified applications should benefit from LITESWITCH across diverse workloads; and (3) the end-to-end overhead of detection, delivery, and scheduling must be as lightweight as possible to maximize harvesting.

Figure 2 demonstrates the overall architectural flow of LITESWITCH. At a high level:

- LITESWITCH detects stalls online and per-access in hardware to leverage first-hand hint of latency formation and performs detection as early as possible in the request path.
- LITESWITCH delivers stall notifications via lightweight control-flow jumps, confining harvesting activities within the same address space.
- LITESWITCH employs a simplified scavenger selection logic and performs context switch with the minimal execution state necessary for correctness.

For detection, LITESWITCH builds on the observation that *any memory access targeting a CXL memory device can be meaningfully harvested*. This intuition arises from the naturally large latency gap (typically 3$\times$ or more) between local DRAM and CXL memory. While more challenging to harvest, treating all CXL memory uniformly allows LITESWITCH to abstract away device and topology variability and simplify stall detection into two hardware operations already on the critical path for every memory request, a cache lookup (i.e., whether in L1/L2/LLC) and a routing decision (i.e., whether the target location resides on a CXL device), making detection trivially feasible. Critically, these operations occur entirely in the host CPU, avoiding the prohibitive delay of traversing the CXL fabric. With the two existing operations, LITESWITCH achieves per-access, online stall detection with near-perfect accuracy and adds negligible hardware overhead. Also, detection only applies to memory *load*, since memory store is either absorbed by CPU cache or triggers a read-for-ownership (RFO) and becomes a load anyways.

For delivery, LITESWITCH makes the design choice that harvesting should occur *within the same address space.* In OS terms, this typically means within the same user process, where the scavenger workers and the stall handler coexist with regular application threads. By restricting harvesting to a single address space, the handler becomes just another function and thus delivery avoids privilege transitions, CR3 changes, IDT lookup, and stack switching. Moreover, because harvestable stalls are tied to specific high-latency loads, the triggering condition is synchronous and precise: the CPU already knows the exact instruction boundary at which control must be redirected (similar to synchronous exceptions like page faults and divide errors) [34]. This further eliminates the need for establishing a precise state for asynchronous events like interrupts. Therefore, the hardware can enter the stall handler via a branch-like redirect that only needs to squash younger speculation, costing only tens of cycles [14, 18, 56].

To realize this, LITESWITCH introduces a new CPU mechanism called *Location-Dependent Memory Branching* (LDMB,

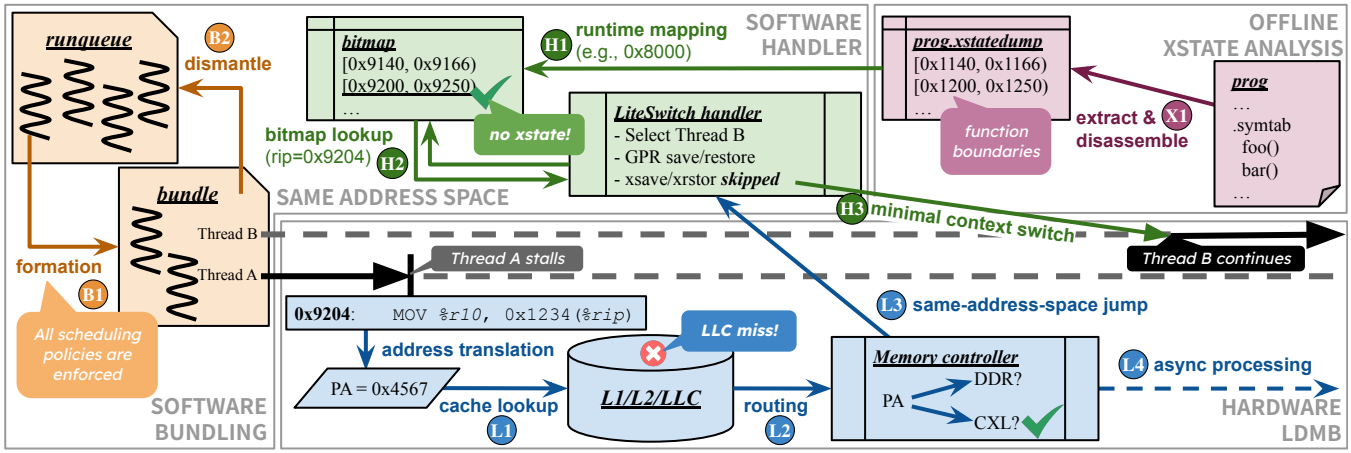

Figure 2: Overall system architecture of LITESWITCH. This figure illustrates the key components and workflow during a stall harvesting event for a multi-threaded program *prog*. When *Thread A* executes a load (rip = `0x9204`) that L1 misses the cache, the memory controller L2 routes it to CXL, triggers a stall, and transfers control to the LITESWITCH handler via L3 a jump while the load L4 is being processed asynchronously. The handler performs H2 a bitmap lookup (derived from X1 offline `xstate` analysis and H1 runtime bitmap mapping) and determines that the stall occurred in an `xstate`-free context, allowing it to skip `xsave`/`xrstor` during H3 the context switch. *Thread B* then executes to harvest the otherwise wasted cycles. Bundles are formed B1 and dismantled B2 dynamically by the application's regular scheduler.

§4.1), which detects stall conditions in the CPU's memory controller based on L1 the cache residency and L2 a routing decision, and delivers the notification to the user process by L3 directly branching to LITESWITCH's software stall handler within the same address space.

For scheduling, LITESWITCH adopts the design choice that *any regular worker thread can act as a scavenger for harvesting*, rather than dedicating separate best-effort threads. This leads to a mechanism called *Bundled Handoff* (§4.2), which multiplexes a small set of user threads, termed a *bundle*, on each CPU hardware thread. A bundle is B1 formed by the user process's regular scheduler (the kernel scheduler or a user-level one), which applies its normal policies when selecting threads, except that it groups multiple threads into a bundle than running a single thread. During the bundle's lifetime, a stall notification from LDMB invokes LITESWITCH's handler, which switches execution among threads within the bundle. Critically, bundle formation is dynamic: when the bundle is de-scheduled (e.g., a thread issued a blocking I/O), the bundle B2 breaks and all threads are returned to the regular scheduler for the next bundling, which will likely not be the same formation. Bundled Handoff does not require changes to the application and operates within the scope and capabilities of the user process's regular scheduler than overshadowing it.

Finally, LITESWITCH minimizes context switch overhead by *selectively skipping saving and restoring CPU's extended SIMD/FP state* (`xstate`), a mechanism termed H3 `xstate`-Aware Context Switch (§4.3). This is based on the observation that `xstate` takes up $>$ 80% of total context switch overhead, but its live usage is sparse in most code paths. For each application, LITESWITCH performs X1 a one-time offline analysis to identify *functions* that do not use `xstate` at all, H2 allowing stalls triggered within these contexts to be harvested safely without doing `xstate` save and restore. This method reduces an impractical register liveness analysis problem to a static, binary lookup, avoids most unnecessary `xstate` save/restore, and preserves context switch correctness.

4.1 Location-Dependent Memory Branching

LDMB is a simple hardware mechanism that LITESWITCH uses for online, per-access stall detection with same-address-space delivery. LDMB builds on the architectural principle in prior "cache-miss trap" mechanisms, which showed that miss-triggered, branch-like delivery to software handlers is feasible in both in-order and out-of-order processors [28]. LITESWITCH does not implement a physical LDMB prototype; instead, it emulates the mechanism's behavioral effect (§5.1). The scope of this work is not to specify a circuit-level design, but to demonstrate that such a mechanism, if available in modern CPUs, enables useful software capabilities. FPGAs are fundamentally unable to reproduce the timing, concurrency, and microarchitectural behaviors of the memory hierarchy in modern server-grade CPUs [13, 38, 39]. This subsection therefore outlines the high-level LDMB design and argues that it is trivially feasible to implement in real CPUs. The design is grounded in modern Intel x86_64, but the ideas should be generally portable to other ISAs.

Detecting CXL memory accesses and branch-based delivery. When a load misses in the LLC, the uncore memory subsystem routes the request to either DDR or CXL. In Intel Flat Memory Mode, CXL serves as a slower tier behind a direct-mapped DRAM cache; the memory controller reads the DRAM line and checks its tag to decide whether the access

missed DRAM and must be re-issued over CXL. In setups where CXL devices are directly exposed to the software (e.g., software-managed tiering), the high-order bits of the physical address (PA) determine DDR versus CXL routing [16]. In both scenarios, cache lookup and routing are already on the standard path; LDMB simply reuses this logic.

After a CXL memory load is detected and a miss status holding register (MSHR) entry is allocated for it, the memory controller raises a short signal back to the core complex, analogous to existing core-interconnect notifications such as "data-return." The signal triggers a brief microcode sequence that flushes younger micro-ops and transfers control to a pre-registered handler address, akin to a branch-misprediction redirect. This redirect is same-privilege by construction: a user-mode LDMB enters a user-mode handler, while a kernel-mode LDMB can only enter a kernel-mode handler. Because signaling occurs after MSHR allocation, the miss has already been issued and will be serviced asynchronously. Therefore, LITESWITCH's handler does not need to explicitly prefetch or manage completion. Upon resumption, the software simply retries the load. By then the line will typically hit in cache. If not, the line buffer coalesces the retry with the outstanding miss, so the retry only waits for the remaining service time rather than incurring another full-latency stall.

Considerations for memory-level parallelism (MLP). In modern out-of-order (OoO) processors, MLP allows multiple outstanding misses to overlap before a data dependency forces the core to stall. Thus, not every CXL-bound LLC miss is a harvestable stall event, and LDMB should redirect only on a *true stall*. Inspired by prior switch-on-event (SOE) mechanisms [5, 11, 24, 53], a true stall can be defined as a CXL-bound miss that is blocking in-order retirement: the miss is unresolved and its corresponding entry is at the head of the reorder-buffer (ROB). This condition is simple to test because OoO cores already maintain the association between an outstanding miss and the instruction that produced it. Therefore, LDMB can follow the principle used in SOE: when the memory controller signals a CXL-bound miss, LDMB's microcode compares that miss's ROB entry with the ROB head. If the entry is already at the head and the miss remains unresolved, LDMB proceeds with the redirect; otherwise, LDMB simply drops the opportunity and lets OoO execution continue.

This one-shot policy avoids complex tracking, such as tagging the ROB entry and redirecting later if it eventually reaches the ROB head. The lost opportunities should be rare. From the time the load issues, the core continues decoding and dispatching while the request traverses the TLB and cache hierarchy, is classified as CXL-bound, and then sends a signal back to the core. This path is a full DDR access ($\sim$100 ns) in Intel Flat Memory mode, and can be modeled as LLC-hit-scale ($\sim$20 ns) in direct-expose CXL configurations. Even at the shorter 20-ns timescale, prior studies show that modern OoO cores often exhaust their effective instruction window on real workloads [40, 41]. Therefore, by the time the LDMB signal arrives, the associated CXL-bound miss is likely already retirement-blocking. The ROB-head test captures these common cases while keeping LDMB's hardware contract deliberately small but effective.

Software interface. LDMB exports a small set of control registers, collectively called `LCR`, modeled after conventional x86 model-specific registers (`MSR`s). Specifically, `LCRc` provides enable bits and optional control knobs (e.g., range masks for advanced features), while `LCRh` stores the address of the LITESWITCH stall handler entry stub that LDMB jumps to. `LCRh` is banked by privilege level, analogous to how the x86 TSS stores per-ring stack pointers RSP0–RSP2.

For resumption, LDMB pushes a minimal *stall frame* onto the user stack, containing only the instruction pointer and flags (`rip` and `rflags`). The handler later uses a single `LRET` return instruction to resume execution, analogous to an interrupt return (`IRET` and `URET`) but without privilege transitions.

Cost estimation. The cost consists of (1) the signaling delay from the memory controller back to the core complex and (2) the microcode-driven branch redirection. A conservative estimate is 10 ns for the signaling [61] and another 10 ns for the branch flush and redirection [14, 18, 56], totaling roughly **20 ns** . This is an order of magnitude lower than a traditional interrupt and well within the 200 ns budget for harvesting.

4.2 Bundled Handoff

When LDMB delivers a stall notification, LITESWITCH transitions into its software handler to select another ready thread to execute. Bundled Handoff is the software runtime mechanism that performs this selection and in-process context switch. Its design follows one key principle: harvesting should operate *within* the scope of normal scheduling. The process's regular scheduler retains full control over fairness, core assignment, etc., while Bundled Handoff merely redistributes execution opportunities at a much finer granularity.

Any regular worker thread is a scavenger. Instead of maintaining a separate pool of best-effort, low-priority threads, LITESWITCH lets any regular worker thread in the same process act as a scavenger. This design rests on two observations. First, threads of a process commonly execute the same hot paths and share frequently accessed data structures (e.g., task queues, metadata, synchronization variables) [29, 51, 62]. Reusing an existing worker therefore preserves locality: L1/L2 cache state and TLB entries remain largely valid across handoffs, minimizing cold starts and interference. By contrast, an unrelated best-effort pool perturbs caches and TLBs, undermining the very cycles being harvested. Second, best-effort tasks must explicitly yield back before the stall resolves to not delay the main tasks, which doubles the switching cost and consequently, wipes out most of the potential gain. Moreover, colocating unrelated tasks with regular worker threads introduces security concerns [50].

Dynamic bundling. When the process's regular scheduler makes a decision, it picks a small bundle of ready threads (rather than a single one) from the runqueue. If a running thread triggers a CXL stall and LDMB branches into the handler, the handler selects another thread in the same bundle (in round-robin) and resumes its saved context. The handoff is *one-way*: the new thread runs until it incurs another stall. Bundles are dismantled at normal descheduling events, including explicit yield, blocking, time-slice expiration, and preemptive interrupts. When any thread in the bundle triggers one of these events, the bundle is torn down and all threads are returned to the regular scheduler. A subsequent scheduling decision forms a new bundle, which may differ due to fairness and load-balancing policies. Therefore, bundling is *dynamic*, not a static pre-assignment, and bundles contain only runnable threads, maximizing the utilization of harvestable stalls.

Bundled Handoff yields a two-tier scheduling hierarchy. The process's regular scheduler forms bundles, enforcing fairness, priority, and load balancing. Within a bundle, LITESWITCH performs handoffs triggered by LDMB at a finer granularity. Because all threads in a bundle have already been admitted by the regular scheduler, Bundled Handoff can bypass policy checks for scavenger selection.

Bundle sizing. A larger bundle exposes more ready threads for harvesting but increases intra-bundle contention on CPU resources; a smaller bundle reduces such contention but risks under-utilization if all threads simultaneously stall. In practice, bundles of *two* threads are often sufficient: returning to the original thread requires two handoffs, by which time the original stall typically resolves; otherwise, the retry simply waits out the remaining stall time than a full stall.

Implementation scope and application transparency. Bundled Handoff naturally fits user-level threading models, where context frames and metadata are accessible without privilege transitions. Language runtimes and user-space schedulers register a stall handler via a write to `LCRh` and use their native threading primitives for intra-bundle handoff. Kernel models can adopt a hybrid interface such as Linux's vDSO: the kernel scheduler manages bundling, while a vDSO-mapped handler runs in user space, so normal scheduling remains in kernel space and stall harvesting occurs entirely in user space. Because Bundled Handoff operates within existing threading abstractions, it preserves application transparency.

Operating regime and workload suitability. Because LITESWITCH harvests stalls by diverting execution to sibling threads, its primary effect is higher aggregate core utilization rather than shorter request latency. In latency-critical services whose end-to-end latency is dominated by the slowest sub-request (e.g., fan-out queries), in-stall handoff may not translate to visible benefits. By contrast, throughput-oriented workloads naturally tolerate short stalls in one thread while others continue. In these settings, LITESWITCH's ability to reclaim tens to hundreds of nanoseconds per stall raises effective instructions-per-core and, consequently, throughput.

How does Bundled Handoff compare to SMT. At a high level, both LITESWITCH and simultaneous multithreading (SMT) aim to improve CPU utilization by interleaving multiple threads on the same core, but they do so in fundamentally different ways. SMT exposes true hardware concurrency: multiple threads issue instructions in the same cycle, allowing more of a core's heterogeneous functional units (issue queues, ALUs, load/store units, etc.) to be utilized than a single thread possibly could. This overlap also allows one thread to make forward progress when its sibling is stalled, but the stalled thread stays blocked, reducing aggregate utilization. By contrast, LITESWITCH turns a blocking wait into an asynchronous one by 'un-stalling' the hardware thread with LDMB, exposing more runnable cycles to the software that SMT would otherwise leave unexploited.

Therefore, the two mechanisms are *orthogonal and complementary*. when hardware threads are stalled, LITESWITCH can continue harvesting cycles independently *within* each SMT thread context, extending SMT's ability to achieve higher aggregate core utilization under long CXL stalls (§6.1).

Cost estimation. The overhead has three parts. First, bundling happens at regular scheduling granularity and thus is amortized to negligible cost. Second, per-stall scavenger selection is lightweight and incurs *no lock contention*: the bundle metadata is small and strictly per-core and implemented via thread-local storage, so accesses are likely cache-hit with no cross-core sharing; empirically, selection takes about 4 ns.

4.3 `xstate`-Aware Context Switch

Context switch is the last step before a scavenger can begin harvesting, and it is also the dominant software cost due to unavoidable memory loads and stores. In this paper, *context switch* means saving the outgoing thread's architectural state and restoring the incoming's last saved state. LITESWITCH's prototype targets Linux on Intel x86_64, but the ideas apply to other ISAs with similar extended state handling.

Raw costs of context switch. Since LDMB appears a raw "interrupt" that can arrive at an *arbitrary* instruction boundary, the handler must treat the CPU's entire architectural state as volatile and handle save and restore properly.

The complete set of CPU state comprises: (i) *general state* with 15 general-purpose registers (GPRs) plus `rip`, `rsp`, and `rflags`; (ii) *extended state* (`xstate`) including floating-point (FP) and single-instruction multiple-data (SIMD) registers (x87/SSE/AVX/AVX-512), opmasks, etc. Saving/restoring the general state is a handful of cache-line stores/loads when laid out contiguously; in LITESWITCH's prototype, this path averages about 10 ns in real workloads. By contrast, `xstate` spans KiBs of data (up to 32 512-bit `zmm` registers plus ancillary state) and must be saved and restored using `xsave` and `xrstor`, whose latency grows with enabled features. In LITESWITCH's prototype, one `xsave` followed by `xrstor`

costs 70–300 ns across workloads, consuming most of a 200 ns harvestable window if paid on every handoff.

Observation: `xstate` usage is sparse in most code. Empirically, most application code paths do not touch `xstate`. Hot `xstate` usage concentrates in dense numerical kernels (e.g., linear algebra, ML inference, cryptography) and in a few library routines (e.g., `memcpy`) that are easy to identify. By contrast, control- and memory-centric paths (e.g., servers, iterator and graph logic, queue management) often run for long stretches without using `xstate`. Figure 12 shows the fraction of execution time spent in `xstate`-using functions across workloads: graph workloads are $< 5\%$ and most others are $< 55\%$. This motivates a design that *skips* `xsave` and `xrstor` when the current execution point is known to be `xstate`-free.

Design: `xstate`-aware skipping via function-range metadata. LITESWITCH performs a one-time offline binary analysis to identify *functions* that contain no `xstate`-relevant instructions. The output, termed `xstatedump`, records the precise ranges of such functions that remain `xstate`-free after inlining and code generation, using function boundaries from the ELF symbol table (`.symtab`).

At process load time, LITESWITCH ingests `xstatedump`, maps these ranges to the process's runtime addresses (via `/proc/self/mappings`), and builds a global, read-only *code bitmap* indexed at a fine granularity (e.g., 64-byte blocks). On each stall delivery, the handler uses the saved `rip` from the LDMB stall frame to index the bitmap, which translates to one shift and one lock-free, likely cache-resident load. If the current block is marked `xstate`-free, the handler skips the unnecessary `xsave` and `xrstor` and switches only the general state; otherwise it falls back to the full path, or simply gives up on this harvestable window if the workload's `xstate` overhead generally exceeds the window, which can be easily analyzed offline as well.

However, this design assumes statically compiled, symbol-rich binaries (e.g., C/C++, Rust, Go, Swift). Stripped binaries or JIT-managed runtimes (e.g., Python, Java) may not expose reliable function boundaries; supporting them require additional mechanisms and is left for future work.

Why function boundaries suffice for correctness. Under the Linux ABI [49], all `xstate` registers are *caller-saved*. A caller that needs `xstate` across a call must save and restore it explicitly; a callee may freely clobber volatile `xstate`. Consequently, `xstate` usage is strictly confined to the bodies of `xstate`-using functions and does not propagate implicitly along the call chain. Therefore, if a function's body contains no `xstate` instructions, switching without `xsave` and `xrstor` is safe. For systems that differ, notably Windows x64, where a subset of `xmm` registers are callee-saved [54], those registers must be saved and restored explicitly on every context switch.

Importantly, the `xstatedump` analysis takes a conservative approach: a code block is marked `xstate`-free only if it lies entirely within `xstate`-free functions. All other blocks (e.g., thunks/PLTs, unknown code) are treated as `xstate`-present.

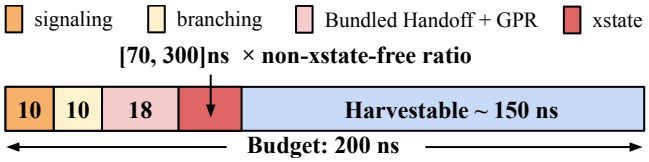

Figure 3: Cost breakdown of LITESWITCH's stall handling path. The costs for LDMB signaling and delivery are estimated. A fixed cost of 18 ns includes scavenger selection, bitmap lookup, and general registers save and restore. A variable cost is paid only when the current context is not `xstate`-free.

Practical considerations. `xstatedump` analyzes only the main program binary; libraries and other mappings default to conservative handling. A code-bitmap in 64-byte blocks balances accuracy and space, typically adding only KiBs of metadata, though some workloads are more sensitive and need a smaller block size to yield effective skipping. The bitmap is read-only and global, so lookup is lock-free. With these choices, the mechanism is simple to implement and effectively skips unnecessary `xsave` and `xrstor` operations (§6.2).

Cost estimation. The *fixed* per-handoff cost is the general-state switch plus a bitmap lookup (14 ns on average). A *variable* cost (i.e., one round of `xsave`/`xrstor`) is paid only when in non-`xstate`-free blocks. Empirically, non-compute-dense kernels take the fast path for most handoffs (§6.2). Even when `xsave`/`xrstor` is needed in every handoff, the total cost remains within the 200 ns budget for some workloads.

4.4 Putting It Together

Figure 3 summarizes the estimated costs of LITESWITCH's three core components: LDMB (detection and branching), Bundled Handoff, and `xstate`-Aware Context Switch. For workloads that require little `xsave`/`xrstor` (e.g., non-compute-dense) and with sufficient number of worker threads per core, the combined per-stall overhead is typically within **50 ns**, leaving most of a 200-ns CXL stall window available for useful scavenger work.

5 Implementation

The prototype of LITESWITCH is implemented on an Intel Emerald Rapids platform running Linux 6.8.12. The LDMB mechanism is realized through a hybrid simulation-emulation methodology (§5.1). The software components, Bundled Handoff and `xstate`-Aware Context Switch, are implemented within the Caladan user-level threading framework [22], which provides complete user-level scheduling and transparent threading semantics for unmodified applications. The resulting prototype is a software environment capable of running real, multithreaded workloads under controlled stall conditions. The artifact of LITESWITCH is open-sourced [45].

5.1 LDMB Emulation

The emulation of LDMB is implemented on a local-DRAM system using a hardware-assisted mechanism that injects stall events into a running workload. The goal is to reproduce two key properties of a real LDMB system. First, it needs to inject breakpoints into a running workload and divert execution to LITESWITCH's stall handler upon injections, as if a hardware LDMB had delivered a stall notification. Second, these injections should match the timing, frequency and duration of CXL-induced stalls observed on real CXL systems.

Repurposing PMIs for stall injection with frequency empirically derived from a real CXL system. The emulation leverages Intel's Performance Monitoring Unit (PMU), which can generate Performance Monitoring Interrupts (PMIs) upon counter overflows. Each core's PMU counter is programmed to track LLC load misses (`mem_load_retired.l3_miss`), a close proxy for DRAM-landing memory loads. The frequency at which these PMIs are triggered is the percentage of LLC load misses that would land on CXL memory, termed CXL access ratio (Table 2). This ratio is empirically derived per-workload on a CXL hardware-tiering system in Intel Flat Memory Mode with 50:50 DRAM-to-CXL ratio. For example, if the CXL access ratio is 20% for a given workload, the PMU counter overflow threshold is set such that a PMI is triggered for every 5 LLC load misses.

Upon a PMI, a kernel-space shim is invoked to inject an emulated stall, prepare an LDMB stall frame containing the user `rip` and `rflags`, and upcall the registered user-space LITESWITCH handler. The stall duration and handler stub are configured via `ioctl`. Since PMU operations are privileged, using a kernel shim as a relay is unavoidable, which introduces microarchitectural side effects (e.g., cache pollution and TLB flushes) absent in real hardware LDMB. To minimize this, the shim performs only minimal PMU bookkeeping and counter resets; its critical path is about 76 lines of code with a footprint of only a few instruction and data cache lines. Moreover, the shim disables Kernel Page Table Isolation (KPTI) and enables Process Context Identifiers (PCID), avoiding address-space switches and TLB invalidations on transitions.

Importantly, the shim's overhead is measured and subtracted from reported workload results. Because PMIs (delivered as NMIs) are non-preemptible, per-invocation cost is computed as lost wall-clock time over equivalent work and normalized by the number of PMIs per run, ensuring fair comparison across configurations with different stall rates.

The emulation also configures PMIs to fire only in user mode, as kernel context is often vulnerable to rapid, arbitrary switching due to severe reentrancy and correctness problems.

PMIs closely mirror the behavior of Intel Flat Memory Mode. PMIs are asynchronous events that arrive after the triggering LLC miss has completed. This largely mirrors how CXL accesses are identified under Intel Flat Memory Mode: the memory controller first reads the corresponding DRAM line and checks its tag to determine a DRAM miss, then immediately re-issues the request over CXL. The key difference is timing: a PMI may arrive many instructions after the triggering LLC miss, whereas in Flat Memory Mode, the tag check and CXL issuance occur back-to-back.

Config	Stall (ns)	Handler
`IFM-{len}`	`len`	none
`LITESWITCH`	20	Bundled Handoff
`SkyByte`	600	full scheduling

Table 1: System configurations. `IFM` stands for Intel Flat Memory Mode. Stall durations for `LITESWITCH` and `SkyByte` are the cost of their delivery mechanisms.

Application	Workload	CXL ratio	CXL-PKI
Breadth-First Search (`bfs`)	`urand`	24%	5.81
	`web`	12%	0.97
Connected Components (`cc`)	`urand`	25%	4.49
	`web`	17%	2.32
SPEC CPU 2017 (`spec`)	`619.lbm_s`	33%	11.57
	`638.imagick_s`	25%	0.01
	`657.xz_s`	25%	0.09
Memcached (`memcached`)	`ycsb_b`	11%	0.01
FASTER KV (`faster`)	`ycsb_a`	16%	0.90
Silo (`silo`)	`tpcc`	16%	0.09

Table 2: Applications and workloads. The CXL access ratios and CXL accesses per thousand instructions (CXL-PKI) are measured in Intel Flat Memory Mode.

Stall emulation. The shim uses Intel `tpause` to emulate stalls of specified lengths. `tpause` quiesces the hardware thread for a programmable number of cycles without microarchitectural side effects, providing a faithful approximation of a true memory stall. Importantly, `tpause` does not affect the sibling SMT hardware thread; the sibling continues to run while the other thread is `tpause`-d, enabling faithful evaluation of SMT under CXL-scale stalls (§6.1). The shim also enforces stall duration on a per-user-thread basis: if LITESWITCH resumes a thread too soon, the shim ensures the outstanding stall completes before that thread proceeds, for cases where a thread is switched back before its prior stall has resolved.

Emulating system configurations. The emulation uses three parameters to model diverse system configurations : (1) *CXL access ratio* (Table 2), the fraction of LLC misses generating injections; (2) *stall duration* (Table 1), the delay before the handler invocation, which could represent either the CXL access latency (without harvesting) or the cost for stall delivery (with harvesting); and (3) *handler activation* (Table 1), whether a software stall handler needs to be invoked.

LDMB's emulation did not factor in memory-level parallelism (MLP). As discussed in §4.1, not every LLC miss induces a pipeline stall due to MLP, but LDMB's emulation conservatively treats every CXL-bound LLC miss as a stall event, which overstates the frequency of harvestable stalls. As future work, one can measure the per-workload fraction of CXL-bound misses that overlap (i.e., a subsequent miss fires with out-of-order execution, while a prior miss is still

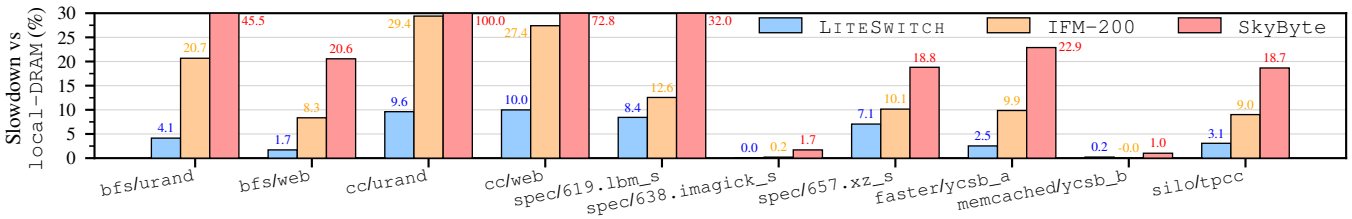

Figure 4: End-to-end application performance slowdown. All slowdown numbers are relative to `local-DRAM` with no CXL stalls.

in flight) and reduce the stall injection rate accordingly. For instance, if 10% of a workload's CXL-bound misses overlap, the emulation should inject 10% fewer stalls.

Modeling accuracy and limitations. The emulation injects stalls at a relatively flat rate and therefore does not model burstiness or short-term correlations in the miss stream. This abstraction aims at reporting end-to-end throughput under a given average CXL access ratio and stall duration. At this macro scale, the dominant factors are the total injected stall time and the fraction of that time LiteSwitch can harvest; preserving these factors should yield similar aggregate completed work even if the exact inter-stall timing differs.

This abstraction is less suitable for micro-scale timing questions. It does not faithfully model request latency, tail behavior, or concurrent misses under MLP. Studying those effects would require a methodology that preserves miss-stream burst structure and dependency behavior and is left for future work.

6 Evaluation

This section answers the following questions:

- How much performance loss induced by CXL access latency can LiteSwitch recover (§6.1.1)?
- How does LiteSwitch perform with SMT (§6.1.2)?
- Can LiteSwitch still deliver meaningful gains if the cost of LDMB is higher than the estimated 20 ns (§6.1.3)?
- How does LiteSwitch's effectiveness scale with increasing CXL latency (§6.1.4)?
- What is the runtime overhead of LiteSwitch's software path (§6.2.1, §6.2.2)?
- How effective is LiteSwitch in avoiding unnecessary `xsave` and `xrstor` operations (§6.2.3)?

Target CXL memory use case. The evaluation models the hardware tiering use case exemplified by the Intel Flat Memory Mode [6, 66], which is a relatively simple use of CXL memory as single-host memory extension where local DRAM acts as a direct-mapped cache for CXL. The CXL access ratios per workload are measured on a real CXL system in Flat Memory Mode configured with a 50:50 DRAM-to-CXL ratio (Table 2). This setting represents the conservative "lower end" of CXL memory stalls, where more complex configurations like CXL memory pools likely exhibit higher CXL latencies. The emulation and evaluation of LiteSwitch runs on a different system with the Intel Xeon Gold 5512U and only local DRAM, using the empirically derived CXL ratios to reproduce realistic stall behavior.

Applications and workloads. The experiments cover a diverse set of memory-intensive workloads (Table 2) representative of several key domains: (1) sparse graph analytics from the GAP Benchmark Suite [9]; (2) dense numerical computation from SPEC CPU 2017 [4]; (3) in-memory key-value stores (Memcached [3] and FASTER KV [12]); and (4) in-memory databases (Silo [58]). Each application-workload pair is denoted as `app/workload`.

System configurations. Four system configurations are compared in end-to-end experiments (Table 1): (1) `local-DRAM`, an oracle baseline assuming infinite local DRAM capacity and no CXL stalls; (2) `IFM-{len}`, a tiered-memory configuration using Intel Flat Memory Mode, with CXL access latency of `len` nanoseconds; (3) `LiteSwitch`, the proposed system with a 20 ns LDMB delivery cost; and (4) `SkyByte`, prior work that uses interrupts for stall delivery and takes a full scheduling path for stall handling [65].

All configurations disable SMT (unless specified otherwise) and use an equal number of physical cores. The number of worker threads per core is chosen independently for each configuration that yields the best performance. Throughput is used as the end-to-end metric, since LiteSwitch's primary effect is improving aggregate CPU utilization.

6.1 End-to-End Performance

Overall, LiteSwitch consistently reduces end-to-end performance slowdowns across a variety of workloads, with or without SMT, and under higher LDMB cost and CXL latency.

6.1.1 End-to-End Slowdown Across Workloads

Figure 4[1] reports the performance slowdown of each configuration relative to the `local-DRAM` oracle across all evaluated workloads. LiteSwitch consistently reduces slowdown compared to `IFM-200` for every workload, empirically validating that the mechanism can extract meaningful harvesting gains even at the lower end of real CXL latencies (200 ns).

LiteSwitch reduces slowdown by 30–80%[2] relative to `IFM-200` for most workloads: `bfs` sees a much smaller 1.7–4.1% slowdown versus 8–21% under `IFM-200`; in-memory

[1] For all figures in the evaluation section, lower values on the y-axis indicate better outcomes.

[2] Throughout this paper, phrases like "reduce slowdown by x%" and "x% reduction" denote *relative* reduction, not absolute percentage-point change.

Figure 5: Individual and combined effects of LiteSwitch and SMT. Completion time measures the time to complete the same amount of work, and is normalized to the baseline without LiteSwitch or SMT. All configurations use a 200-ns CXL latency setting. SMT uses a 2× hyperthreading factor. The right y-axis marks the corresponding speedup, with 2× being the perfect speedup from 2× hyperthreading.

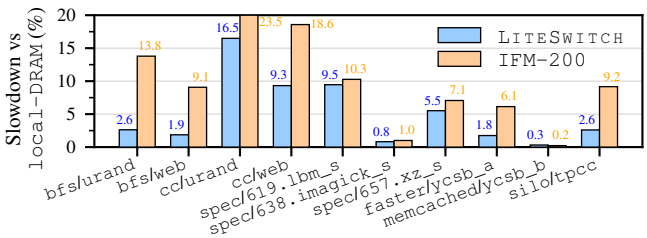

Figure 6: End-to-end slowdown with SMT. All configurations are measured with SMT turned on. SkyByte is excluded from this figure because it yields consistently the worst slowdowns.

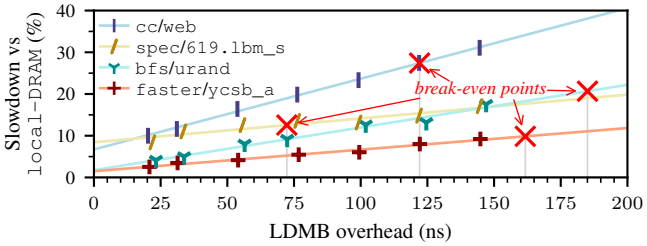

Figure 7: LiteSwitch effectiveness under higher LDMB overhead, ranging roughly 20–150 ns at 200 ns CXL latency. The lines are linear fit. The red break-even points mark where each fit matches the corresponding workload's IFM-200 slowdown.

stores, faster and silo, see 2.5–3.1% versus 9–10%. These workloads all remain under 5% slowdown, enabling practical CXL memory adoption. memcached and 638.imagick_s are particularly cache-friendly with negligible slowdowns for all configurations. cc is more sensitive to memory latency, exhibiting 9.6–10% slowdown in LiteSwitch, but still reduces slowdown by roughly 65% relative to IFM-200's 27–29%.

SPEC workloads (619.lbm_s, 657.xz_s) show higher slowdowns of 8.4% and 7.1%, respectively, with a more modest 30% reduction over IFM-200. These benchmarks make heavy use of SIMD/FP instructions, preventing xstate-Aware Context Switch from skipping xsave/xrstor on most context switches. Even so, LiteSwitch remains beneficial. SkyByte exhibits the worst performance by a wide margin across all workloads. This is because its interrupt-based delivery incurs a ∼600 ns overhead inappropriate for harvesting CXL memory stalls.

6.1.2 LiteSwitch with SMT

Figure 6 reports slowdown with SMT enabled. LiteSwitch continues to provide substantial slowdown reduction: graph workloads and KV engines see comparable reduction (30–80%) to the no-SMT case. By contrast, SPEC workloads 619.lbm_s and 657.xz_s show smaller reductions of 7% and 22%, versus 33% and 31% without SMT. The likely cause is higher intra-core contention inherent to SMT: by un-stalling hardware threads, LiteSwitch increases the fraction of time both SMT siblings are active contending for core resources. SMT alone also partially mitigates IFM-200 stalls. For example, cc workloads slow down by 27–29% without SMT and 18–23% with SMT. While SMT can hide some CXL memory stalls, the benefits of LiteSwitch are complementary to SMT, since LiteSwitch 'un-stalls' SMT hardware threads that are blocked on CXL access.

To quantify the individual and combined effects, Figure 5 compares the normalized completion time (and the corresponding speedup) under a baseline (no LiteSwitch, no SMT), LiteSwitch alone, SMT alone, and both combined.

LiteSwitch and SMT each improve performance independently, and their benefits largely compose when combined. For example, bfs/urand speeds up by 1.16× with LiteSwitch alone, 1.69× with SMT alone, and 1.87× when both are enabled. A similar pattern holds for graph workloads and KV engines. For most workloads, SMT alone provides higher speedup than LiteSwitch alone. This is expected: SMT enables true hardware concurrency at the instruction level, whereas LiteSwitch only opportunistically harvests stall cycles when CXL-bound misses occur. They both show considerable variation across workloads. 638.imagick_s is the extreme case where SMT sees little speedup, likely due to intense contention between SMT siblings.

6.1.3 Effectiveness under Higher Cost of LDMB

Figure 7 isolates the effect of increasing LDMB delivery cost while holding the target CXL latency at 200 ns. Across workloads, higher LDMB overhead shifts LiteSwitch's slowdown upward by a fairly fixed per-event penalty. It does not introduce a disproportionate or qualitatively different failure mode: the fitted lines remain close to linear, indicating that the added cost is paid per delivered stall event.

The marked *break-even points* indicate where each fitted LiteSwitch slowdown matches the corresponding workload's IFM-200 slowdown. Beyond this point, increasing LDMB overhead starts to eliminate LiteSwitch's net end-

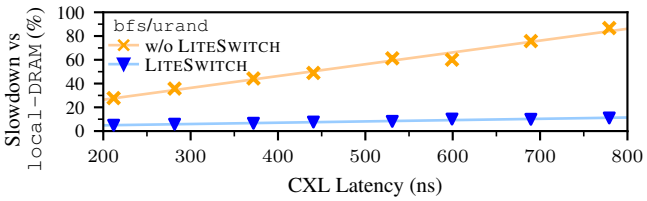

Figure 8: LiteSwitch effectiveness under varying CXL latencies (bfs/urand), ranging roughly 200–800 ns. Lines are linear fit.

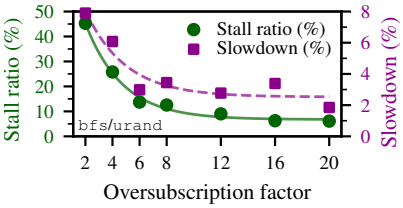

Figure 9: Oversubscription reduces stall ratio and slowdown (bfs/urand). The curves are exponential fit.

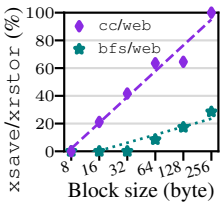

Figure 10: Sensitivity of bitmap block size.

to-end gain. The x-axis value varies substantially across workloads because the software-path overhead differs by workload (§6.2). For instance, spec/619.lbm_s reaches break-even near 72 ns, whereas bfs/urand remains beneficial until roughly 185 ns. This gap reflects their different software-path costs: bfs/urand rarely pays for expensive xsave/xrstor because it exercises much less xstate than spec/619.lbm_s (§6.2.3). These break-even values can be interpreted as the available LDMB-overhead "headroom" for preserving positive end-to-end gains.

The fitted slopes also differ across workloads. A steeper slope means that slowdown is more sensitive to additional per-event cost, which largely tracks how sensitive the workload is to memory-access latency in the first place.

6.1.4 Effectiveness under Varying CXL Latency

Figure 8 examines how slowdown evolves as CXL latency increases from roughly 200 ns to 800 ns, using bfs/urand as a representative workload (all other workloads see the same qualitative pattern). Without LiteSwitch, slowdown grows roughly linearly with CXL latency: longer memory stalls inject proportionally more idle time per access.

With LiteSwitch, slowdown remains nearly flat across the tested range. The slight upward trend arises because a bundle can occasionally contain only one runnable thread, leaving no scavenger available; those stalls must be waited out in full. Empirically, such single-thread cases are mostly fewer than 10%, so the aggregate impact is small (§6.2.1).

The key observation is that overall, LiteSwitch pays a rather *fixed* per-stall cost per workload, largely independent of the underlying CXL latency. This highlights LiteSwitch's potential to convert a wide range of CXL latencies into a fixed, per-invocation cost in perceived progress, yielding consistently low slowdowns even under greater CXL device variability and deeper topologies.

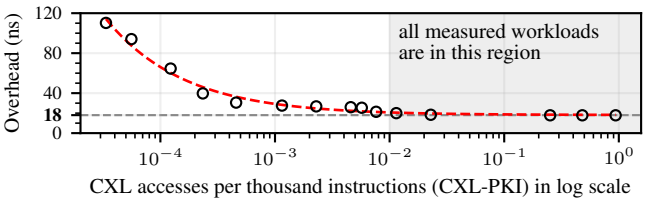

Figure 11: Handler overhead (excluding xsave/xrstor). The data points are measured on a synthetic matrix multiplication workload where CXL-PKI can be easily tuned; The 18-ns stable cost is verified on all workloads. The curve is exponential fit.

6.2 Overhead of the Software Path

The per-invocation cost of LiteSwitch's software path has three parts: (1) unharvestable stalls when the bundle has only one runnable thread (the stall is waited out); (2) a fixed handler cost, including scavenger selection, xstatedump bitmap lookup, and general-register save and restore; and (3) a variable cost for xsave and xrstor, paid only when the current context is not xstate-free.

6.2.1 Thread Oversubscription

A strong empirical correlation exists between the stall ratio (the fraction of LiteSwitch invocations with only one runnable thread in the bundle) and the thread oversubscription factor (total software worker threads divided by CPU hardware threads). For bfs/urand (Figure 9), at 2× oversubscription, 45% of invocations have only one runnable thread because workers frequently block on synchronization; as oversubscription increases, the stall ratio falls quickly (to 12–14% at 6–8×) and then plateaus. Workload slowdown closely tracks this decline. In practice, about 4–8× oversubscription sharply reduces the stall ratio, and roughly 6–12× keeps a scavenger available for >90% of stalls for most workloads.

Oversubscription is a general multi-threaded tuning knob rather than a requirement specific to LiteSwitch: too little oversubscription risks under-utilization when threads block, while too much increases contention and scheduler overhead. LiteSwitch benefits when the workload provides enough runnable threads to exploit the exposed stall windows.

6.2.2 Handler Overhead Excluding xstate

Figure 11 reports the fixed overhead of LiteSwitch's handler (scavenger selection, general-register save/restore, and xstatedump bitmap lookup) as a function of trigger rate, expressed as CXL accesses per thousand instructions (CXL-PKI). At very low rates ($< 10^{-4}$), overhead exceeds 100 ns; it then drops sharply and plateaus near 18 ns once the rate reaches 10^{-2}. The effect is due to cache residency: at higher frequencies, the handler's memory footprint (bundle metadata, bitmap, context frames) stays hot between invocations. All evaluated workloads operate at or above 10^{-2} CXL-PKI (Table 2) and often much higher. Thus, 18 ns is the effective fixed handler cost in practice.

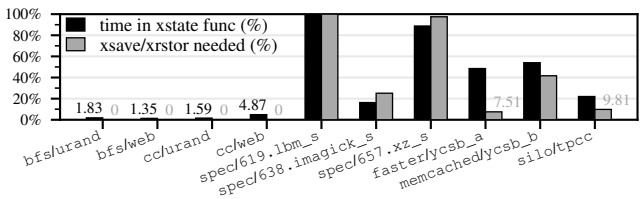

Figure 12: Effectiveness of `xstate`-aware skipping. The left bar measures the execution time spent in `xstate`-using functions; the right bar measures the fraction of handoffs requiring `xsave`/`xrstor`.

6.2.3 Effectiveness of `xstate`-Awareness

Figure 12 compares time spent in `xstate`-using functions with the fraction of LITESWITCH context switches that require `xsave`/`xrstor`. Across workloads, these two measurements are largely equivalent, indicating that `xstate`-aware skipping is effective. A few cases deviate: `faster`/`ycsb_a` requires far fewer `xsave`/`xrstor` than its time in `xstate` functions. This discrepancy is because `xstate`-heavy functions tend to be compute-bound with few memory loads, so stalls are disproportionately triggered in non-`xstate` code paths.

Figure 10 shows how the granularity of `xstatedump` bitmap impacts the fraction of context switches that require `xsave`/`xrstor` for two `xstate`-light workloads. For `cc`/`web`, the default 64-byte blocks still pay `xsave`/`xrstor` for more than half of the switches, whereas 8-byte blocks reduce this to near zero. This is likely because `cc` has a scattered `xstate` usage pattern that widely taints blocks when the granularity is coarse. `bfs`/`web` is less sensitive but follows the same trend. Empirically, 64 bytes suffices for most workloads.

7 Discussions and Limitations

The applicability of LITESWITCH. LDMB detects CXL accesses by relying on the CPU memory subsystem's cache-miss and routing path. Regardless of topology (e.g., direct-attach, multi-headed, switched), on-chip routing is the earliest point in the request path that can reliably determine whether a load will go off-chip to CXL. Measurements show that LITESWITCH's mechanisms are already effective for the simplest memory-expansion case with 200 ns CXL latency; as latencies grow (e.g., deeper fabrics, contention, heterogeneous devices), the recoverable stall window only increases. While there is ongoing debate about which CXL deployments are actually viable [43], LITESWITCH remains broadly useful and benefits more as stalls lengthen.

Considerations for Intel Flat Memory Mode. In this simple setup, the memory controller must read in the corresponding DRAM line first to determine whether an access missed DRAM. With this model, while LDMB can still make detection before a CXL access is issued, thus leaving the full latency window for harvesting, detection is still technically delayed by a full DRAM read. In deployments where CXL devices are directly exposed rather than a slower caching tier, detection does not need a full leading DRAM read and can use the high-order bits of the physical address. The speculation is that LITESWITCH could even outperform the oracle case (i.e., infinite local DRAM), because LITESWITCH's detection and harvesting routine begin at roughly the same moment a DRAM or CXL request is sent off-chip. Therefore, if LITESWITCH can switch to a scavenger faster than a DRAM load completes, LITESWITCH observes stalls even shorter than DRAM in perceived progress, thus better performance.

Potential real-world effects of LITESWITCH on memory-level parallelism (MLP). LDMB's pipeline flush might reduce Out-of-Order (OoO) depth, thus decreasing MLP. As discussed in §4.1, however, LDMB's return signal arrives only after a load traverses the cache hierarchy and is detected as CXL-bound; this path is at least LLC-hit-scale. During that interval, the core continues dispatching independent instructions, and prior studies show that OoO cores typically exhaust their instruction window within that timescale [40,41]. Consequently, data-independent loads that could exploit MLP have typically already been issued before LDMB can redirect, so the pipeline flush sacrifices little MLP opportunity. Critically, Bundled Handoff allows additional threads to issue their own independent memory loads while the original miss is in flight, effectively widening the core's useful miss concurrency beyond what a single stalled thread could achieve.

Double-emulation methodology. LITESWITCH emulates both LDMB delivery and CXL memory latency, compounding uncertainty into the evaluation. Two discrepancies matter most. First, the emulation injects stalls at fixed intervals derived from each workload's CXL access ratio. Real inter-miss intervals are more variable, and closely spaced misses can overlap through MLP rather than producing separate pipeline stalls. This can overstate the number of harvestable events and therefore modestly overstate LITESWITCH's absolute gain. Second, the evaluation uses 200 ns CXL latency, representative of the simplest direct-attached CXL. Deeper topologies (e.g., multi-headed, switched) and systems under load (e.g., in Intel Flat Memory Mode, every DRAM miss doubles bandwidth demand) push real latencies higher. Because LITESWITCH pays a mostly fixed per-stall cost, longer stalls widen the harvestable window; in those settings, the 200 ns results likely understate potential gains.

8 Related Work

Switch-on-event (SOE) multithreading. SOE is a hardware scheme from earlier multithreaded processors that switches between hardware threads when a retirement-blocking stall occurs [5, 11, 24, 53]. SOE shares the basic intuitions, but it always performs a costly full context switch with all architectural state. While this cost was acceptable for the more limited architectural state of older processors, modern CPUs continue to expand `xstate` (e.g., AVX-512 and beyond), making full-state switching increasingly prohibitive. LITESWITCH reduces this cost by selectively saving

xstate only when needed. Besides, LITESWITCH triggers only when a CXL-bound miss is determined, which selects for stalls with a sufficiently long expected latency, rather than committing to potentially short stalls when the hardware does not distinguish the root cause of a retirement-blocking stall.

Software-based harvesting. MSH [50] harvests DRAM-scale stalls within a single address space and uses fine-grained register-liveness analysis to minimize general-register save/restore. However, its reliance on offline profiling to place yield points is brittle in CXL. SkyByte [65] targets CXL-SSD latencies (tens-hundreds of µs) using device-provided hints delivered as interrupts so the OS can preempt and reschedule. That interrupt-driven path is appropriate at SSD timescales but is too costly for sub-µs CXL memory stalls. These limitations motivate LITESWITCH's combination of reactive, per-access hardware detection with same-address-space handoff.

Mitigating SIMD/FP overhead in context switch. In µs-scale user-level scheduling, context-switch overhead can also dominate. Shinjuku [36] made a similar observation that contexts that do not use SIMD/FP need not preserve xstate, and arranges its scheduler worker to be xstate-free so that switches between a user context and the worker omit FP save in one direction and FP restore in the other. However, an end-to-end handoff between two user contexts still incurs a full round of xstate save and restore. LITESWITCH's xstate-Aware Context Switch instead skips xsave/xrstor for direct handoffs between two user contexts.

Existing hardware capabilities for hiding memory stalls. Modern Intel server-class CPUs employ aggressive microarchitectural techniques such as out-of-order (OoO) execution, speculative execution, and prefetching to overlap backend stalls with useful work. These mechanisms can hide some memory latency, but are fundamentally limited by bounded resources such as the reorder buffer (ROB), issue queues, and the number of outstanding cache misses tracked by MSHRs. Long-latency DRAM accesses typically exceed what the ROB can cover, and prefetchers often fail on irregular access patterns or cause contention. Prior work has quantified these limitations and shown that cores still frequently stall despite deep speculation and scheduling windows [7, 20, 40, 41].

Asynchronous memory semantics. Asynchronous memory access instructions (AMIs) [60] decouple memory request issuance from completion in hardware, exposing explicit memory-level parallelism to the software but requiring a radical asynchronous execution model. Beehive [46] applies a similar principle in software for disaggregated memory, using compiler-generated Rust coroutines to overlap µs-scale remote accesses while preserving a synchronous-style programming model. At a high level, both AMI and Beehive hide memory latency by fitting in more concurrent outstanding memory requests through asynchrony. LITESWITCH is orthogonal: it targets cases where memory-level parallelism may still fall short, turning true pipeline stalls into useful work by intentionally switching to another worker thread.

9 Conclusions

LITESWITCH is a lightweight system for stall detection, delivery, and scheduling that effectively harvests sub-µs CXL memory stalls. LITESWITCH uses a combination of a simple hardware-based detection method with lightweight branching into the same user address space, together with fast scavenger selection while avoiding the cost of saving and restoring xstate registers when not necessary. Importantly, the ability to sustain consistently low workload slowdowns largely independent of CXL latency variability across diverse workloads highlights LITESWITCH's broad applicability.

Abstract

Today's distributed data processing frameworks (DDFs) have large memory and network transfer overheads because these frameworks require that each node (server or VM) copy objects into local memory before processing. Emerging shared disaggregated memory (SDM) clusters enable an alternate approach because they allow nodes to access data in a shared memory. However, using SDMs for DDFs is challenging: current SDM clusters provide weak coherence guarantees, and even for emerging SDMs coherence poses a scalability and complexity challenge. Thus, to adopt SDMs, a DDF would need to modify its logic and implement software coordination. In this paper, we describe Duhu, an SDM-based object store that is designed to allow DDFs to use SDMs without these changes, simplifying their adoption. We have integrated Duhu with Ray, and evaluated our system on an SDM cluster with a prototype CXL-attached memory pool. We show that Duhu can improve job completion time (JCT) by up to 3.39× on a shuffle workload.

1 Introduction

Distributed data processing frameworks (DDFs), including Ray [38] and Spark [60], play a crucial role in data analytics and machine learning. These frameworks make it easy to distribute program logic across multiple nodes (servers or VMs), making it feasible to process large datasets.

Performance, scheduling flexibility, and fault tolerance have long been concerns for these frameworks, and most frameworks address these concerns by using in-memory object stores to transfer immutable intermediate data between nodes. These data stores decouple tasks that produce data from those that consume them, thus allowing for more flexibility in when (and where) tasks are scheduled and reducing the amount of recomputation required when a node fails. By storing objects in memory rather than on disk, performance is greatly improved.

However, in-memory object stores incur significant overheads because, prior to access, they require that a node copy the object into local memory. This copying consumes CPU cycles (for serialization and deserialization) and network capacity (for the transfer). Furthermore, it increases the memory required to execute a job so that it far exceeds the job's memory footprint (i.e., the size of the job's inputs, outputs, and intermediate data).

Copying objects into local memory before access—a paradigm we refer to as pass-by-value—is needed because, until recently, processors could only access data in local memory. However, as the amount of data being processed by DDFs increases, this paradigm is increasingly unsustainable. Thus, we need to develop an alternative paradigm that eliminates these overheads without compromising the performance, fault tolerance, or scheduling flexibility of today's DDFs.

Emerging shared disaggregated memory (SDM) clusters provide an opportunity to move away from the pass-by-value paradigm used by DDFs today. These clusters consist of several memory blades that are connected to cluster nodes via a dedicated fabric running protocols such as CXL [10] or OpenCAPI [42]. Here, processors can use load-store instructions to directly access data in the memory blades, and thus SDM allows multiple nodes to share access to the same data. In the DDF context, this potentially allows multiple nodes to access the same copy of an object—rather than having to create local copies—enabling a paradigm that we refer to as *pass-by-reference*. Thus, the pass-by-reference paradigm alleviates memory pressure by reducing the number of object copies, without affecting fault tolerance or scheduling flexibility.

Prior work [38, 56] has suggested moving to a pass-by-reference-like approach where remote procedure calls (RPCs) include references (keys) to objects rather than the objects themselves. However, because these proposals did not target SDM clusters, servers still create a local copy (by fetching the object from the store) before access. Therefore, these proposals do not reduce network transfer overheads, nor do they reduce memory footprint. We detail these differences in §9, and our evaluation (§8) shows that our proposed approach improves on Ray.

In this paper, we describe Duhu, a pass-by-reference approach that targets SDM systems—specifically SDMs that do not implement global cache coherence protocols and hence do not guarantee cache coherence across servers. As we explain in §2.3, although emerging standards (e.g., CXL 3.0) include support for global cache coherence, this support carries a *coherence tax* [21] that limits scalability and performance, which Duhu avoids. Additionally, this choice allows Duhu to be deployed on existing memory blades [8, 22, 24] that do not provide global cache coherence.

The lack of coherence posed the most significant challenge when designing Duhu: it required that nodes coordinate and

synchronize caches when accessing shared data stored on the SDM. The need to coordinate adds performance overhead and makes it harder to integrate with existing DDFs, which were designed without awareness of SDMs. Our core contribution is our design (§3) that addresses both challenges.

Reducing Coordination Overheads. Our approach to reducing coordination leverages differences in mutability and access frequency for DDF objects and metadata. Specifically, our approach builds on the observation that object metadata is mutable (e.g., changes when other nodes get access to objects) but object data is immutable (it is only written when the object is first created). Furthermore, in most workloads, access to an object's data is more frequent and voluminous than to its metadata.

Our design requires inter-node coordination when accessing metadata. We reduce overheads for this coordination by partitioning the SDM into *segments* and associating each segment with an *owner*—a node responsible for sequencing and performing metadata operations on objects in the segment. This partitioning eliminates cross-node contention and reduces the cost of metadata operations.

Partitioning metadata into segments necessitates inter-node communication for metadata operations. To reduce communication overheads for these operations, we use Duhu-Channels (§5), a low-latency inter-node RPC mechanism that we designed to work over SDM. A Duhu-Channel uses SDM to send RPC requests and receive responses, and uses the network to signal the other endpoint. This combination enables low-latency communication.

Data access in Duhu does not necessitate communication or coordination. This is because objects are immutable, and thus the data changes only when an object is created. When creating an object, nodes use non-temporal writes to ensure that SDM contains a consistent version of the object. Additionally, nodes flush the corresponding cache lines before reading an object for the first time. This combination of non-temporal writes and cache flushes before first access ensures that readers always access the last consistent version of an object from SDM.

Simplifying DDF Integration. Our design simplifies integration with existing DDFs in two ways. First, Duhu provides a key-value store API that is similar to the API of object stores used by DDFs like Ray. Duhu implements its coordination logic within these API calls, thus ensuring that DDF logic need not change when using Duhu.

Second, Duhu implements reference counting to eliminate safety problems due to the garbage collector implemented by existing DDFs. Pass-by-value DDFs include a garbage collector that deletes the local copy of an object to regain space. This is safe, even if another node is concurrently accessing the object, because each node operates on its own copy. However, this is not true for Duhu or other pass-by-reference object stores that use a single copy of the object. We address this by tracking which nodes have references to the object, and freeing the object only when it is safe to do so, without requiring changes to DDF logic.

We implemented Duhu and integrated it with Ray [38]. We evaluated the Duhu version of Ray on an SDM cluster with four nodes and a prototype CXL-attached memory pool. The pass-by-reference semantics open up new possibilities; our evaluation (§8) describes FlexShuffle, a new shuffle approach enabled by Duhu. We show that, by replacing the physical transfer of shuffle data with only metadata reorganization, FlexShuffle improves job completion time for a multi-stage shuffle job by up to 3.39×. Further, in this case, Duhu can reduce an individual shuffle stage's runtime by 3.59–13.81×. Finally, we evaluated its impact on existing applications by modifying Modin [44] to use Duhu, and show that Duhu improves TPC-H query completion time for Modin by 1.08×.

2 Background

2.1 Distributed Data-Processing Frameworks

A Distributed Data Processing Framework (DDF) is a framework that allows users to process large amounts of data by distributing computation across multiple nodes (servers or VMs). These frameworks play an important role in data analytics and machine learning, and frameworks such as Spark [60, 61], TensorFlow [1], and Ray [38, 57] are widely used for this purpose.

In these frameworks, the nodes that implement the processing logic need to communicate with each other by sending intermediate values of the computation. These intermediate values are *immutable* data chunks that are written once and consumed one or more times, possibly by other nodes, depending on the workflow and scheduling of the computation. Most frameworks use object stores for this inter-node communication. The use of object stores provides several benefits: it increases scheduler flexibility by decoupling data producers and consumers, it allows intermediate data to be reused multiple times, and it enables fault tolerance because backup nodes can retrieve and operate on a failed worker's inputs and intermediate results.

Early DDFs, including Google's MapReduce [11] and Hadoop, used disk-based object stores (GFS [15] and HDFS [50], respectively). But the use of disk-based object stores was a performance bottleneck. Therefore, recent DDFs including Spark and Ray use in-memory immutable object stores: Spark stores intermediate data in RDDs [60], which are managed by a centralized block store, and Ray stores intermediate data in the Plasma store [43].

However, the pass-by-value paradigm used by in-memory object stores causes DDFs to experience a performance and scalability wall. Because processors can traditionally only operate on local DRAM, each node must copy an object from the object store into local memory before processing. This creates multiple physical copies of the same immutable object across the cluster. In turn, this copying wastes limited memory capacity, imposes serialization and deserialization

CPU overheads, and consumes valuable memory bandwidth and network resources that could otherwise support compute.

Our goal in this paper is to build an immutable object store that enables an alternative paradigm: pass-by-reference that does not copy objects into local memory. To do so, we need a mechanism that allows processes running on different nodes to directly access data. Thus, we target shared disaggregated memory (SDM) clusters, which we describe next.

2.2 Shared Disaggregated Memory

Duhu is designed to run on shared disaggregated memory (SDM) clusters, where memory blades [8, 22, 24] are decoupled from compute nodes and accessed via a high-performance fabric supporting load/store semantics, such as CXL [10] or OpenCAPI [42].

Modern and future SDM systems rely on one of two coherence implementations: *Hardware-coherent systems* (e.g., future CXL 3.0 SDMs) enforce global cache coherence via directory-based protocols. In contrast, *software-defined coherent systems* only provide coherence within a compute node; they do not coordinate accesses from different nodes. Duhu specifically targets the latter, and for our implementation we use CXL 2.0 memory expanders. Concretely, we use Type 3 devices that provide memory expansion but do not implement global coherence [10]. As we discuss below, this is to reduce performance overheads, improve scalability, and enable compatibility with today's memory blades.

Performance. These memory blades allow servers to access memory at a byte granularity. Prior work [28, 32] has reported expected latencies approximately 3–6× higher than local DRAM, and bandwidth approximately 4–16× lower than the total bandwidth of a local CPU socket, and our SDM prototype achieves 600–800ns latency and ≈10GB/s bandwidth (details in §8).

Failure domains. We assume memory blades are deployed in groups called memory units. Each unit has its own power supply and fabric connection. Thus, when a memory unit fails, the data in its blades is lost, but other units remain unaffected. We detail Duhu's assumed failure model in §3.

2.3 The Coherence Tax

While hardware coherence simplifies programming, it imposes significant overheads for cost, performance, and complexity. We refer to these overheads as the Coherence Tax, and discuss them below.

Straggler penalty. In directory-based protocols (e.g., MESI), writing to shared memory requires collecting invalidation acknowledgments from sharers. Thus, in the worst case, the write latency is bounded by the tail latency of the slowest sharer in the cluster.

Bandwidth tax. Hardware cache coherence adds protocol overhead (e.g., state updates) to data transfers. For bulk transfer of immutable objects, this incurs unnecessary overheads for every cache line written and fetched.

Complexity barrier. Scaling hardware coherence to petabytes of memory faces a storage wall. Directory structures (e.g., snoop filters) must track state for every cache line. Scaling to disaggregated capacities would require untenable amounts of on-chip SRAM and complex lookup and update logic in the fabric.

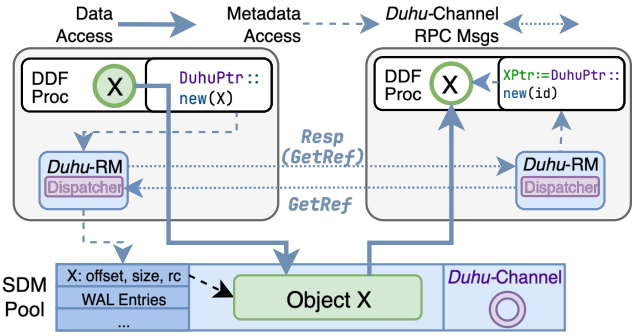

Figure 1: *Architecture of Duhu integrated with a DDF. Duhu-RM provides the same pointer view in address space for nodes to load and store (solid arrows) as native local memory objects. DDF processes call the Duhu API to perform metadata operations (dashed arrows). The API calls are handled by the local Duhu-RM, which uses the in-SDM Duhu-Channel mechanism to coordinate operations for remote objects (dotted arrows).*

3 Duhu Overview

Duhu is a pass-by-reference object store for in-memory DDFs running on SDM clusters that do not provide hardware cache coherence between nodes (§2.2). It improves DDF performance by reducing network overheads and decreases memory usage by eliminating redundant object copies. Duhu (Figure 1) stores two types of information in SDM: (1) *metadata* indicates where objects are stored and which nodes have access, and tracks information for failure recovery; (2) *data* consists of the actual content of an object.

Beyond enabling pass-by-reference semantics, our design aims to meet four requirements:

1. **Simplify integration with existing DDFs.** Our design ensures that core DDF logic does not need to change when integrating Duhu. We accomplish this by providing an API (§4) that is similar to what is provided by the immutable data stores [43] used by DDFs today. However, as we explain below, to meet our remaining goals, we limit the choice of keys (unlike standard key-value stores). Through the API, frameworks can put objects, get references, and drop references with a key, while directly reading bytes in SDM without copying the object to a local variable.
2. **Minimize coordination overheads.** Cross-node coordination is required to ensure the correctness of operations that read or modify object metadata. For example, coordination is required when allocating an object (so that the memory for any two objects does not overlap) and freeing an object (to ensure an object is freed only if no nodes plan to access it). Our design minimizes coordination overheads for these operations by partitioning the object store into segments, each of which is owned by a single node. When other nodes need to access the object, they issue an RPC to the owner. To reduce the overhead of contacting the owner, we provide an efficient

RPC mechanism, Duhu-Channel (§5), that uses the SDM for data transfer with the help of the network for signaling.

3. **Efficient but consistent access to shared object data.** DDFs allow multiple nodes to access the same object stored in an object store, and assume that all nodes get a consistent version of this object. Our design leverages object immutability to provide efficient, consistent object access from multiple nodes: when creating an object, a node uses non-temporal instructions to ensure that all updates are written to the SDM, and before reading an object for the first time, nodes flush cache lines to ensure that they read data from the SDM. Nodes need to flush cache lines before they read the object for the first time because an object might reuse SDM memory that was previously allocated to a different (now freed) object.

4. **Avoid resource leaks.** Current DDFs assume that each node accesses a locally stored copy of the object and can garbage collect that copy independently (in response to the node being done or local memory pressure). Duhu's pass-by-reference model violates the assumption made by these frameworks because multiple nodes can access the same copy stored in disaggregated memory. This in turn renders the garbage collection logic implemented by these frameworks incorrect.To address this, Duhu asks its user (the DDF) to indicate when it drops references to an object, so Duhu can track outstanding references (§4.2). This is usually straightforward, since most DDFs already have a local garbage collection mechanism where they drop references. With this information, Duhu ensures that a shared object is freed only after no nodes have references to it.

Failure model. Duhu is designed for use with DDFs that can reconstruct objects lost due to failures, using lineage or other recomputation mechanisms. Nearly all commonly used DDFs, including Ray and Spark, meet this requirement because alternative approaches such as object replication require significant additional memory.

We further assume that Duhu and the DDF that uses it are deployed in a cluster with multiple memory units and multiple nodes. The cluster is monitored by an orchestrator that notifies Duhu when a memory blade or node fails. Further, we assume that node failure does not affect the contents of the SDM; that is, data written by a node to the SDM remains available even after the node fails.

Duhu places all data and metadata for an object in the same memory unit to limit the blast radius. Under this model, our failure mechanisms (§6) ensure that a DDF that uses Duhu continues to function as long as enough nodes are available (dictated by the DDF) and the available memory units provide sufficient memory (dictated by the workload).

3.1 Duhu Design Principles

1. **Share data, but not metadata.** Sharing read-only data—such as the contents of immutable objects—is relatively easy even with incoherent memory. But metadata is constantly changing, so we keep it private: a single node is responsible for reading and writing it (possibly on behalf of other nodes). This node may change if there are failures.

2. **Streamline coordination using the SDM.** Cross-node coordination requires communication, and cross-node communication adds latency. Duhu reduces this latency by implementing Duhu-Channel, an RPC channel that communicates over SDM. The lack of coherence means that one node cannot be notified about SDM writes made by another node, i.e., `MWAIT` and similar instructions cannot be used with SDM. Therefore, when necessary, Duhu-Channel uses the network to signal nodes. This combination enables low-overhead cross-node communication, thus reducing coordination overheads.

3.2 Architecture Overview

Duhu provides an object store that DDFs use to store and access objects. The Duhu API (§4) provides a key-value-store-like API that DDFs can use to allocate objects, gain access to an existing object, and release references. Our design requires that objects be immutable: they are written once when allocated and are not modified subsequently. This assumption holds for most common DDFs, including Ray and Spark. Note that the Duhu API is called by DDFs, rather than applications. Application code does not need to change when using Duhu.

Duhu-RM. The Duhu API is implemented by a Duhu Reference Manager or Duhu-RM (§4). A Duhu-RM instance runs on each node and implements all of the coherence and coordination logic required to safely access the SDM. Duhu-RM is also responsible for updating and maintaining object metadata. Any node may wish to modify an object's metadata, and thus metadata maintenance requires coordination between Duhu-RMs running on different nodes. For performance and scalability, each Duhu-RM instance runs multiple threads.

The Duhu-RM also maintains the write-ahead log (WAL) that is used for failure recovery (§6): each thread writes an entry to the WAL before making changes to the SDM.

Duhu-Channel. Duhu-RMs coordinate with each other using a Duhu-Channel (§5), an RPC channel that allows nodes to communicate over SDM. Each Duhu-Channel provides client-server style communication. Multiple threads on the client Duhu-RM can issue RPC calls by writing to the same channel, and any thread on the server Duhu-RM can execute an RPC received on a channel. Furthermore, multiple RPC calls received on a single channel can be processed concurrently by different threads on the server Duhu-RM. Duhu-Channels are designed for small messages of less than 63 bytes in size. The restriction on small messages does not impact our design: all current inter-node requests in Duhu are smaller than 63 bytes; if larger payloads are required in the future they can be accommodated by passing SDM references.

When communicating over a Duhu-Channel, clients might need to notify the server about pending requests, or servers might need to notify clients about pending responses. The lack of global coherence prevents us from using SDM for notifications: a node receives no communication when another node modifies an SDM location. Therefore, we rely on messages sent over a traditional network for notifications.

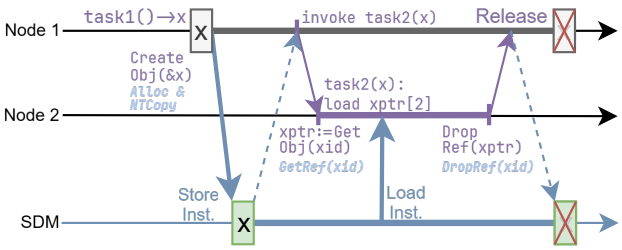

Figure 2: *A timeline view of object lifecycle events when integrating distributed computing frameworks with Duhu. DDF elements are purple, and Duhu elements are blue. Duhu-RM internal calls are specified under corresponding DuhuPtr API invocations.*

Dispatcher. Each Duhu-RM includes a dispatcher that is responsible for assigning requests received on a Duhu-Channel to a Duhu-RM thread. For correctness, the recovery logic requires that operations on a single object must be performed in the same order as recorded in the WAL. To ensure this, all requests to the same object are dispatched to the same thread: all RPCs issued by Duhu-RMs include an object ID that the dispatcher uses to select the appropriate thread. The dispatcher is also responsible for sending and processing channel notifications.

3.2.1 Illustrative Example

We illustrate how DDFs integrate with Duhu below by describing how a version of Ray that is integrated with Duhu creates an object, gains access to an object, and eventually releases its reference to an object (Figure 2).

Referencing objects. DDFs use two types of references, `ID` and `DuhuPtr`, to refer to objects stored in Duhu. An `ID` is meaningful for the entire cluster and serves as a reference that can be shared between different nodes. The `ID` encodes the segment in which an object is stored, which is used to route calls to the appropriate node.

However, an `ID` cannot be used to access object data. On the other hand, a `DuhuPtr` is node-specific and can be dereferenced to access object data. Duhu's reference counting keeps track of which nodes have valid `DuhuPtr`s to each object. DDFs can convert between the two types: the `GetObj` function (Table 1) returns a `DuhuPtr` given an `ID`, and the `GetID` function does the opposite.

Object creation. A DDF worker on node 1 creates and initializes a copy of object `x` in local memory. Once the object is initialized, the worker calls `CreateObj` to allocate and place object `x` in the object store. Once this call completes, `x` is stored in the SDM and is immutable. The call also returns a `DuhuPtr` through which node 1 can read `x`. Finally, node 1 can use the `GetID` API to get an ID that other nodes can use to get a reference to `x`.

Getting an object reference. A DDF worker on node 2 executing a newly launched task with a reference to `x` can gain access by calling the `GetObj` API. The `GetObj` and `CreateObj` calls update object metadata to track what nodes have outstanding references, thus ensuring that space allocated to an object cannot be reclaimed while a valid reference exists.

Figure 3: *Duhu-RM's memory layout in SDM pool.*

Releasing a reference. To enable space reclamation, a DDF worker must eventually release its reference to object `x` and does so by calling the `DropRef` method. To simplify integration, we invoke `DropRef` automatically from the `DuhuPtr` destructor when the reference goes out of scope. The object is freed and space is reclaimed once no node has a reference to `x`.

4 Duhu Reference Manager

Next, we detail the design of Duhu-RM. Our design partitions the SDM into segments to reduce coordination overheads for metadata operations. Furthermore, it leverages the immutability of objects to allow DDF workers to directly access object data while maintaining data consistency (§4.1).

The Duhu-RM implements the API (Table 1). DDFs use this API to create and gain access to objects, and to eventually release a reference as described in §3.2.1. The API itself closely resembles those of existing object stores, making it easier for DDFs to integrate with Duhu.

Internally, each Duhu-RM instance requires consistent access to object metadata, despite the metadata being stored in incoherent memory. Consequently, Duhu-RM instances must coordinate among themselves. Duhu simplifies and distributes this coordination by partitioning the data structures in SDM into segments (Figure 3).

Each segment has an *owner*, a node that has exclusive access to the metadata in the segment. Limiting metadata access to a single node ensures consistency. If a non-owner node wishes to access metadata in the segment, it issues an RPC to the owner's Duhu-RM. Table 2 shows the RPC interface exposed by Duhu-RMs. The RPCs require cross-node communication over a Duhu-Channel (§5).

Duhu guarantees that a segment has at most one owner. If a segment's owner fails, the Duhu recovery mechanism (§6) reassigns ownership to a different node and ensures that the segment's metadata is consistent.

Partitioning memory into segments whose ownership is distributed provides the benefits of centralized coordination without the scalability bottleneck of a central metadata manager, and without the locking complications of schemes where all nodes can access the metadata concurrently. In fact, we tried to design such concurrent schemes and found that the lack of cache coherence created overhead and complexity. Conceptually, Duhu shifts this complexity into the Duhu-Channel.

Segment layout. Each Duhu segment consists of four regions: (a) a Duhu-Channel region, containing data structures of channel used by the owner to send RPC requests to other nodes; (b) a write-ahead log (WAL) that is used during failure recovery to ensure metadata consistency; (c) a metadata region, containing a hash-map that maps *object identifiers* to object

API	Description
`CreateObj(*src, siz, owner) -> DuhuPtr`	Create an object in SDM with the data in `src` (in local memory). Returns a pointer to the SDM object.
`GetID(DuhuPtr) -> ID`	Get an ID from a `DuhuPtr`. The ID can be shared with other workers.
`GetObj(ID) -> DuhuPtr`	Get a `DuhuPtr` for an object ID, increasing the object's reference count in the process.
`DropRef(DuhuPtr)`	Invalidate the `DuhuPtr`, thus decreasing the object's reference count.

Table 1: *The API that DDFs use to interface with Duhu.*

Duhu-RM internal RPC	Description
`Alloc(id,*src,siz) -> *dst`	Requests space in the segment owned by a remote Duhu-RM.
`GetRef(id) -> *obj`	Gets a reference to object `id`, returns the address of the object. Records the client in the reference bitmap.
`DropRef(id)`	Releases a reference previously obtained by the node using a `GetRef` call. Erases the client in the reference bitmap.
`CreateId(segment)->id`	Returns an unused object ID that will be stored in the given segment.

Table 2: *The Duhu-RM internal RPC endpoints that Duhu-RMs use to talk to each other.*

metadata including the object's address, its size, and a bitmap recording nodes that hold references to the object; and (d) a data region, containing the data of objects. An object's metadata and data are co-located in the same segment. Co-location simplifies failure recovery because an object's data and metadata share fate, and avoids coordination for object allocation and reclamation, as updates to the object metadata and free list are performed by the same node.

Implementing the Duhu API. DDFs that use Duhu are unaware of segments, and the API they use (Table 1) exposes object IDs (which are recorded as a part of the object's metadata) and references to the object data (wrapped in a `DuhuPtr` type, which includes the ID).

API calls made by the DDF worker are handled by the local Duhu-RM running on the same node. Most of these API calls require manipulating object metadata, and the Duhu-RM uses RPCs (described below) for this if the object metadata is stored in a segment that it does not own.

API calls are cheaper when handled by the node that owns the segment containing the target object's metadata because no communication is required. Therefore, object placement can impact performance, and the `CreateObj` call allows DDFs to use the *owner* parameter to specify object placement.

RPCs to manipulate metadata. As we mentioned above, nodes must use RPCs (Table 2) to modify the metadata for any segment they do not own. To aid in failure recovery (§6), all RPC operations are idempotent. Furthermore, we require that, before executing a metadata operation, a node write (and flush) operations to the segment's WAL. The WAL entry includes all arguments, the Duhu-Channel ID, and additional metadata (including slot ID and version) that are required for the recovery logic to safely respond to the request.

Figure 4 illustrates API handling and RPC calls in Duhu:

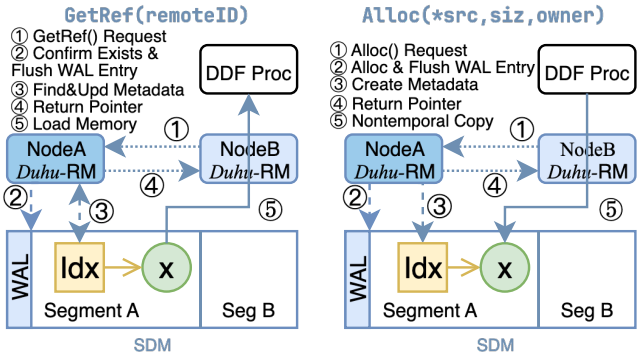

Figure 4: *The detailed protocol of GetRef and Alloc internal RPCs.*

the DDF worker running on node B issues an API call that is processed by the local Duhu-RM. The API call requires changing metadata in a segment owned by node A, and node B sends an RPC request to node A. Node A first writes the RPC request to its WAL, then performs the necessary operations and sends the response to node B. Communication between the two nodes is performed over a Duhu-Channel (§5).

4.1 Safe and Direct Data Access

A DDF can access data objects by dereferencing a `DuhuPtr`. Duhu implements this by having all nodes map SDM segments to the same virtual address, thus ensuring that no additional address translation is necessary. While this ensures direct data access, additional mechanisms are necessary to ensure that all nodes access consistent data, i.e., to ensure safety. Object immutability helps Duhu ensure consistency.

Immutable objects and consistency. As an immutable object store, Duhu requires that nodes first create and populate objects in local memory before adding them to Duhu. DDFs add objects to Duhu by calling the `CreateObj` API and providing a reference to the object in their local memory. Duhu then allocates space in the appropriate SDM segment and copies the object to this location. We copy the object asynchronously to allow pipelining and further reduce Duhu overheads.

The immutability of objects *almost* solves the problem of data consistency in the face of incoherent memory, but not quite: objects are eventually freed and new objects are created in the same locations in SDM. Thus, the actual data in an SDM location is not immutable; if not handled carefully, a node could potentially access stale data from a previous object that remains in the node's processor cache. To address this problem, nodes in Duhu carefully manage their processor caches as we explain next.

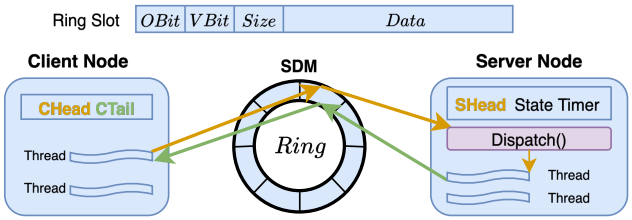

Figure 5: *Duhu-Channel Architecture Overview*

Low-overhead cache synchronization. With Duhu, the data in SDM changes infrequently and at well-defined points, namely when new objects are allocated in the same place in SDM as previously deleted objects. As observed by prior work [2, 18], this pattern allows us to use cache synchronization instructions sparingly to avoid their overhead, while ensuring consistency of access at all times.

More specifically, objects are cache-line aligned, and the object's creator uses non-temporal instructions (e.g., the `_mm512_stream_si512` intrinsic [23]) to ensure that writes are flushed to the SDM. This ensures that after the writer is done, any reads from the SDM return a consistent version of the object. Because no other worker can gain access before the writer finishes and no mutations are performed after `CreateObj`, reads from other workers can be safely served from the SDM without worrying about data inconsistency. To ensure that nodes access the SDM copy, the `GetObj` function invalidates the appropriate cache lines before returning a pointer to the object's data.

4.2 Reclaiming SDM Memory

Nodes allocate SDM memory when they invoke `CreateObj`. Duhu uses reference counting to safely reclaim an object's memory. Initially, an object's creator holds a reference to the object, and the reference count is 1. Subsequent calls to `GetObj` by other nodes increment the reference count. Nodes (regardless of whether they are the object's creator or not) can signal that they are done accessing the object by calling Duhu's `DropRef` function. It is unsafe for a node to access object data after calling `DropRef` without invoking `GetObj` again. Duhu reclaims the object's memory when the reference count reaches 0.

5 Duhu-Channel

A Duhu-Channel is an RPC channel that Duhu-RMs use for inter-node communication and coordination. A Duhu-Channel uses SDM to transfer RPC requests, arguments, and responses, and a network connection to signal Duhu-RM dispatchers when required. A Duhu-Channel connects a client Duhu-RM—which issues RPC requests—to a server Duhu-RM—which executes and responds to requests. Note that a channel is used by only two nodes (the client and the server).

5.1 Architecture and Functioning

A Duhu-Channel (Figure 5) has components in the SDM, and at the client and server Duhu-RMs:

1. **SDM**: Each channel allocates a ring-buffer (i.e., an array which is indexed using modulo arithmetic) consisting of n cache-line sized (64-byte sized) slots in the SDM, allowing up to $n-1$ RPC requests to be issued simultaneously. We ensure that slots are cache-line aligned, which in addition to them being cache-line sized means that nodes can read or write the slots atomically. Clients write to slots to issue an RPC, and servers write their responses back into the same slot.
2. **Client**: At the client Duhu-RM, a Duhu-Channel maintains a *client head* (*CHead*), the index of the slot that the client should use for the next RPC it issues. The client also maintains a *client tail* (*CTail*) which tracks the index of the slot beyond which all slots are unused. The *CTail* ensures that the client does not overwrite a slot being used by an in-flight RPC.
3. **Server**: At the server Duhu-RM, a Duhu-Channel maintains a *server head* (*SHead*) that tracks the next slot that a request will arrive on; and a variable tracking the state (*State*) of the server and a timer (*Timer*) that are used to switch between polling and using notifications for requests.

In addition to these components, each Duhu-RM maintains a network connection to every other Duhu-RM, and the dispatcher uses this to notify other nodes.

Slot structure. Figure 5 shows the structure of a channel slot: it contains metadata indicating message size, an 'ownership' bit (*OBit*) that indicates which endpoint (i.e., the client or the server) can access the slot, and a version bit (*VBit*) that the failure recovery logic (§6) uses to ensure correct re-execution. Initially, the *OBit* is set to *C*, indicating that the client owns the slot, and *VBit* is set to 0.

The slot also contains a data section: the client Duhu-RM issues an RPC by writing the request (and all required arguments) to this section, and similarly, the server responds to an RPC by writing the return value to this portion of the slot.

Observe that we use a single Duhu-Channel to carry both requests (from client to server) and responses: we chose this design in order to minimize Duhu's working set size, and thus reduce cache pressure on the nodes.

Algorithm 1: Client Request Submission

```
   Input: size, data                          // Payload size and data
   Output: result                             // Slot index or error
1  if CHead + 1 = CTail then return E_NO_SPACE
2  do
3      slot ← CHead.load()
4      next ← (slot + 1)  mod RingSize
5      until next ≠ CTail.load()
6  while CHead.CompareSwap(slot, next) fails
7  Msg ← PackedMsg{S; V; size; data}
   // S: set OBit to server.
   // V: current version.
8  WriteToSDM(Ring[slot] ← Msg)
```

5.1.1 Submitting an RPC Request

Algorithm 1 shows the procedure that a thread running on the client Duhu-RM invokes to submit a request to a Duhu-Channel. The client thread uses atomic operations to reserve a slot (lines 1–6); then it prepares a local copy of the message (line 8); and finally it writes the message to SDM (line 9).

When preparing the message (line 8), the client thread

Algorithm 2: Server Dispatch Loop

```
   Input: Timer
   Input: ChannelID
1  while State ≠ EXIT do
2      do
3          if State = EXIT then return
4          if State = IDLE then block until notified
5          InvalidateCacheline(Ring[SHead])
6          OBit ← Ring[SHead].owner
7      while OBit ≠ S
8      Timer.Reset()
9      slot ← SHead
10     size, data ←Load(Ring[slot])
11     SHead ← (SHead + 1)  mod RingSize
12     Dispatch(ChannelID, slot, size, data)
```

updates the slot's *OBit* to indicate that a request has been issued and the server Duhu-RM should take ownership.

The `WriteToSDM` function (line 9) atomically writes the message to SDM. It does so by using non-temporal write instructions that invalidate and flush the cache line containing $Ring[slot]$ to SDM. It follows the non-temporal write with a store-fence to ensure that the write cannot be reordered with respect to other store operations.

Finally, the client increments the slot's *VBit* (thus flipping it) upon receiving an RPC response.

5.1.2 Dispatching an RPC Request

Algorithm 2 shows the server side logic for receiving and dispatching RPC requests: The server polls the slot pointed to by *SHead* to check if its *OBit* is set to *S*, i.e., if the slot is owned by the server (lines 2–7). Once it owns the slot, the server copies the data from SDM into local memory (line 10), and then calls the Duhu-RM dispatcher which dispatches the request to a thread. Recall that the Duhu-RM dispatcher ensures that requests to the same object are dispatched to the same thread. Once a thread has finished processing the request, it writes a response to the same slot and changes the slot's *OBit* to *C* to indicate that a response is available. We omit this response logic in the interest of space. We also omit the logic of how the client receives this response, except to note that it is similar to the RPC request dispatch logic discussed here.

For safety and efficiency, the server must consider a few factors when polling for the slot to change ownership:

First, frequent polling affects the performance of other nodes (and threads) accessing the SDM. We address this using a backoff mechanism: the server uses a timer (*Timer*) to track time since an RPC request was last received. When the timer expires, the server marks the channel as `IDLE`, which causes the poll loop to block (line 4). Clients send a network message when sending a request over an `IDLE` channel (not shown), and on receiving this message the Duhu-RM dispatcher notifies (and thus unblocks) the poll loop. The server resets the timer each time it receives a message (line 8).

Second, while polling the server must ensure it is reading the value from SDM rather than from the local cache. To do so, it uses the `InvalidateCacheline` function (line 5) to invalidate the cacheline before the read. This function uses a memory fence to ensure that load reordering does not result in the poll loop reading a stale value.

6 Failure Recovery

Duhu depends on an orchestrator[1] to detect failed memory blades and nodes, and implements a failure recovery algorithm to deal with both. Below, we describe the core invariants used by both protocols, and then describe the protocols themselves.

6.1 Invariants

Duhu's mechanism for recovering from memory blade failures builds on the assumption that DDFs include mechanisms, e.g., lineage-based mechanisms, to recover lost data.

The mechanism for recovering from node failures depends on the following three invariants:

1. The Duhu-RM records all RPC requests to a write-ahead log (WAL) before executing them. WAL entries are used to ensure metadata consistency by re-executing operations that were interrupted by node failure.
2. The `Alloc()` logic ensures that updates to the segment's metadata hashmap have been flushed to SDM (by using non-temporal writes and an `sfence`) before returning a reference to the newly allocated memory. This ensures that all allocations are tracked in SDM, and prevents in-use memory from being reallocated after recovering from node failures.
3. Duhu-Channels allow at most k requests to be outstanding at a time; as we explain below, this helps ensure idempotent re-execution of incomplete operations.

6.2 Memory Blade Failure

Memory blade failure results in object data and metadata being lost. Duhu relies on the lineage-based fault-tolerance mechanisms implemented by DDFs to reconstruct this lost data on available blades. This recovery mechanism uses the object store APIs we provide, and thus implicitly recovers the lost metadata. We rely on these existing DDF-specific mechanisms because they can be better optimized.

However, Duhu's pass-by-reference paradigm does add one complication when memory blades fail: a node might hold a reference that points to an address on the failed blade. We address this by requiring that the node's operating system generate a SIGBUS signal when the DDF accesses memory on a failed blade, and Duhu catches this signal and invokes the DDF routine responsible for handling unavailable objects.

6.3 Node Failures

The failure of a node affects Duhu in two ways: (a) The metadata for any segments that the node owns might be inconsistent because of partially completed operations; and (b) References held by the failed node and Duhu-Channels created by it will never be freed, leading to resource leaks. Duhu uses different recovery algorithms for each effect. The orchestrator triggers both when a node failure is detected.

[1] Duhu uses the DDFs scheduler as its orchestrator, only requiring that it be extended to detect SDM failures (in addition to node failures).

6.3.1 Metadata Consistency

A Duhu metadata operation requires at least two accesses to SDM: one to read (or update) the metadata, and a second to write the return value to the appropriate channel slot. Many require more than one update. Consequently, node n crashing can render the metadata for any segment s owned by n inconsistent. Furthermore, no node can perform metadata operations on s until the segment is assigned a new owner. Our metadata consistency logic addresses both these problems.

During normal operation, each Duhu-RM thread records operations to a per-segment write-ahead log (WAL). The WAL entry records the request, the channel on which it was received, the channel slot, and the slot's *VBit*.

When the orchestrator detects that node n has failed, it assigns each segment owned by n to a different node (e.g., segment s to node n') and broadcasts this change.

Upon taking ownership of segment s, n' iterates through the metadata hashmap to reconstruct what portions of the segment memory have already been allocated, and to which objects. This process allows node n' to reconstruct (a) the set of objects in segment s; and (b) information required to reconstruct local allocator state. The latter is required to ensure that subsequent allocations (including those required during the recovery process) do not overlap existing objects, preserving data consistency.

Next, n' inspects the segment's WAL entries in descending timestamp order to find the last k entries for each Duhu-Channel, and re-executes them. Dropping all other entries is safe because a Duhu-Channel can only hold k outstanding requests, and thus older entries have already been processed. However, note that a previous owner (e.g., n) might already have processed and responded to some of the last k entries. Therefore, for correctness, Duhu needs to ensure that (a) responses generated during replay do not lead to bugs; and (b) replayed operations are idempotent.

Our use of in-band responses can be a problem when replaying and responding to operations: a previous owner might already have responded to a re-executed request before crashing, and the client (who issued the request) might already have reused the slot to issue a different request. We address this problem by restricting the number of requests re-executed from each ring and using the per-slot version bit. Before replaying a WAL entry, n' first reloads the Duhu-Channel slot for the request and compares the slot's version bit to that recorded in the WAL entry. If the channel slot and WAL entry have the same version, then the client has not reused the slot, and is still awaiting a response. The recovery logic re-executes the entry in this case, and discards it otherwise. Checking that version bits match suffices because we replay at most k WAL entries, and the version bit can change at most once in k entries.

A previous owner might have failed while processing a request, and thus ensuring idempotence during replay is necessary despite the Duhu-Channel slot version check described above. Ensuring idempotence during replay is simple for `GetRef()` and `DropRef()` calls, since they manipulate a bitmap using bitwise operations and are thus inherently idempotent. Similarly, for `CreateId()`, Duhu records the generated key in the WAL, and replay merely returns the recorded key, thus ensuring idempotence. Idempotence for `Alloc()` calls is slightly more involved: the replay logic first checks if the object ID is present in the segment's metadata hashmap. If so, the object has already been allocated, and the recovery logic uses the metadata entry to find the appropriate location. On the other hand, if the object ID is not present, it allocates space for the object.

Finally, the recovery procedure needs to ensure that any references held by n to objects on other nodes are released, thus avoiding resource leaks. To this end, on detecting that node n has failed, the orchestrator broadcasts a failure message to all other nodes. On receiving a failure message, node m finds and releases any references n holds to objects in segments owned by m by clearing the corresponding bit in each object's reference bitmap.

In sum, the use of a write-ahead log and idempotent operations ensures that replay can correctly restore metadata consistency.

6.3.2 Recovery Time

Finally, we analyze recovery time for node failures when using Duhu. As we show in §8, our current cluster has relatively high SDM access latency (600–800 ns) and 10GB/s bandwidth. In addition, the lack of coherence means that a newly assigned segment owner must invalidate the appropriate cache line before reading a slot or metadata. Lastly, for consistency, we need to use non-temporal writes and an `sfence` when writing to SDM. The net result is that recovery time is dominated by SDM access time rather than by computation, and we use SDM accesses as a way to estimate recovery time.

Metadata dictionary scan. The new owner of a segment needs to iterate over the segment's metadata hashmap to reconstruct local allocator state. The metadata hashmap can be quite large, and the recovery logic cannot make progress until this is completed. This stage tends to be a significant contributor to recovery time.

WAL scan. Next, the recovery logic needs to read the last k WAL entries for each channel. The layout of the write-ahead log means that newer entries are towards the beginning of the WAL and can be scanned sequentially. In the common case, where all Duhu-Channels are used at the same rate, only $O(p \times k)$ entries need to be read (where p is the number of channels) to find the last k WAL entries for each channel.

Replay of WAL entries. During replay, each operation requires at least one SDM access to check the version bit in the corresponding Duhu-Channel slot. Additional accesses are necessary during re-execution, e.g., to update metadata and write responses. These writes need to be synchronized with `sfence`s. Therefore, in most cases, this step is a significant contributor to recovery time.

Releasing references held by the failed node. This step has nearly no impact on recovery time because it runs concurrently with the rest of the recovery protocol and requires fewer SDM accesses than the other steps.

Thus, recovery time in Duhu is dominated by the metadata dictionary scan and operation replay. Changing the layout of the metadata dictionary might help improve both, though this might affect performance in the non-failure case.

7 Implementation and Integration

We implemented Duhu in C++ and integrated it with Ray, a popular open-source DDF. Integrating Duhu with Ray only required changes to Ray's object manager logic: we modified Ray's `PushLocalObject` method (which is used to transmit data from the local store to the remote one) to lazily allocate and move objects to the Duhu SDM. Similarly, we modified Ray's `GetRef` method so that it no longer allocated a local copy of the object, and instead (when appropriate) called Duhu's `GetRef` method to get a pointer to the object in SDM. Finally, we modified the `FreeObject` method to call `DropRef` when necessary. All of these changes were contained in a single module, demonstrating that our API simplifies integration.

During integration, we observed that many Ray objects are only accessed by the node that creates them. Copying objects that are only accessed locally to SDM adds significant overheads. Therefore, our implementation lazily copies objects: we delay calling `Alloc` on a sealed object until either (a) a remote node tries accessing the object, which causes Ray's object manager to try to send a copy over the network; or (b) the node that created the object encounters memory pressure.

Our implementation uses a standard free-list-based allocator to manage memory within each segment.

8 Evaluation

We evaluated Duhu by comparing the performance of a Duhu-integrated Ray (denoted as DR in the graphs) to a baseline Ray without Duhu (denoted as Ray in the graphs). Our evaluation answers the following questions:

1. Does Duhu enable new compute paradigms? Do they improve application performance? (§8.2.1)
2. Do our gains translate to future SDM implementations that have higher bandwidth and lower access latency? (§8.2.1)
3. Can Duhu improve the performance of Ray jobs? (§8.2.2)

Our results show the benefits of the pass-by-reference strategy enabled by Duhu, which reduces both memory usage and redundant data movement, albeit with additional overheads when accessing SDM.

In addition, we present results from microbenchmarks (§8.3) that quantify the benefit of Duhu-Channel, Duhu's impact on intermediate-data transfer time, and its benefits for applications whose tasks only randomly access a portion of the intermediate data they are provided.

8.1 Evaluation setup

Our evaluation was run on an SDM cluster that consists of four servers connected to an external disaggregated memory pool over CXL. Each server has four Intel Xeon Gold 6530 processors, 512 GB of memory, and runs Linux (kernel version 6.6.0). Each server is equipped with a ConnectX NIC, and all servers can communicate with each other over a 100Gbps network. We disabled hyperthreading and power saving features on the servers.

The disaggregated memory is an early FPGA-based research prototype with 128GB of RAM, with memory bandwidth of ≈10GB/s and access latency of 600–800 ns. The memory was partitioned into 16 segments, and in each segment we reserved 65536 WAL slots. The WAL slots and metadata region for each segment consumed 8MB of space, and in total ≈128MB of space was used by the WAL and metadata.

Our experiments use containers to partition server resources: each container is provided 12 cores and 30GB of memory. In each container, 8 cores are used for computation, and the remaining are used for communication (and other auxiliary functions). Local memory was not a bottleneck in any of our experiments.

To avoid cross-container interference, each container is placed on a different NUMA node and is allocated node local memory. Containers on the same server communicate over the Linux bridge, and we use `tc` to limit inter-container bandwidth within the server to 5Gbps (except in §8.3). This ensures that the aggregate bandwidth over the network is the same as SDM bandwidth (i.e., 10GB/s or 80Gbps), enabling fair comparison. Finally, for inter-server communication, containers are bound to the physical NIC using `macvlan`.

Even when using Duhu, Ray requires a local object store (whose size is specified using the `object-store-memory` flag). We specify the local object-store size used for this when describing individual experiments.

8.2 End-to-end Applications

We use two workloads based on existing DDFs to answer the three evaluation questions: shuffle-based workloads, for which we implement a new approach and compare to Exoshuffle [34]; and database workloads, for which we use Modin [44], a distributed dataframe library to run TPC-H [54].

8.2.1 Duhu's Impact on Shuffle

Duhu can improve the performance of distributed shuffle jobs by enabling new approaches. Below, we describe and compare Exoshuffle, an existing approach for distributed shuffle; and FlexShuffle, an approach enabled by Duhu.

Exoshuffle [34]. Exoshuffle is a state-of-the-art efficient distributed shuffle architecture built atop Ray. Like other pass-by-value shuffle architectures, Exoshuffle requires map tasks (data producers) to partition intermediate data using a user-defined partitioning scheme. These partitions are written to each mapper's local object store. Reduce tasks are assigned partitions that they copy from the mappers' object store and then combine to produce their output.

FlexShuffle. FlexShuffle is an architecture that we developed to target pass-by-reference implementations, e.g., Duhu. The

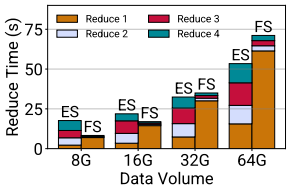

Figure 7: *Breakdown for each stage of the jobs shown in Figure 6.*

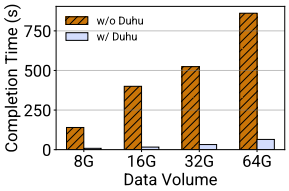

Figure 8: *JCT for a job with one shuffle stage when using FlexShuffle with and without Duhu.*

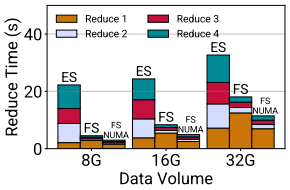

Figure 9: *JCT for a four-stage shuffle job on Exoshuffle, FlexShuffle, and FlexShuffle on NUMA.*

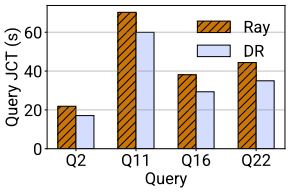

Figure 10: *Query execution time for the four most improved TPC-H queries.*

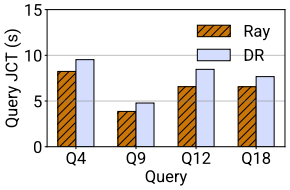

Figure 11: *Query execution time for the four slowest TPC-H queries when executed using Duhu-Ray.*

core difference is that in FlexShuffle, map tasks do not partition their output. Instead, map tasks write the unpartitioned output to Duhu, and produce a *slice* for each partition.

A partition's slice contains the set of offsets (and length) within the intermediate data that belong to the partition.

Reduce tasks use the slices and references to the mappers' output to access inputs and compute their output.

Thus, FlexShuffle replaces data movement with metadata reorganization. This change is particularly beneficial for jobs with multiple shuffle stages: after the first shuffle stage, only the set of slices changes, and thus no additional data transfer is required for these stages. Multiple shuffle stages are common for many applications including implementations of optimization algorithms like stochastic gradient descent [20, 41, 55].

FlexShuffle improves multi-stage shuffle performance. We evaluated FlexShuffle and Exoshuffle using 32 map tasks and 32 reduce tasks (2 per instance). We tested four scenarios where we varied the amount of shuffle data and the size of the local store: (1) 8GB data and 0.75GB object store; (2) 16GB data and 1.5GB object store; (3) 32GB data and 3GB object store; and (4) 64GB data and 6GB object store. In all scenarios, the intermediate data is split uniformly across 32 partitions, one for each reduce task.

Figure 6 shows job completion time (JCT) for a job with four shuffle stages in each scenario. Observe that FlexShuffle can improve JCT by up to 3.39×. However, we also observe a slight slowdown with large reduce size: FlexShuffle takes 1.01× longer than Exoshuffle. Figure 7 explains this performance difference: the first reduce stage takes longer under FlexShuffle than under Exoshuffle, because all intermediate data needs to be copied over to the SDM. In subsequent reduce stages, FlexShuffle outperforms Exoshuffle (by 3.59–13.81×) because no additional data movement is required. In the 64GB scenario, the initial data copy onto SDM dominates, leading to the slight slowdown.

FlexShuffle is impractical without SDM and Duhu. Next, we consider an implementation of FlexShuffle without SDM: in this case all workers keep a copy of the intermediate data in their local object store, and thus reduce inputs require only slices. The significant increase in local memory requirements is a problem in this case, since the data must be spilled into SSDs and reloaded from there. Figure 8 shows that without Duhu (and SDM), the JCT for a job with a single shuffle stage is 13.34–24.69× higher.

FlexShuffle's benefits increase with newer hardware. Finally, we considered how these improvements would translate to a better SDM implementation. As we noted above, our results are from using an FPGA-based SDM prototype, which likely has lower bandwidth and higher access latencies. Actual ASIC-based implementations are likely to perform better, and we use an approach inspired by Pond [28] to evaluate FlexShuffle's performance on these future implementations.

For this experiment, we emulated a faster SDM using NUMA nodes on a single server. The server had the same specifications as what we used for the experiments so far, and we used NUMA nodes 0 and 1 as servers, and reserved 100GB of memory attached to NUMA node 2 for use as SDM. Because we used a smaller number of servers, we only used up to 32GB of reduce data.

In Figure 9, we compare the performance of FlexShuffle on this NUMA setup (FS NUMA) to (a) FlexShuffle on a 2-node SDM cluster (FS); and (b) Exoshuffle on a 2-node cluster. As expected, the NUMA setup improves performance, and the biggest gains are in the first reduce stage where data movement costs dominate. In this setup, FlexShuffle with NUMA improves over FlexShuffle running on CXL by 1.10×. Furthermore, FlexShuffle on NUMA always outperforms Exoshuffle (it is 2.43–5.79× faster), leading us to conclude that FlexShuffle's benefits will increase as better SDM implementations become available.

8.2.2 TPC-H Benchmark on Modin

Next, we evaluate Duhu's impact on existing jobs, by measuring its impact on TPC-H [54] performance when the benchmark is executed using Modin [44].

For this evaluation, we used a scale factor of 10, which produced a 3.4GB compressed Parquet file as input. We set the per-node object-store size for each node to 5GB. As expected, this led to memory pressure in the Ray object store for some join queries. We found that running four containers on each server led to significant slowdowns for both unmodified Ray

and Duhu because of redundant data transfers to each server. Therefore, we ran only one container per physical server. Furthermore, we found that unmodified Ray workers frequently crashed due to memory exhaustion when running query 5, so we omitted it in our evaluation.

On average, across queries, Duhu-Ray had 1.08× better query time than vanilla Ray. However, the degree of improvement depended on the queries' intermediate data size and access patterns. Duhu seems to be particularly helpful for 'big' queries where each worker accesses a significant amount of data which is unlikely to fit in the worker's local object store. In this case, Duhu-Ray's ability to store objects in SDM is a significant benefit: Figure 10 shows query processing time for the four queries where we observed the most benefits, and we observe that at best Duhu-Ray can improve query completion time by 1.26× on average and by 1.30× at most.

However, for small queries that often run in less than 10 seconds and access a small amount of data, the use of Duhu can worsen performance. This is because each worker accesses only a limited amount of data in this case, and the objects being accessed can fit in the local object store for vanilla Ray. On the other hand, Duhu-Ray places objects in SDM by default, and the additional access latency leads to a slowdown. Figure 11 shows query execution times for the four slowest queries where Duhu-Ray is 1.2× slower.

Our results show that Duhu is most helpful when a query's intermediate data size exceeds a node's object store capacity. For smaller queries, SDM's increased access latency reduces Duhu's benefits, suggesting that a hybrid policy that keeps small or frequently reused objects on a server could improve Duhu-Ray's performance.

8.3 Microbenchmarks

Finally, we use microbenchmarks to evaluate Duhu's RPC and object transfer performance, the impact of accessing a portion of an object, and the impact of workload characteristics. All microbenchmarks use a producer-consumer pattern, and to ensure fair comparison, we increase network bandwidth for producers so that the aggregate bandwidth across producers is 80Gbps, matching write-bandwidth to SDM.

8.3.1 RPC Performance

First, we evaluate the benefits of using Duhu-Channel as compared to using network-based RPCs. We consider both RPCs implemented over TCP (using the kernel network stack), and implemented using the RDMA WriteImm operator. To fairly evaluate across these settings, our RDMA implementation has one outstanding request at a time.

In Figure 12, we report latency as we change the request rate. Our results show that Duhu-Channels have lower latency and higher throughput than either TCP or RDMA: they can achieve a latency of 3.8μs while supporting 3 million RPS. By comparison, RDMA achieves a latency of 11.74μs at 1 million RPS.

8.3.2 Object Transfer Performance

Next, we evaluate the benefits of transferring objects over SDM (as enabled by Duhu) rather than over the network. We do so using a fan-out benchmark, where we run a varying number of *fan-out task groups*.

A fan-out task group consists of a producer task that creates a 200MB array of floats, and four consumer tasks. Each consumer task is run on its own server, and computes the sum of all elements in the array. Observe that this setup means that three out of the four consumer tasks are remote, i.e., they are on a different server than the producer. In both Ray and Duhu-Ray, remote consumers need to wait for data transfer before they can begin computation, i.e., they are blocked. In Ray, tasks are blocked so that the remote worker can access a local copy of the data, while in Duhu-Ray tasks are blocked due to our lazy-copy optimization (§7).

In Figure 13 we report average blocking time when running 16, 32, and 64 fan-out task groups. Increasing the number of task groups increases the amount of data produced from 3.2GB to 12.8GB. We observe that Duhu-Ray's average blocking times are 2.80–4.29× smaller than Ray's. This is because Ray needs to transfer 3× more data, since the array must be copied into each server's local memory.

Furthermore, we analyzed where Duhu-Ray's blocking time went, by measuring time spent by the producer copying data into SDM, time spent by a consumer getting a reference, and the remainder. We found that allocating and putting data into SDM (done by the producer) comprises 18.83% of the

blocking time, and getting a remote reference and getting access at the consumer takes 10.96%. This is expected because the producer portion requires more data movement.

8.3.3 Accessing Partial Intermediate Data

Tasks that access a small portion of a large amount of data can benefit significantly from Duhu's pass-by-reference semantics. We evaluated this benefit using a benchmark where 128 tasks (8 on each of the 16 containers) read portions of a 6.4GB array of floats and computed the sum of the portions they read. We report on three scenarios while varying the portion of the array read by each task: (a) whole array; (b) $\frac{1}{1000}^{th}$ of the array; and (c) $\frac{1}{10000}^{th}$ of the array. For the latter two scenarios, each task chose elements at random.

Figure 14 shows JCT for all three scenarios: as expected, Duhu-Ray's benefits increase as a smaller portion of the array is accessed. JCT when reading $\frac{1}{10000}^{th}$ of the array is 4.45× smaller than when reading the entire array. By contrast, Ray's performance does not change significantly because data transfer costs dominate computation time.

However, the high access latency and low bandwidth of SDM (compared to local memory) might be a concern for computation. In Figure 15 we report compute time (averaged across the 128 tasks) for the experiment above. We observe that Ray always spends less time computing: for the $\frac{1}{1000}^{th}$ and $\frac{1}{10000}^{th}$ scenarios, Ray takes approximately 0.29× the compute time of Duhu-Ray. The compute difference is higher when summing over the entire array, because tasks then perform sequential access and can benefit from prefetching and caching. Nevertheless, our results show that the reduced data transfer time leads to lower overall JCT.

8.3.4 Impact of Workload Characteristics

The previous evaluations report on how data size affects Duhu-Ray's performance. We also measured the impact of three other workload characteristics: object lifetimes; number of tasks concurrently accessing an object; and access pattern.

We relied on the same benchmark for all three: we started 4 producer tasks (one on each server), and 128 consumer tasks (evenly distributed across the whole cluster). Producers and consumers ran for four iterations. Every few iterations (specified as a parameter), each producer created 8 float arrays, each 200MB in size. In each batch, a consumer was assigned an array and summed a randomly selected 1% of its elements.

Object lifetimes. As object lifetimes increase, objects are more likely to be re-accessed by some task on a server, and thus less likely to incur data movement for both Ray and Duhu-Ray. We measured this effect by varying the number of iterations after which a producer creates new arrays, e.g., if lifetime is 2, producers create 8 new arrays every other iteration (i.e., new objects will be created in iterations 1 and 3).

Figure 16 shows JCT as we vary lifetime from 1 to 4. As expected, both Ray and Duhu-Ray have better performance as the lifetime increases because data transfer costs are amortized. The benefit is more pronounced for Ray because later batches access objects from local memory, encountering significantly lower latency. By contrast, for Duhu-Ray, SDM access latency and bandwidth limit gains for later batches.

For the rest of the workload evaluation we set object lifetime to 4, i.e., arrays are allocated once for each experiment.

Concurrent access. The number of objects being accessed also has an effect on data transfer, and thus performance: data transfer can be amortized if all tasks access the same object. We evaluate this by comparing the performance in two scenarios: (a) scatter, where each consumer accesses a different array; and (b) hotspot, where all consumers access the same array. Figure 17 (left) shows the result. As expected, hotspot has better performance than scatter for both Ray and Duhu-Ray. Furthermore, we also observed that for the hotspot scenario, Ray and Duhu-Ray have similar performance. This is because each array is small, thus requiring minimal time for data transfer.

Task access pattern. Finally, task access patterns can affect the amount of data movement, and thus performance. We evaluated this by implementing two scenarios: (a) same, where each consumer accesses the same array for all four iterations; and (b) random, where each consumer accesses a different array in each iteration. Figure 17 (right) reports job-completion time for this experiment, and as one would expect, same has lower job-completion time for both Ray and Duhu-Ray.

9 Related Work

The idea of a hardware-based disaggregated memory predates CXL and was first proposed in [31]. However, that work does not consider using the shared memory as a means of communication (data sharing) among clients.

Recently, CXL has attracted the attention of the research community and several papers have appeared to address different aspects of this technology, including *memory pooling*, *memory tiering*, and *performance*. With memory pooling [16, 28], external CXL memory is dynamically assigned to hosts to improve memory utilization. A given chunk of memory is assigned to at most one host, so hosts do not use CXL memory to share data. With memory tiering [27, 35, 51, 58, 62, 64], the CXL memory is viewed as a slower tier of memory compared to local memory, and the system tries to place frequently accessed hot data in the faster tier, while moving colder data to the slower (CXL) tier. Other work provides a performance characterization of CXL memory and its implications for applications [17, 28, 32, 52, 53]. None of these works considers CXL memory as a medium to share data across hosts.

There is significant prior work on building distributed object stores and key-value stores on disaggregated memory accessible via RDMA (e.g., [12,13,25,30,33,37,49]). Similar to our setting, one or more memory servers store the key-value data. But unlike our setting, clients use RDMA operations to access the data in the memory server(s). RDMA is a different

mechanism to access remote data compared to memory operations in SDM: RDMA requires submitting IO operations, so there are no problems of hardware coherence of client caches; RDMA has lower performance on small transfers (say 64 bytes) due to the overhead of issuing IOs; and RDMA servers typically have some computation power, which many systems use to run client operations (e.g., RPCs). By contrast, we are focused on SDM, which is accessible by processors via loads and stores without cache coherence across nodes, and without the ability to run code at the memory. Therefore, our techniques differ from prior work.

Work on far memory systems (e.g., [4, 14, 19, 46, 59, 63]) aims to augment local memory with additional external memory. Early work assumes the external memory is accessible over the network, while more recent work considers CXL.

We are not the first to consider sharing data in CXL without full coherence [8, 22, 24]. Prior work differs from ours in two ways. First, they make a different hardware assumption: the CXL memory has a coherent and a non-coherent region, and applications can use both. Second, they target a different problem. Pasha [22] aims to build a database system using CXL shared memory, while [24] proposes general high-level ideas and directions of how to use this hybrid coherence model, without targeting specific applications.

Systems without cache coherence have been explored in both research [9, 26] and industry [6, 36]. The general consensus is that it is hard to program with such systems.

Using pass-by-reference instead of pass-by-value for efficiency is an idea that goes back to early work in programming languages. Recent distributed systems such as Ray [38, 56], Ciel [39], and Distributed PyTorch [45] use pass-by-reference in remote procedure calls (RPCs), whereby data gets stored in an object store, and applications use the key rather than the value as the parameters (or results) of the RPC; the RPC handler (or caller) later fetches the parameters (or results) from the object store. These systems differ from ours because their references are keys in an object store rather than addresses in SDM, and ultimately nodes still create copies of the object by fetching it from the object store, which is pass-by-value. As a result, these systems do not address the problem of memory and network transfer overheads in DDFs that we address (they solve a different problem), and they are not faced with the SDM cache-coherence issues that we tackle.

Lightning [65] is an in-memory object store that allows multiple threads to directly address objects in local memory without requiring inter-process communication or a mediating daemon. Thus, Lightning implements pass-by-reference semantics within a single node, but cannot be extended to the distributed setting we target because it requires cache coherence and does not consider cross-node synchronization.

There is a long line of work on distributed shared memory (e.g., [3, 5, 7, 29, 40, 47, 48]), which seek to implement a shared memory abstraction on top of a message-passing system, including both software and hardware-based implementations. Our goal is not to build shared memory but rather to use it.

10 Discussion

Support for copies. Duhu reduces unwanted copies of the data in DDFs by keeping objects in SDM. However, in some cases it is desirable to have copies to avoid bottlenecks. For example, a small immutable object may need to be accessed frequently by all nodes. We observe that Duhu can be used to provide copies—and can do so in a controlled manner. The DDF can put many objects with the same content in Duhu, and these objects can be given to different nodes. The DDF scheduler can decide how many objects (replicas) to create, including having a replica per node if desired.

Creating objects in SDM. Currently in Duhu, an object needs to be fully initialized in local memory before putting it in SDM. It could be useful to create the object directly in SDM to support large objects that do not fit in the remaining local memory, and to avoid the cost of copying the object from local memory to SDM. We can extend Duhu to support this functionality by adding a function that allocates space in a segment's data region and returns a pointer to SDM. Then, the DDF uses this pointer to populate the object. Finally, the DDF can use `Put`, augmented with a flag to indicate the object is already in SDM, to make it accessible by other nodes.

Loading objects from disk to Duhu. A DDF job often takes as input data from disk; currently, Duhu incurs some overhead in loading from disk, because objects must first be loaded into local memory before putting them into Duhu. Instead, it would be useful to extend Duhu with a function that loads data from disk by directly performing IO on buffers in SDM.

11 Conclusion

Duhu is an immutable object store designed for use with current and future shared disaggregated memory systems. It stores data in SDMs, which may not offer full cache coherence guarantees. Duhu is targeted at distributed data processing frameworks, which often copy data from the node that produces it to the nodes that wish to consume it; these copies incur significant memory and network transfer overheads. With Duhu, such frameworks avoid these copies by placing data in a common shared space. We integrate Duhu with Ray and evaluate the resulting system, Duhu-Ray, on a prototype CXL disaggregated memory system. We find that Duhu-Ray can outperform Ray by up to 3.39× on a shuffle workload.

FlexShuffle	`duhu`	`duhu-eval/flexshuffle`
Modin	`duhu`	`duhu-eval/modin`
Microbenchmarks	`duhu`	`duhu-eval/microbenchmark`

Table 3: *The contents of our artifact.*

A Artifact Appendix

Abstract

This paper's artifact includes the code for Duhu, and a version of Ray that is integrated with it. It builds on Ray branch `releases/2.40.0`, and most of the modifications are in the `object_manager`. These changes include logic to allocate, get (and drop) references, and delete objects in a Duhu-managed SDM.

The repository also includes the workloads we used in our evaluation.

Scope

When run in the same setup as described in the paper, the artifact reproduces the workload-performance results reported in §8.

Contents

The artifact is within a single repository, with (1) a branch forked from the original Ray repository, (2) a modified Ray with Duhu integrated, and (3) a set of workloads we run to evaluate the performance of Ray and Duhu-Ray, including FlexShuffle, TPC-H on Modin, and microbenchmarks. Table 3 lists the contents of the artifact in detail.

Hosting

The artifact is hosted in a GitHub repository (https://github.com/nyu-systems/duhu-ray), with all contents listed above.

Abstract

Cold memory rebalancing exhibits unique challenges to the existing memory overcommitment mechanisms, such as page tracking under Transparent Huge Pages (THP) and frequent remapping of page tables, leading to a series of throughput and latency issues. In this paper, we propose Blowfish, a memory overcommitment framework built on disaggregated memory, performing cold (and free) memory reclamation and restoration at µs-scale. Based on paravirtualization, Blowfish leverages a lightweight guest-level THP-aware hotness tracker to monitor page access and let the hypervisor directly reclaim and reallocate host physical memory across VMs with a dedicated cross-layer path for cold memory, bypassing the modifications of guest page table and modifications of I/O page table while benefiting from the rich program semantics of guest VM when recognizing the cold memory. As a result, Blowfish significantly speeds up the page reclamation and restoration, 2.48× and 2.14× faster than the state-of-the-art solution, HyperAlloc, respectively, and improves memory reclamation ratios by 1.6×–6.1× within 5% performance degradation.

1 Introduction

Memory overcommitment promises to improve memory utilization and has been widely adopted in multi-tenant data centers. However, the existing memory overcommitment research [9, 24, 27, 30, 39, 53, 56, 59] mainly focuses on free memory rebalancing, *i.e.*, reclaiming free memory and reallocating it across virtual machines (VMs), overlooking cold memory, which accounts for a large portion of VM memory usage [19, 40, 50, 58]. In the existing research, the conventional approach to reclaiming cold memory relies on either guest-level swapping, in which cold pages are first swapped out within the guest and then reclaimed as free pages, or host-level swapping, in which the guest's underlying host pages are swapped without the guest's awareness. Both techniques require moving infrequently accessed data to disk. Accessing reclaimed cold memory then requires restoring it, typically by triggering a page fault, allocating free memory, and swapping the data back. However, writing to and reading from disk are slow and costly (up to milliseconds for a 4 KB page), leading to Service-Level Objective (SLO) violations. As a result, prior work often overlooks opportunities to reclaim cold memory for memory overcommitment, even though doing so could provide substantial benefits.

Memory disaggregation enables µs-scale memory overcommitment. Thanks to the unprecedented development of emerging fabrics, *e.g.*, InfiniBand [1], RoCE NICs [43], and CXL [22, 37], the time of sending a page to another server is reduced to a few microseconds (µs) and more than 200× faster than swapping to disk [23, 49, 54, 61], bringing great opportunities to further improve the memory utilization through cold memory swapping. Given that more than 50% of data center memory remains idle [7, 21, 58] due to the bin-packing inefficiencies in VM placement, the emerging fabrics make it possible to use this idle memory of other servers as the secondary memory (referred to as *far memory*) and swap out the cold data of a VM to far memory to reclaim the memory space for overcommitment.

Software overhead starts dominating the inefficiency of VM memory overcommitment. Even with high-speed interconnects, existing memory overcommitment frameworks still suffer from substantial inefficiency, as presented in §3. There are two main reasons for this inefficiency: (1) With guest-level swapping, reclaiming and restoring cold memory involves three page tables: the guest page table (GPT), which maps guest virtual addresses to guest physical addresses, the extended page table (EPT), which maps guest physical addresses to host physical addresses, and the I/O page table (IOPT), which maps I/O virtual addresses to host physical addresses, causing software overhead to be 3.4×–6.8× higher than network data transfer. (2) With host-level swapping, reclaiming cold memory requires tracking page hotness on the host side, which involves frequently resetting the host's PTE

* Corresponding author: Chenxi Wang.

access bits and results in 5× more TLB flushes than tracking on the guest side.

Transparent Huge Pages (THPs) further complicate memory overcommitment. Making things more challenging, virtualized environments commonly rely on THPs to reduce page-table translation overhead. However, cold memory is often non-contiguously distributed, creating complex trade-offs in page granularity. Keeping huge pages preserves translation efficiency but inflates apparent hotness, since a single hot subpage can mark the entire huge page as hot. Splitting huge pages allows more accurate hotness tracking but sacrifices the benefits of huge pages and incurs overheads of fine-grained page-table operations. Moreover, memory overcommitment mechanisms often need to manage pages of mixed granularity when THP is enabled, because fine-grained memory operations (such as allocation, deallocation, permission changes, and swapping) frequently break huge pages. Existing mechanisms treat all pages uniformly, leading to unfair hotness comparisons between 2 MB huge pages and 4 KB base pages, since a huge page aggregates the hotness of all its constituent base pages.

Major insights. **First, cold memory overcommitment suffers from a misplaced division of responsibilities across layers.** We propose that an ideal decomposition should place hotness tracking in the guest, where access semantics are naturally visible and can be monitored at low cost, while leaving data transfer and physical memory management to the host, which actually controls memory resources. This organization minimizes software overhead of page tracking and repeated page-table modifications. **Second, THP fundamentally changes the design space by introducing mixed-granularity memory.** We identify that an effective mechanism should be explicitly aware of mixed granularity: it should detect cold subpages within hot huge pages, fairly compare pages across sizes, and exploit THP benefits when possible. This requirement calls for rethinking hotness tracking and huge page management to efficiently operate across granularities.

Blowfish. Based on the preceding insights, we propose Blowfish, an elastic VM memory adjustment framework built for the memory-disaggregated server. Blowfish's design targets two main challenges:

First, *how to reduce the software overhead to avoid SLO violations during cold memory overcommitment?* Blowfish adopts a *paravirtualized, cross-layer* design that splits responsibilities between the guest and the host. The guest VM runs a lightweight hotness tracker that integrates with existing kernel mechanisms (*e.g.*, MGLRU stack) to accurately identify cold pages without introducing additional page-table or TLB overheads. The host hypervisor runs a backend that transfers cold data and reclaims pages by modifying only the EPT mappings, avoiding the costly modification overhead of guest page table and IOPT normally incurred by guest-level I/O. In addition, the guest and host exchange only a small amount of metadata through a shared memory interface, an effective and widely used technique [10, 56, 59].

Second, *how can we efficiently support mixed-granularity memory under THPs during cold memory overcommitment?* Blowfish leverages a mixed-granularity hotness tracker in the guest to identify cold subpages within otherwise hot huge pages in a lightweight manner. This identification is done by dynamically splitting and merging guest page table mappings rather than actual physical pages, minimizing overhead. To ensure fair hotness comparison across page sizes, Blowfish adjusts the promotion policy of huge pages, giving them lower weight than base pages. Together, these mechanisms allow Blowfish to efficiently rebalance memory even in the presence of THP-induced fragmentation and uneven hotness distribution.

Our evaluation shows that Blowfish reduces software overhead by more than 50% compared to state-of-the-art work, such as HyperAlloc [59]. Moreover, it further improves memory reclamation ratios by 1.6×–6.1× within a 5% performance degradation. Blowfish is available at https://github.com/ICTPLSys/blowfish.

In summary, this paper makes the following contributions:

- We analyze cold memory overcommitment in virtualized environments, revealing inefficiencies in existing mechanisms and outlining the principles of an ideal system, *i.e.*, guest-level hotness tracking guiding host-level reclamation, and THP awareness.
- We design a lightweight, subpage-aware hotness tracker that enables fair comparison across mixed-granularity pages, benefiting any scenario that requires hotness tracking under THPs.
- We propose Blowfish, an efficient memory overcommitment framework optimized for THP and cold memory.
- We implement Blowfish in Linux and QEMU, and demonstrate its effectiveness with seven real-world workloads.

2 Background and Related Work

2.1 Disaggregated Memory System

Benefiting from emerging fabrics, the disaggregated memory systems [8, 16, 37, 49, 51, 54, 61, 63] can provide extremely low data movement latency and high throughput, such as moving a 4 KB page to another server in less than 5µs through the 100Gbps InfiniBand [49, 61], enabling the opportunity of rebalancing the cold memory across VMs. Among different approaches to realizing disaggregated memory, the kernel-paging-based approach [8, 17, 23, 49, 54, 61] attracts attention for its transparency to applications and easy-to-procure hardware platforms, *e.g.*, RoCE NIC [43] and InfiniBand [42].

The disaggregated memory system uses the far memory (offering bandwidths up to 800Gbps [44]), rather than slow disks (around 200MB/s), as the secondary memory via the swap system. Under memory pressure, the kernel swaps out cold data to the far memory to release the local memory. When the evicted data is accessed, the memory management unit (MMU) raises a page fault exception, which traps the control flow into the kernel to swap in the original data from far memory and reconstruct the corresponding page table entry. In this work, we use the state-of-the-art paging-based data path, *i.e.*, Hermit [49], to manage the data transmission at the microsecond scale.

2.2 VM Memory Overcommitment

This section discusses how to integrate the paging-based disaggregated memory with the existing memory overcommitment framework to support cold memory overcommitment.

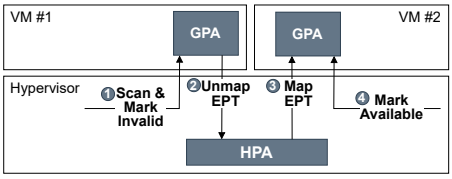

Figure 1: Reallocating free memory from VM1 to VM2.

Free memory rebalancing. A series of memory overcommitment techniques supporting free memory rebalancing across VMs have been proposed, such as Balloon [53], free page reporting [57], virtio-mem [24], V-Probe [56], HyperAlloc [59] *etc.*, some of which are even adopted by the industry virtualization platforms [5,12,31]. As shown in Figure 1, **reclaiming a free guest page** (❶–❷) needs only to unmap the extended page table (EPT), while **reallocating a host page** (❸–❹) to another VM also involves only one page table, *i.e.*, EPT. Taking HyperAlloc as an example, ❶ the hypervisor first checks the physical memory allocator of the VM to select a free guest page and marks it as invalid to prevent the guest VM allocator using it. ❷ Then the hypervisor unmaps the corresponding guest-physical-to-host-physical mapping. At this point, the reclaimed host page can be reallocated to another VM by ❸ mapping EPT and ❹ marking the originally invalidated guest page as available.

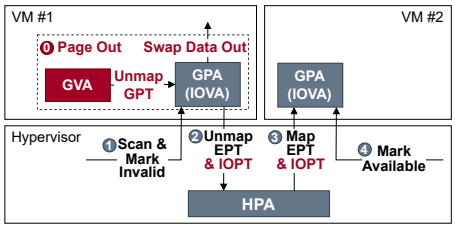

Figure 2: Reallocating cold memory from VM1 to VM2.

Cold memory rebalancing. The free memory overcommitment framework can be extended to rebalance cold memory by cooperating with the kernel paging (swapping)—swapping infrequently used data to the second-tier memory through emerging IO fabrics to release the cold memory, and then, the released memory pages can be reallocated to other VMs as conventional free pages. The paging can be done in either the guest VM or the hypervisor. These two options are referred to as *guest-level swapping* and *host-level swapping*, respectively.

Figure 2 demonstrates the procedure of reclaiming a cold page through the guest-level swapping (❶–❷) and reallocating it to another VM. Reclaiming a cold page first ❶ needs to select a cold page and swap out the infrequently used data on it to release the cold page by unmapping the GPT. And then, similar to reclaiming a free guest page (❶–❷), the hypervisor needs to unmap the corresponding EPT to reclaim the corresponding free host page. Note that the hypervisor also needs to unmap the IOPT (❷) due to the utilization of the emerging fabrics for data transmission. The IOPT translates the I/O virtual addresses (typically guest physical addresses in the VM) to the actual host physical addresses, ensuring correct DMA operations for passthrough devices. To maintain DMA correctness, memory overcommitment must synchronize updates to the IOPT whenever the underlying physical pages are reclaimed or remapped. The cold-page reclamation procedure involves three page tables, the guest page table (GPT), the extended page table (EPT) and the I/O page table (IOPT), consuming non-trivial CPU resources. Restoring a cold page performs the reverse steps of reclaiming a cold page.

The host-level swapping, which is usually referred to as *uncooperative swapping* meaning that hypervisor swaps out data and reclaims host pages without cooperating with the guest VM, is usually less efficient due to a lack of VM visibility (detailed in §3.2.3). In particular, double-paging issues [53] can arise when both host-level and guest-level swapping are enabled independently. In this case, the guest may attempt to swap out a page that has already been swapped out by the host. This double-paging behavior can cause the page to be faulted back into memory, only to be re-evicted shortly thereafter, leading to redundant data movement.

Pressure Stall Information (PSI) . To assess the performance risks of memory overcommitment, we leverage Pressure Stall Information (PSI) [58], which quantifies the fraction of time that tasks are stalled due to resource shortages. To adopt PSI as a common control and evaluation lens for VM memory overcommitment with memory reclaim allows us to compare systems under a consistent "bounded pressure" objective.

3 Motivation

In this section, we first demonstrate that the datacenter applications contain a large amount of cold memory (§3.1). Then

we discuss why existing overcommitment mechanisms fail to effectively reclaim cold memory (§3.2).

3.1 Cold-Memory Reclamation Opportunity

Prior studies [38,40,50,58] show that datacenter applications keep a large amount of cold memory (*e.g.*, 19–62% in Meta's clusters). This finding suggests considerable reclamation opportunity: a large fraction of cold pages can be reclaimed with negligible performance impact and repurposed to satisfy memory demands from busy tenants or newly spawned tasks.

To better quantify the upper bound of this opportunity, we evaluate seven representative datacenter applications (see Table 2) without THP. Disabling THP avoids hotness amplification and mixed-granularity artifacts, allowing us to measure the cold-memory reclamation space under ideal fine-grained page accounting. Guided by PSI [58], we dynamically swap out memory pages by triggering Linux swapping, using an RDMA-based far-memory backend [49]. By tuning the PSI threshold to bound performance degradation within 5%, we measure the corresponding amount of swapped-out memory to quantify the reclamation opportunity. In our experiments, we observe that 33–49% of application memory can be swapped out with less than 5% performance degradation.

However, turning this large cold-memory reserve into practical benefits in virtualized environments is non-trivial. Strict per-VM memory isolation limits the ability to reclaim cold memory, since adjusting VM allocations requires overcommitment mechanisms. Unfortunately, as we show next, existing mechanisms struggle to effectively exploit this cold-memory reclamation opportunity.

3.2 Inefficiencies in Existing Mechanisms

Existing overcommitment mechanisms are primarily optimized for free memory. Reclaiming cold memory instead requires cooperation with guest- or host-level swapping, both of which exhibit fundamental inefficiencies. To illustrate these inefficiencies, we evaluate a representative state-of-the-art mechanism, HyperAlloc [59].

3.2.1 THP Complicates Cold-Memory Reclamation

To reduce page-table-walk overhead, modern virtualized systems often enable THP, typically configured in the `always` mode. However, THP introduces additional complexity for cold-memory reclamation. We repeat the earlier opportunity study (§3.1) with THP enabled, keeping all other settings by default. In our experiments, the available cold-memory reclamation space drops to 16–25% of application memory.

Two factors drive this degradation. First, enabling THP results in a mixture of 2 MB and 4 KB pages for multiple reasons, such as Linux's allocation behavior, fine-grained deallocations, and subpage-level permission changes. These

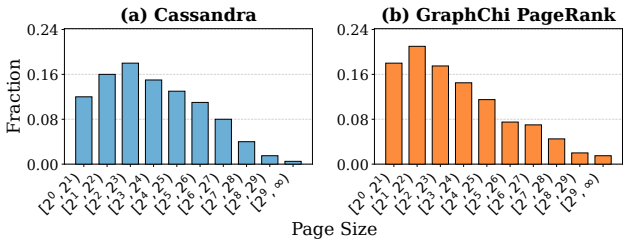

Figure 3: Cold memory fraction by region size at mid-phase. Cold memory is defined as untouched memory in 10s time window, monitored by DAMON [47,48].

mixed-granularity pages are managed uniformly (*e.g.*, `folio`), creating unfair hotness ordering. A 2 MB page aggregates 512 base pages and therefore has many more chances to be accessed, making it appear much hotter than scattered 4 KB pages. As a result, the swapping often evicts hot 4 KB pages while overlooking cold 2 MB pages, ultimately degrading application performance. We refer to this phenomenon as *unfair hotness*. Second, THP suffers from the well-known *hot bloat* problem: a few hot 4 KB subpages can cause the entire 2 MB huge page to appear hot, preventing the system from reclaiming the numerous cold subpages that it contains. Several prior efforts [35,36,41] attempt to mitigate this effect by selectively splitting hot-skewed huge pages. However, they struggle to balance the overheads of fine-grained monitoring and splitting against the potential reclamation benefits under memory overcommitment. Moreover, the 4 KB pages created by proactive splitting further exacerbate the unfair hotness problem.

Together, the effects of **unfair hotness** and **hot bloat** highlight the need for a THP-aware cold-memory reclamation design, rather than relying on an existing paging system that remains oblivious to the unfair and skewed hotness of huge pages.

3.2.2 Limitations of Guest-Level Swapping

We evaluate guest-level-swapping-augmented HyperAlloc on representative datacenter applications, tuning PSI threshold to bound performance degradation within 5%. We enable THP in both the guest and the host, following the recommended practice for virtualized environments [29]. In our experiments, HyperAlloc reclaims only 35–47% of the cold memory identified as reclaimable in prior profiling (§3.2.1). The shortfall stems from a fundamental granularity mismatch. HyperAlloc performs reclamation at a granularity of 2 MB huge pages to reduce the overhead of page-table operations. However, cold pages in real applications are highly scattered (as shown in Figure 3), and guest-level swapping faces a granularity dilemma. On one hand, swapping a 2 MB huge page as a whole preserves contiguity but exacerbates read/write amplification effects. On the other hand, swapping at 4 KB granularity produces fragmented free pages, making it hard for HyperAlloc to reclaim at 2 MB granularity, thus leaving most

Table 1: TLB flush comparison between host-level and guest-level swapping HyperAlloc under KMeans workload.

System	TLB Flush	KMeans Elapsed (s)
HyperAlloc-H	14819979	142.58
HyperAlloc-G	2946318	56.77

cold memory unreclaimable. We follow Linux's default behavior: THPs are swapped out as a whole, but swap-in happens at 4 KB granularity. The reason is that (1) the kernel usually cannot find a contiguous 2 MB free page for THP swap-in, and (2) swapping in a 2 MB page would severely stall application execution as swapping in lies at the critical path. Under this configuration, about 43% of overall reclaimable memory is at 4 KB granularity, directly limiting the effectiveness of 2 MB-based reclamation. Other designs that rely on 2 MB huge pages, such as virtio-mem [24] and hugepage-balloon [25], suffer from the same limitation.

A natural question is whether simply reducing the granularity can close this gap. To answer this question, we extend HyperAlloc to operate at the 4 KB base-page granularity while still opportunistically reclaiming 2 MB huge pages when available. We refer to this variant as HyperAlloc-4K. Under the same experimental setup, HyperAlloc-4K reclaims only 46–60% of the reclaimable cold memory. The root cause is the significant overhead of fine-grained page-table operation. Reclaiming and restoring a single 4 KB cold page of VM incur 36 µs and 21 µs, respectively, latencies that are 1.7× and 2.1× higher than those of guest-level swapping alone. The additional page-table overhead introduced by overcommitment slows both reclamation and restoration. The reduced reclamation throughput prevents HyperAlloc-4K from reclaiming cold pages at the rate that they are identified, while the high restoration latency lies directly on the application's memory-access critical path, tightening the allowable performance headroom. Together, these factors significantly limit the amount of cold memory that can actually be reclaimed. Similar drawbacks arise in other 4 KB-granularity mechanisms (*e.g.*, V-Probe [56] and Balloon [53]), which face the same tradeoff between granularity and page-table overhead.

In summary, guest-level-assisted mechanisms inevitably face a fundamental granularity tradeoff. Using 2 MB huge pages amortizes overhead of page-table operations, but the inherently non-contiguous distribution of cold memory limits the applicability of hugepage-level reclamation. Extending the design to support 4 KB granularity increases coverage, yet the high overhead of 4 KB page-table operations lowers throughput and tightens performance constraints. These limitations, **granularity mismatch** and **high-latency reclamation and restoration at 4 KB granularity**, highlight the need for a low-latency design that supports mixed granularity.

3.2.3 Limitations of Host-Level Swapping

We use HyperAlloc to reclaim free memory and delegate cold-memory reclamation to host-level swapping. However, when applied to VMs, host-level swapping suffers from well-known limitations. First, the host swapping cannot observe guest memory accesses. To overcome this limitation, we integrate Linux PTE scanning with the KVM MMU notifier, enabling the host to track guest accesses by scanning and clearing EPT access bits. Second, the host cannot distinguish free memory from cold memory, since the entire VM footprint appears as allocated memory. We bridge this semantic gap by exposing HyperAlloc's guest-allocator metadata to the host, allowing host-level swapping to bypass free guest pages. Under the same experimental setup (§3.1), this hybrid design reclaims only 34–55% of the reclaimable cold memory.

One primary bottleneck is the high overhead of tracking page hotness at the host level. As shown in Table 1, host-level swapping performs 5.0× more TLB flushes than guest-level swapping to reclaim the same amount of cold memory, including expensive full TLB flushes. These flushes directly degrade application performance, a finding also reported in prior work [26]. Moreover, host-level swapping is invisible to the guest. As a result, guest kernel services (such as khugepaged and kcompactd) may access reclaimed pages, triggering unnecessary page restorations. Our measurements show that 26% of all restorations under host-level swapping are caused by such system-service accesses. These unintended restorations affect the amount of reclaimed memory.

In summary, the preceding limitations—**heavy hotness tracking** and **guest-blind reclamation**—are inherent to host-level swapping and persist regardless of the overcommitment mechanism used for free memory. These limitations highlight the need for a guest-aware design with lightweight hotness monitoring.

4 Design and Implementation

4.1 Design Goals

To guide the design of Blowfish, we distill three fundamental observations. First, cold memory is inherently non-contiguous, making granularity tradeoff inevitable: huge pages inflate actual hotness, while 4 KB pages incur excessive overheads. Therefore, effective reclamation should operate and be optimized at mixed granularity. Second, accurate hotness information cannot be efficiently obtained at the host level due to limited visibility. Third, reclamation should be guest-aware to prevent misaligned or unintended interactions with guest kernel services. These observations point to three key design requirements.

- Lightweight mixed-granularity hotness tracking: monitor page temperature with minimal overhead, identify

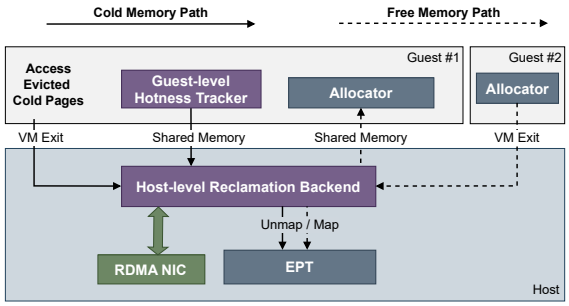

Figure 4: Design overview of Blowfish.

cold subpages within huge pages, and place mixed-granularity pages under a fair hotness comparison.

- Efficient mixed-granularity operations: enable low-latency fine-grained (4 KB) reclamation/restoration while preserving contiguity when beneficial.
- Guest-aware reclamation: align host-level overcommitment with guest kernel services to prevent blind restorations.

4.2 Design Overview

Following the requirements, we introduce Blowfish, whose architecture is shown in Figure 4. At a high level, Blowfish leverages guest-level hotness tracking to instruct the host-level reclamation to enable efficient overcommitment.

At the guest level, Blowfish piggybacks on existing Linux MGLRU, and dynamically splits or collapses THPs to capture subpage coldness. It also adjusts MGLRU's promotion rules to ensure fair comparison between 4 KB and 2 MB pages (§4.3). At the host level, Blowfish performs reclamation and restoration without modifying GPT or IOPT, avoiding expensive page-table operations (§4.4). Blowfish further leverages guest-reported hotness to coordinate guest kernel services and prevent behaviors that conflict with host overcommitment (§4.5).

We describe each component of Blowfish in the following sections, and then present a practical automatic policy (§4.6) together with the mechanisms that ensure correct behavior under limited guest cooperation (§4.7).

4.3 Guest-Level Hotness Tracker

A key design choice in Blowfish is to build on Linux's existing MGLRU mechanism for hotness tracking. Unlike hardware-assisted schemes (*e.g.*, PEBS [26,35] or PML [18,52]), which introduce additional accuracy-overhead trade-offs, reusing MGLRU gives Blowfish an effective in-kernel hotness ordering without new monitoring costs. However, performing hotness tracking at the host level would require page-table scans that trigger expensive global TLB flushes (as shown in §3.2.3). To avoid heavy costs, Blowfish shifts hotness tracking into the guest and integrates it into the guest MGLRU.

To mitigate unfair hotness and hot bloat problems introduced by THP, Blowfish makes two lightweight extensions: a fair promotion rule of MGLRU that equalizes hotness treatment across 4 KB and 2 MB pages (§4.3.1), and a subpage tracker that refines THP-level hotness (§4.3.2).

4.3.1 Fair MGLRU

Traditional MGLRU promotes a page of any granularity to the youngest generation when its PTE or PMD is scanned as accessed, and gradually ages unaccessed pages until they reach the oldest generation for reclamation. However, this policy implicitly favors huge pages. A 2 MB page is far more likely than a 4 KB page to receive accesses, allowing 2 MB huge pages to stay young disproportionately longer and making them much harder to reclaim. This page-size-amplified hotness distortion is the root cause of unfair hotness.

Based on this observation, Blowfish introduces Fair MGLRU. The key idea is to discount the reward associated with an access to a 2 MB page: a 2 MB page should not receive the same reward as a 4 KB page, because the probability of observing an access on a 2 MB page is inherently 512× higher than on a 4 KB page. Fair MGLRU preserves the original promotion behavior for 4 KB pages, that is, each access immediately promotes a 4 KB page to the youngest generation. For 2 MB pages, in contrast, Fair MGLRU performs incremental promotion: upon each observed access, the page is promoted only to the next younger generation, rather than being promoted to the youngest one in a single step. This design exploits MGLRU's structure. Since reclamation drains only the oldest generation, a truly hot 2 MB huge page will still climb toward younger generations through repeated accesses, whereas a huge page that is only moderately warm will eventually drift into the oldest generation and become reclaimable.

We note that incremental promotion is meaningful only when multiple generations exist. With two generations, the original and Fair MGLRU behave identically. Linux, however, uses four generations by default, so Fair MGLRU is effective in practice, which is also confirmed by evaluation (§5).

4.3.2 Subpage Tracker

To address hot bloat, Blowfish introduces a subpage tracker that identifies cold 4 KB base pages inside a 2 MB huge page. Prior approaches face inherent limitations. HugeScope [36] obtains subpage-level access bits by splitting EPT entries and relying on transient inconsistencies in EPT state; this approach becomes impractical in overcommitment settings where EPT updates are frequent. PEBS-based sampling [35], on the other hand, incurs well-known accuracy-overhead trade-offs and can easily miss accesses. In contrast, Blowfish's

subpage tracker is designed to maintain both low overhead and high accuracy.

Blowfish's subpage tracker works by dynamically splitting and re-coalescing guest huge-page mappings to expose the PTE-level access bits of constituent 4 KB subpages. The core observation is that tracking accesses on subpages requires splitting only the page table mapping, instead of the underlying physical huge page, avoiding heavy `struct page` overhead (the main overhead as reported in previous work [36]).

Specifically, the subpage tracker operates in periodic epochs. Every 100 ms, it selects a small set of huge pages from the second-youngest MGLRU generation, where hotbloat pages naturally concentrate, and temporarily splits their mappings, *i.e.*, turning PMD-mapped THP to PTE-mapped THP. We cap each batch to at most 32 huge pages to bound overhead. After splitting, the tracker monitors subpage access bits in a 100 ms window. All the parameters are empirically determined to impose negligible overhead.

After the monitoring phase, the tracker classifies each huge page based on access skewness. If fewer than 20% of its subpages are accessed, the tracker considers the huge page hotbloat and reports its cold subpages to the host for reclamation. Regardless of whether a huge page exhibits access skewness, the subpage tracker re-coalesces huge-page mapping to avoid generating extra fine-grained page table entries. For huge pages with more than 80% of subpages accessed (*e.g.*, evenly hot), the tracker marks them as balanced and skips them in the next epoch to avoid unnecessary splitting.

4.4 Host-Level Reclamation Backend

While Blowfish performs hotness tracking inside the guest to minimize monitoring overhead, relying on guest-level swapping for overcommitment introduces substantial latency of modifying the guest page table and the IOPT (see §3.2.2). In contrast, Blowfish introduces a host-level reclamation backend that executes both reclamation and restoration entirely on the host side and optimizes the critical path of each operation. The backend consumes guest-reported hotness, reclaims cold pages through host-managed page remapping, and supports restoring pages without involving the guest page table or IOPT. This design is based on the following observations. (1) The isolation boundary for VM memory is enforced by the EPT, not the guest page table, meaning that the guest page table can remain unmodified during overcommitment while the host manages reclamation purely via EPT remapping. (2) Moving the RDMA-based data path from the guest into the host avoids the expensive IOPT updates that passthrough NICs would otherwise trigger during data movement.

We next detail the procedures of the reclamation and restoration. Unless otherwise noted, we describe reclamation and restoration without distinguishing page granularity. The operations for 2 MB and 4 KB pages are structurally identical: the former operates on PMD entries and the latter on PTE entries.

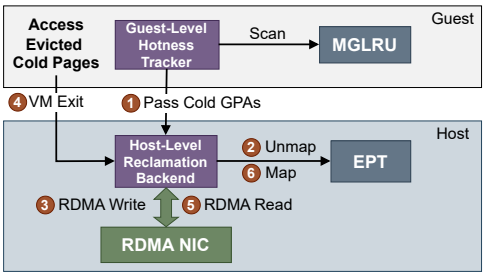

Figure 5: Cold memory path of Blowfish.

Reclaim a cold page. As shown in Figure 5, the guest-side hotness tracker selects cold pages from the oldest MGLRU generation, moves them to an isolated list to avoid repeated reclamation, and pushes their guest physical addresses into a shared-memory channel. On the host side, Blowfish's reclamation backend runs a lightweight daemon thread that ❶ polls this channel for incoming guest physical addresses. The thread sleeps when the channel is empty and can be awakened via a hypercall, following a standard low-overhead design that avoids occupying a dedicated core. The reclaiming process proceeds as follows. ❷ Upon receiving a cold guest physical address, the backend invalidates the corresponding EPT entry and flushes its TLB entry. This mechanism guarantees that any subsequent access will trigger an EPT violation, enabling Blowfish to intercept the access and restore the page safely or prevent in-flight modifications before data backup. ❸ The backend extracts the host physical address from the invalidated EPT entry, allocates a far-memory address, and transmits the page's content to far memory via RDMA. After the transfer completes, the backend encodes the far-memory address into the EPT entry's upper bits, which are ignored when the present bits of EPT entry are cleared [28]. This process finalizes reclamation without modifying either the GPT or the IOPT.

Restore a cold page. As shown in Figure 5, when the guest accesses a reclaimed cold page, ❹ the access triggers an *EPT violation* because the corresponding EPT entry is not present. Blowfish installs a lightweight EPT violation handler in the host-level backend to restore both the mapping and the data for the faulting guest physical address with minimal latency. ❺ Upon a fault, the backend extracts the far-memory address embedded in the invalidated EPT entry, allocates a free host page, and fetches the data from far memory. ❻ It then reconstructs the EPT entry for the restored guest page and places the guest physical address into a shared buffer, enabling the guest to reinsert the page into its MGLRU structures during routine maintenance. This restoration completes with only a single far-memory read and one EPT update, introducing min-

imal overhead and mirroring the low-cost design principles of Blowfish.

Reclaim and restore free pages. Identifying free pages is straightforward: the backend only needs to scan the guest's free page list or allocator metadata. Reclaiming and restoring free pages are also simple and efficient, as they merely require updating the corresponding EPT entries and can naturally benefit from defragmentation and huge-page optimizations [59,60]. We extend HyperAlloc [59] and integrate it into Blowfish's unified reclamation backend, delegating both free page reclamation and restoration. Specifically, the backend scans the shared guest allocator to identify free pages, unmaps their EPT entries, and synchronizes their state with the guest allocator using atomic updates. This process completes the reclamation of a free page. When the guest later allocates a page marked as reclaimed, it issues a hypercall to the backend, which allocates a fresh host page and reconstructs the corresponding EPT mapping. The guest allocator naturally prefers pages not marked as reclaimed, thereby avoiding unnecessary restorations.

4.5 Hotness-Aware Kernel Service

Modern Linux kernel services (*e.g.*, kcompactd, khugepaged) make page-level decisions without considering access hotness, a long-standing inefficiency in Linux memory management. Under host-level reclamation, however, these services can unnecessarily trigger restorations of reclaimed pages, amplifying their cost. To mitigate all the preceding problems while preserving normal kernel functionality, Blowfish introduces minimal but effective hotness-aware adjustments to existing guest kernel services.

Among these services, khugepaged is both always enabled under THP and highly active [6]. It periodically scans guest page tables with bounded throughput to identify 2 MB regions that can be promoted to huge pages, moving data to physically contiguous 2 MB pages and forming a new huge-page mapping. Because khugepaged is oblivious to page hotness, it may (1) merge unevenly hot pages, exacerbating hot bloat, and (2) inadvertently touch reclaimed cold pages under host overcommitment. Blowfish augments khugepaged with a lightweight filter: during the scan, it inspects access bits of all PTEs in the candidate region and skips promotion if more than half of the pages were not recently accessed. This simple check adds little extra scanning cost and effectively suppresses low-benefit promotions in practice.

kcompactd is triggered when the guest kernel requires high-order pages, *e.g.*, when khugepaged finds no available free 2 MB pages. It compacts memory by migrating data from lower addresses toward higher addresses to create contiguous free pages. During scanning, kcompactd may migrate hot pages, hurting application performance, or touch reclaimed cold pages, triggering unnecessary restorations. Blowfish extends kcompactd with a lightweight filter: during the scan, it inspects the generation of each page and skips pages in the youngest generation (treated as hot). It also skips reclaimed pages by checking whether the page is absent from the MGLRU; in Blowfish, all reclaimed cold pages are removed from the MGLRU to avoid repeated reclamation. In more aggressive paths (*e.g.*, direct compaction), Blowfish issues explicit restoration requests to the host backend and allows hot and reclaimed pages to be migrated, ensuring that memory compaction remains effective. Since direct compaction occurs infrequently and involves only a limited number of pages at a time, these restorations introduce only modest overhead.

We primarily optimize khugepaged and kcompactd because, with THP enabled, khugepaged is always active, kcompactd is frequently triggered during huge-page allocation, and together they account for the vast majority of unnecessary accesses in our experiments. Other kernel services, such as NUMA balancing, are either inactive in typical VM deployments or can be extended in a similar fashion, so we omit their details.

4.6 Automatic Policy

In this section, we present an automatic policy used in our evaluation: (1) prioritize reclaiming free memory, whose pages can be efficiently restored with negligible impact on application performance; and (2) reclaim cold memory only when free memory becomes scarce, while regulating its performance impact through PSI. This PSI-guided policy is purely practical and heuristic; Blowfish does not rely on a specific control policy, and alternative policies can be easily plugged in.

Initially, Blowfish tries to reclaim free memory until the remaining amount reaches a predefined watermark (*e.g.*, 100MB by default), a design inspired by the Linux memory watermark. Specifically, the host-level reclamation backend periodically scans the guest allocator every 100ms to identify and reclaim free guest pages, a frequency that has proven effective in practice with minimal CPU consumption. Restoration of reclaimed free memory is performed on demand when the guest allocates it, following HyperAlloc's policy.

Once the remaining free memory falls below the predefined watermark, Blowfish begins reclaiming cold memory, with the reclamation rate regulated by PSI to minimize application performance degradation. The PSI follows the definition introduced in §2, *i.e.*, the real-time process stalls due to memory shortages. Specifically, when PSI remains below a predefined threshold, Blowfish continues reclaiming cold memory. As reclamation progresses, reclaimed pages may be accessed more frequently, causing PSI to rise. Once PSI exceeds the threshold, Blowfish pauses cold-memory reclamation and proactively restores cold pages until PSI falls back below the threshold.

4.7 Guest Cooperation and Isolation

Similar to prior cooperative memory overcommitment mechanisms (*e.g.*, Balloon [25, 53], virtio-mem [24], HyperAlloc [59]), Blowfish operates under the assumption that the guest and the host adhere to a simple, well-defined protocol. In practice, this cooperation model is widely adopted in modern cloud virtualization environments, where guests typically adhere to the prescribed interface. Nevertheless, protocol deviations, whether accidental or intentional, may still arise. We discuss how Blowfish handles such cases and what guarantees it preserves. We focus on the mixed-granularity cold-memory reclamation path unique to Blowfish and exclude free-memory reclamation, whose correctness properties are inherited from HyperAlloc.

For cold-memory reclamation, a guest may provide guest physical addresses that do not correspond to valid memory regions. Blowfish's reclamation backend verifies each guest physical address against the EPT mappings and simply ignores those that are invalid. A guest may also fail to report its cold guest physical addresses. In this case, if necessary, Blowfish can safely fall back to the uncooperative host swapping, which identifies cold pages by scanning EPT access bits and directly reclaims guest-occupied host pages. This fallback preserves correctness and, in critical situations, prevents host-level out-of-memory conditions, though it may reduce the guest's performance benefits. If a guest submits an unusually large number of guest physical addresses, the backend continues to process only the valid ones. The backend employs a balanced polling strategy across all VMs, ensuring that excessive submissions from one VM do not impact the progress or performance isolation of others.

We also handle concurrent host and guest operations. On the guest side, pages selected for reclamation are synchronized using LRU locks. For the shared memory channel between host and guest, atomic indexing ensures that each location is accessed by at most one reader or writer at a time [55]. On the host side, Blowfish coordinates concurrent reclamation and restoration using per-EPT-entry locks.

5 Evaluation

We implement Blowfish in C, based on the Linux kernel (version 6.1) and QEMU (version 8.2.1), with approximately 6000 lines of code added to the host kernel and 1700 lines to the guest kernel. The RDMA backend is inspired by Hermit [49], a state-of-the-art paging-based far memory system.

Setup. We run experiments in a cluster with one CPU server and one memory server connected by NVIDIA 100Gbps Mellanox ConnectX-5 InfiniBand adapters. Each server has two Intel Xeon Gold 6342 CPUs and 256GB of memory. We configure the servers following common practice for low latency [45], including disabling Turbo Boost, CPU frequency scaling and hyperthreading. Besides, we enable Transparent Huge Page (THP). All systems being evaluated are running on Ubuntu 20.04. The virtual CPUs on the guests maintain a 1:1 mapping with the host physical CPUs. The threads for reclamation and proactive restoration share physical CPU cores with the VM and utilize no more than a single core.

Baseline and methodology. We evaluate against HyperAlloc [59], and its 4 KB-granularity variant HyperAlloc-4K for fine-grained 4 KB reallocation. Because HyperAlloc targets free-page reclamation, we extend HyperAlloc and HyperAlloc-4K to support cold-memory rebalancing: we install Hermit [49] for µs-scale data movement and add a reclaimer to support paging. All baselines are configured to follow the same policy as Blowfish.

For paging type (§2.2), guest paging offers low overhead of hotness tracking but introduces granularity mismatch and high-latency for memory adjustment; host paging is transparent but risks mis-eviction and extra context switches/data movement due to limited visibility and burdens heavy hotness tracking. We pair HyperAlloc and HyperAlloc-4K with guest paging to enable cold-page reclamation, where HyperAlloc-H denotes the host-paging variant of HyperAlloc, HyperAlloc-G denotes its guest-paging variant, and the same notation applies to HyperAlloc-4K (*i.e.*, HyperAlloc-4K-H and HyperAlloc-4K-G). Since HyperAlloc and HyperAlloc-4K show no significant performance difference when reclaiming contiguous free memory, the host paging responsible for reclaiming cold memory is implemented only on HyperAlloc (*i.e.*, HyperAlloc-H).

Slow Down for throughput is defined as the ratio between the runtime increase under the current configuration and the runtime when using all-local memory, while for latency, it represents the percentage of latency increase. *Reclamation Ratio* is formally defined as

$$ReclamationRatio = 1 - \frac{1}{n} * \frac{\sum M_i^{now}}{M^{VM}}$$

where n denotes the number of sampling points. M_i^{now} represents the memory usage of the VM at sampling point i, and M^{VM} denotes the initial memory size allocated to the VM. We measure the throughput and latency of applications under different PSI thresholds.

For §5.1, we use different baseline systems to reclaim as much VM memory as possible under the PSI threshold constraint, in order to assess their ultimate capabilities. For §5.2, we follow the unified PSI threshold setting used in Senpai [58], namely 0.04. We run different applications in pairs under the condition that their combined memory usage is at most 50% of their combined peak memory demand to investigate how different systems perform memory rebalancing.

Note that for host-level reclamation mechanisms (*e.g.*, HyperAlloc-H and Blowfish), guest-level PSI cannot accurately reflect the actual memory demand, because host-level page faults are invisible to the guest. To address this gap, we place each VM process in a separate host cgroup and monitor the PSI at the cgroup level for these mechanisms. In this

Table 2: Benchmarks and workloads.

Application	Dataset	Size	Characteristics	Memory Footprint	#vCPU

way, host-level PSI captures memory pressure induced by host-level page faults during restoration, providing a more accurate measurement of memory demand.

Workloads. As shown in Table 2, we evaluate five native applications written in C/C++ and two managed applications written in Java, covering varied memory access patterns. We evaluate the throughput (§5.1.1) and latency (§5.1.2) of applications listed in Table 2.

5.1 Performance of Single VM

5.1.1 Throughput

At the coordinate origin, the memory overcommitment mechanism is disabled, such that no system engages in memory allocation or reclamation, and applications observe no slowdown. Across different PSI thresholds, Blowfish demonstrates superior performance by achieving a higher reclamation ratio and incurring less performance degradation than the baselines.

For application performance, Blowfish uses fair MGLRU to get the hotness of THP, and avoids maintaining the guest page table (GPT) and IOPT, enabling faster memory provisioning when application demand increases. Moreover, its more efficient reclamation and restoration reduce CPU contention with applications. For memory reclamation ratio, rather than depending on contiguous memory pages, Blowfish performs adjustments at the granularity of 4KB pages through a dedicated mechanism, thereby enabling fast reclamation of a substantial amount of non-contiguous memory. Although HyperAlloc-H avoids page table modifications by adopting host paging, the applications running on it perform worse than those on Blowfish and other variants of HyperAlloc. The underlying causes are twofold: (1) HyperAlloc-H relies on heavy hotness tracking at the host level, inducing up to 4.78× more TLB flushes than HyperAlloc-G. (2) Due to its lack of program semantics, host paging often misidentifies cold pages, resulting in unnecessary evictions, context switches (incurring 33% more VM exits), and extra data transfers. For reclamation, HyperAlloc-H suffers from host-side semantic loss: it fails to differentiate page states (*e.g.*, short-lived cache, writeback pages), leading to misguided evictions and unnecessary swapping. In addition, daemon in kernel service introduces hotness interference, and the absence of guest-level semantics further causes invalid reclamations that are quickly restored, collectively degrading throughput. HyperAlloc-G imposes minimal performance overhead on applications, but fails to take advantage of potential memory reclamation opportunities due to its dependence on contiguous pages. In HyperAlloc-4K-G, costly cold memory reclamation reduces its reclamation throughput (on average 2× lower than Blowfish across the applications), and costly restoration increases reclaimed-page access latency, and this higher latency degrades application performance.

Memcached and Cassandra The workload of Memcached is skewed with churn, while the one of Cassandra is more random. This behavior stems from Cassandra's garbage collection threads accessing memory via graph traversal. Under the constraint that application performance degradation does not exceed 5%, for average reclamation ratio, Blowfish has 3.1×, 5.3×, and 3.2× improvement compared to HyperAlloc-4K-G, HyperAlloc-H, and HyperAlloc-G, respectively in Memcached. Besides, in Cassandra, provided that application performance degrades by no more than 5%, Blowfish improves the reclamation ratio by 2.1×, 4.0×, and 3.3×. The reclamation of Cassandra is more challenging due to its larger working set and more complex memory access patterns. Our profiling reveals that more than 80% of reclaimable free memory pages are non-contiguous, severely limiting HyperAlloc's ability to reclaim memory. For HyperAlloc-H, Memcached consists of 96% anonymous pages versus 67% in Cassandra, yielding higher reclamation ratio as fewer file pages are misevicted. However, due to the semantics gap, 27% of reclaimed pages are restored within 1s, resulting in a lower reclamation ratio compared to Blowfish.

GAPBS TriangleCount and GraphChi PageRank are graph-centric workloads that traverse the entire graph and exhibit pronounced phase-changing behavior in their memory usage patterns. TriangleCount is executed on an evolving graph [17], where we divide the input dataset into three parts and feed them to GAPBS. During the update and analysis of the evolving graph, HyperAlloc-4K-G cannot reclaim the memory in time due to its low reclamation throughput. Subject to the condition that application performance drops by no more than 5%, Blowfish offers a favorable trade-off between reclamation and performance, achieving up to 2.1×, 2.8×, and 2.4× higher reclamation ratios than baseline systems (HyperAlloc-4K-G, HyperAlloc-H, and HyperAlloc-G, respectively). GraphChi PageRank reads and processes the graph in blocks, during which it repeatedly allocates and frees memory. The frequent memory allocation and deallocation in GraphChi [33] exacerbate the problem of memory fragmentation. Its slowdown on HyperAlloc-H stems primarily from (1) frequent TLB flush. (2) reclaiming an extra 48% short-lived page cache pages; this behavior interferes with hot-cold classification, causing many hot pages to be swapped out. In our measurements, VM exits due to this factor account for 32% (296M in total). For HyperAlloc-4K-G, rapid working set fluctuations lead to excessive memory restoration operations, incurring high overhead. Blowfish detects the gaps during application working set transitions and promptly reclaims memory. At the constraint of 5% slowdown, Blowfish reaches 3.4×, 6.1×, and 3.9× higher memory reclamation ratio than HyperAlloc-4K-G, HyperAlloc-H, and HyperAlloc-G, respectively.

Liblinear and KMeans are representative of machine learning applications. The memory fluctuation characteristics of Liblinear are subdued because matrix multiplication exhibits sequential access patterns, where non-contiguous pages account for only 34% of the total. Hence, the improvement of Blowfish is modest compared to the baselines. With respect to HyperAlloc-4K-G, HyperAlloc-H, and HyperAlloc-G (at 5% slowdown), Blowfish improves the reclamation ratio by 2.0×, 2.9× and 2.2×, respectively. KMeans is an iterative algorithm composed of multiple phases. Furthermore, as KMeans has a relatively large working set, the reclamation ratio tends to stabilize with increasing PSI threshold. In KMeans under a slowdown of 5%, for reclamation ratio, Blowfish has 3.0×, 5.6×, and 3.7× improvement compared to HyperAlloc-4K-G, HyperAlloc-H, and HyperAlloc-G, respectively.

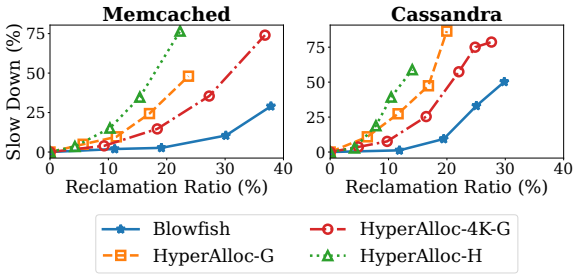

Figure 7: Tail latency of benchmarks.

602.gcc_s is a benchmark that simulates the GCC compiler compiling large C programs, displaying multi-phase memory usage characteristics. HyperAlloc-G's reclamation ratio remains significantly lower across PSI thresholds, owing to its limited ability to reclaim non-contiguous memory (up to 75%). The memory access pattern of 602.gcc_s aligns well with Blowfish's optimizations. With a slowdown of 5%, Blowfish outperforms HyperAlloc-4K-G, HyperAlloc-H, and HyperAlloc-G by 1.6 ×, 3.2 × and 1.9× for reclamation ratio. Notably 52% of the pages swapped out by HyperAlloc-H are page cache.

5.1.2 Latency

We evaluate the tail latency (p95) of Memcached and Cassandra. As shown in Figure 7, with increasing reclamation ratio, applications running on HyperAlloc-G and HyperAlloc-H exhibit a sharp increase in p95 latency. Besides low restoration overhead, Blowfish consumes only 11% and 14% of the CPU resources allocated to the VM for Memcached and Cassandra, respectively (compared to 24% and 26% in HyperAlloc-4K-G), reducing competition with application threads during memory rebalancing. At the challenging case with a throughput slowdown of 5%, Blowfish reduces the latency slowdown of Memcached by 2.8×, 4.7×, and 3.9× compared to HyperAlloc-4K-G, HyperAlloc-H, and HyperAlloc-G, respectively (1.9×, 2.5×, and 2.1× for Cassandra).

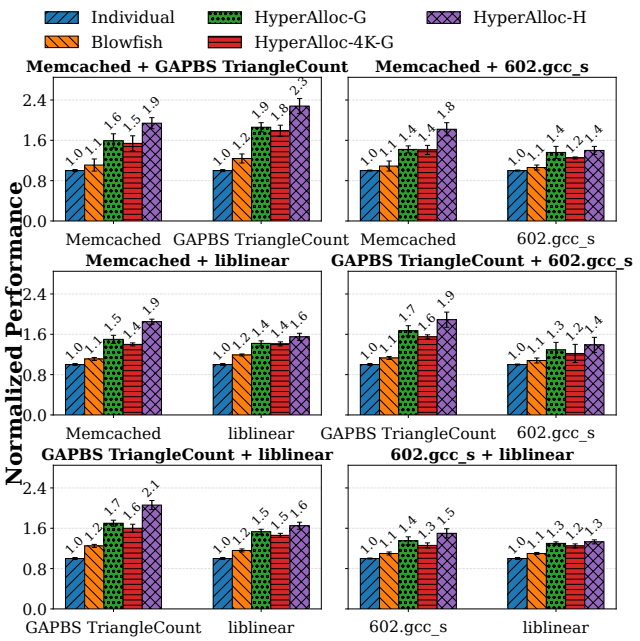

Figure 8: Normalized end-to-end performance when co-running workloads. Lower is better.

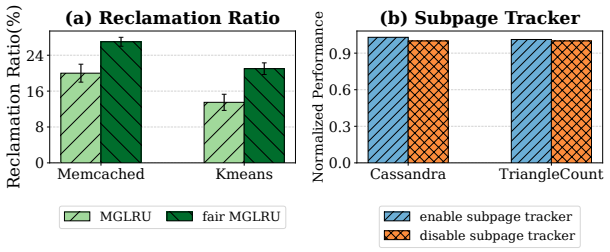

Figure 9: (a) Effectiveness of Fair MGLRU. (b) Normalized performance with and without Subpage Tracker. Lower is better.

5.2 Memory Rebalancing Across VMs

We select four applications and evaluate end-to-end memory rebalancing under co-running VMs. Figure 8 shows that Blowfish consistently preserves co-run performance closer to running individually ("Individual" refers to running an application in isolation on a VM without memory pressure). Across all six workload pairs, Blowfish's normalized performance degradation factor remains in a narrow range (1.06×–1.25×), whereas the baselines exhibit substantially larger degradation. Blowfish can quickly adjust the amount of memory available to an application by leveraging its phase-changing behavior, thereby avoiding SLO violations.

5.3 Drill Down

Effectiveness of Fair MGLRU. We measure the effectiveness of fair MGLRU. We select two applications and replace

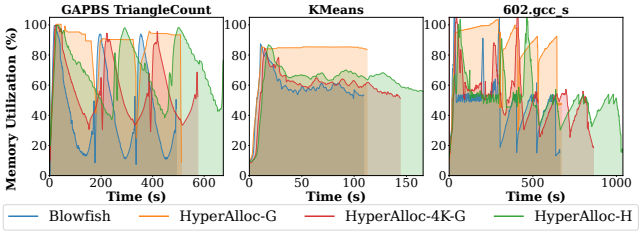

Figure 10: Memory utilization over time during rebalancing, defined as the ratio of the current VM size to the initial VM size.

the fair MGLRU in Blowfish with the standard MGLRU. As shown in Figure 9(a), fair MGLRU effectively distinguishes pages at different granularities and improves the memory reclamation ratio. Enabling fair MGLRU increases the reclamation ratio by 7.2% for Memcached and by 6.5% for KMeans.

Overhead of Subpage Tracker. To investigate the overhead introduced by the Subpage Tracker in Blowfish, we select two applications and evaluate the performance impact of enabling or disabling this configuration. As shown in Figure 9(b), the Subpage Tracker has a modest impact on application performance (3.1% for Cassandra and 0.9% for TriangleCount). This modest overhead is mainly due to that it splits only the page table mappings, rather than the actual physical pages, at a modest rate, avoiding the high cost of updating the `struct page` metadata.

Automatic Reclamation. Figure 10 illustrates how Blowfish and the baseline systems dynamically resize VM memory. To balance the performance and accuracy of sampling, we sample the memory footprint of guest every 0.5s at the PSI threshold to guarantee the slowdown of 5% on Blowfish. For GAPBS TriangleCount, we split the input graph into three parts to construct the evolving graph [17]. The algorithm involves three passes over the entire graph structure. For each pass, cold pages are gradually reclaimed. In comparison to HyperAlloc-4K-G and HyperAlloc-H, Blowfish can promptly reclaim memory regions that are unlikely to be accessed in the near future with higher reclamation throughput. HyperAlloc-G, on the other hand, is hindered by memory fragmentation and can reclaim only a limited amount of memory shortly after each pass. For KMeans, there are multiple distinct stages. Upon JVM startup, the heap is initialized with a relatively low memory footprint. As the application proceeds to initialize memory and load data, memory consumption gradually increases. During the subsequent phases, memory usage exhibits cyclical fluctuations. Blowfish maintains high performance while offering flexibility in memory usage across various applications. However, the baselines miss the opportunity to harvest the cold memory due to their poor elasticity. For 602.gcc_s, Blowfish is capable of aggressively reclaiming memory while swiftly responding to sudden bursts of memory

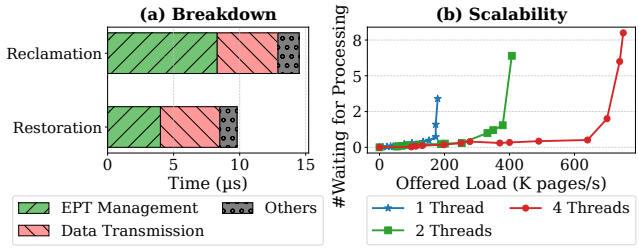

Figure 11: (a) Latency breakdown for reclaiming and restoring. (b) The scalability of the reclamation backend.

requests, achieving a sweet spot between performance and reclamation ratio.

Latency Breakdown. We use a microbenchmark to measure the single-page reclaim and restore latency of Blowfish. We run a program with random memory access in the VM and trigger Blowfish to reclaim pages individually, thereby avoiding batching optimizations. Figure 11(a) presents the results. Blowfish eliminates the overhead of guest page table and I/O page table modifications, making EPT handling the dominant software overhead, accounting for 41%-57% of the total. By removing redundant overheads of page table modifications, Blowfish reduces the single-page reclaim and restore latencies to 14.5µs and 9.8µs, which are 53% and 60% lower than HyperAlloc-4K-G, respectively. The latency could be further reduced with lower-latency hardware.

Scalability of the Reclamation Backend. We evaluate the scalability of the reclamation backend. "#Waiting for Processing" denotes the average number of pages waiting to be reclaimed. We assess scalability by running a microbenchmark with a large cold memory footprint in the VM and varying the reclamation request rate (the offered load). As shown in Figure 11(b), with a single reclamation thread, the number of pages queuing quickly reaches an inflection point as the load increases. At a load of about 170K pages/s, the queue length surges, indicating that a single thread is nearing its processing capacity. Increasing the number of threads alleviates this bottleneck, enabling the reclamation backend to handle higher loads. For example, using 2 threads and 4 threads increases the processing capacity of the backend by nearly 2.0× and 3.9×.

6 Limitations

The components of Blowfish exhibit different portability characteristics. The host-level reclamation backend operates entirely in the host and has no guest kernel dependency. The subpage tracker relies only on access bits and page table operations, making it applicable to any OS with standard page table support. The Fair MGLRU component, however, depends on MGLRU's multi-generational structure. On systems with classical two-list LRU implementations, the same principle can still be approximated by gating huge-page promotion with an additional access-count condition, requiring multiple observed accesses before promoting a 2 MB page to the active list. While this approximation may reduce effectiveness due to coarser promotion granularity and additional gating overhead, the core idea of correcting unfair hotness still applies.

7 Prior Work

Memtis [35] and Demeter [26] are the two pieces of prior work most closely related to Blowfish. Although these systems focus on tiered memory management, Blowfish shares several design considerations with them while introducing new ideas to tackle the related but distinct problem of VM memory overcommitment. This section discusses the similarities and differences between Blowfish and these prior systems.

7.1 Memtis

Both Blowfish and Memtis adopt THP-aware hotness tracking, but in different problem settings. This similarity stems from a shared observation: THPs introduce hot bloat issues, where a few hot subpages can cause the entire THP to appear hot, leaving many cold subpages unreclaimable (for Blowfish) or unevicted (for Memtis). Both systems, therefore, need to identify such THPs and split them to mitigate this issue.

However, the two systems differ substantially in both deployment environment and problem setting. Memtis is designed for bare-metal tiered memory management, while Blowfish targets VM memory overcommitment in virtualized systems. These differences lead to distinct designs. Memtis relies on PEBS-based sampling for page access tracking, which introduces an accuracy-overhead tradeoff and requires non-trivial deployment effort [26, 40]. Blowfish instead uses A/D-bit-based tracking, which is more virtualization-friendly and provides more deterministic access signals. Moreover, Memtis assumes a relatively stable fast tier for computing hot-set/hit-ratio statistics, an assumption that becomes difficult to maintain under dynamic memory overcommitment.

7.2 Demeter

Both Blowfish and Demeter adopt a decoupled architecture and perform page tracking within the guest. This similarity stems from a shared observation in virtualized environments: performing page tracking at the host incurs substantial system overhead.

However, the two systems differ in how to partition page table management functionality between the guest and the host. Demeter delegates the full tiered memory management pipeline, including data migration, to the guest, introducing overheads from GPT and IOPT updates under memory overcommitment. In contrast, Blowfish decouples page tracking and page management: the guest is responsible only for page

tracking, while the host handles data transfer and page table updates, reducing the latency of individual operations by 53-60%. In addition, Demeter operates on coarse-grained memory regions (*e.g.*, 2 MB), making it difficult to handle hot bloat and unfair hotness under mixed-granularity scenarios. It also lacks page-type awareness, reducing reclamation effectiveness. Blowfish instead uses subpage-level tracking and page-type awareness for more effective reclamation.

7.3 Takeaways

Blowfish, Memtis, and Demeter address different problems (VM memory overcommitment vs. tiered memory management) in different deployment contexts (virtualized vs. bare-metal), yet converge on similar techniques due to shared requirements for effective hot-bloat tracking and low-overhead page access tracking. However, different goals lead to distinct designs, as discussed earlier. These comparisons show that efficient VM memory overcommitment requires rethinking both tracking mechanisms and system design for responsive, low-overhead memory management.

8 Conclusion

In this paper, we have proposed Blowfish, a memory overcommitment framework built on disaggregated memory. Blowfish can perform cold/free memory reclamation and restoration at a µs-scale, reaching up to 2.48× and 2.14× faster than the state-of-the-art work, *i.e.*, HyperAlloc.

Abstract

Enterprise SSDs integrate substantial computing resources (e.g., ARM processor and onboard DRAM) to handle I/O bursts. However, these resources significantly raise SSD monetary cost and suffer severely underutilized in JBOF deployments due to the sporadic nature of I/O bursts. In this paper, we present *Espresso*, a cost-efficient JBOF design that provisions only moderate computing resources per SSD at low monetary cost, while delivering demanded I/O performance through efficient inter-SSD resource sharing. Specifically, Espresso first disaggregates SSD architecture into functionally distinct components, enabling fine-grained SSD internal resource management. Espresso then employs a decentralized scheme to manage these disaggregated resources and harvests the computing resources of idle SSDs to assist busy SSDs in handling I/O bursts. This idea is facilitated by the cache-coherent CXL fabric, with which the busy SSDs can directly utilize the harvested computing resources to accelerate metadata processing. The evaluation results show that Espresso can improve SSD resource utilization by 50.4% and reduce monetary cost by 19.0% with negligible performance degradation, compared to the state-of-the-art JBOF designs.

1 Introduction

I/O-intensive scenarios, such as cloud storage, large language model inference, and burst cache [46, 61, 69, 70, 97, 118], eagerly demand extremely high I/O throughput to accelerate the ever-expanding dataset access. Following this trend, solid-state drives (SSDs) have become one of the most indispensable storage media and have experienced continuous technical advancements in both *scale-up* and *scale-out* ways.

From the *scale-up* aspect, SSD manufacturers integrate more hardware resources within each SSD device to enhance I/O parallelism. For example, the emerging PCIe 5.0 SSDs [85] boost the performance of embedded ARM processors by 1.7× over the PCIe 4.0 ones [84] to accelerate the execution of SSD firmware. Moreover, SSDs typically equip large onboard DRAM (1 GB per TB flash [90]) to accommodate the entire metadata (mainly FTL mapping tables [16]) for fast access. From the *scale-out* aspect, SSD suppliers cluster tens of high-performance SSDs as *just a bunch of flash* (JBOF) [34, 40, 75, 108, 110], which aggregates the hardware resources from every SSD to deliver extremely high throughput.

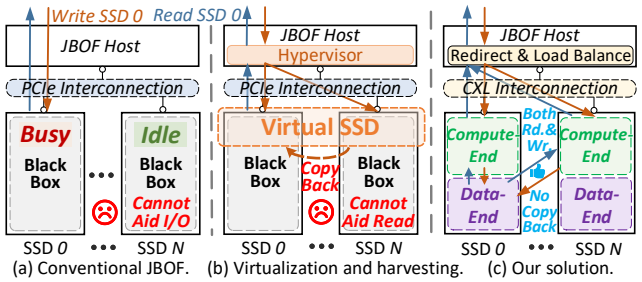

Figure 1: Comparison of different JBOF designs.

Unfortunately, these technical trends place SSD consumers in a *cost-utilization dilemma*. To be more precise, while the increasing hardware resources elevate the *bill of material (BOM)* costs of SSDs to satisfy the performance requirement of burst I/O, the sporadic nature of I/O bursts causes severe SSD resource underutilization in JBOF level (cf. Figure 1a). For instance, in 94.6% uptime of a Tencent storage server [134] equipped with 25 drives, at least 20 drives are underutilized (i.e., bandwidth utilization is lower than 75%, cf. § 2.2). This is because in modern cloud platforms [66, 86], storage drives (e.g., SSDs) are commonly allocated (or sold) to different tenants. These tenants utilize their own drives to serve different application instances with diverse I/O patterns, which experience I/O bursts at different times.

A straightforward idea to improve utilization is storage virtualization and harvesting [5, 86, 107, 119, 126]. As shown in Figure 1b, the hypervisor [86, 107] can harvest idle SSDs by dynamically grouping a busy SSD with multiple idle ones as a *virtual SSD*. Subsequently, parts of write requests originally targeting the busy SSD are redirected to the idle ones via the virtual SSD abstraction, leading to a higher burst performance and SSD utilization. Once the burst period concludes, these

idle SSDs will be reclaimed and set aside for future harvesting. While this approach succeeds in exploiting idle SSDs, it unfortunately faces three prominent challenges:

• *Coarse-grained SSD harvesting causes resource stranding issues:* Different I/O tasks impose varied degrees of burden on the computing (e.g., ARM processor and DRAM) and flash (e.g., flash channels) resources within SSDs. For example, 4 KB sequential reads consume 96% of processor clocks while only exploiting 39% of flash times. 4 KB sequential writes, in contrast, are flash-hungry (99%) while keeping the processor underutilized (27%, cf. § 3.1 for details). However, the hypervisor treats SSDs as monolithic black boxes, which leads to *resource stranding* issues [5, 58, 119]. For instance, when an SSD is flash-hectic for write bursts, its computing resources may still be idle. These computing resources cannot be harvested as the entire SSD is considered busy.

• *Limited profit in read-dominated workloads:* The simple virtualization and harvesting approach yields minor benefits for read-dominated workloads. This is because, without storing the target data of incoming read requests beforehand, the temporarily harvested SSDs cannot aid the busy SSDs in read services. Our evaluation shows that this simple approach only brings 0.5% throughput improvement in read-dominated workloads (cf. § 3.1 for details).

• *High overheads brought by written data copyback and resource management:* Although redirecting write requests to the harvested SSDs can improve SSD utilization, this benefit comes at high costs. To be specific, when reclaiming the harvested SSDs, the hypervisor has to copy back the written data to the initial destination SSD for availability [86]. Such write amplification drastically shortens SSD lifetimes (22.5% reduction). Moreover, the centralized virtual SSD management in the hypervisor imposes huge burdens [52, 86] on the host CPU (e.g., 16 ARM cores in SuperMicro SSG-229J [110]), compelling it to become the performance bottleneck of JBOF (21.4% throughput loss, cf. § 3.1).

In response to these challenges, we introduce *Espresso*[1], a cost-efficient JBOF design, which tackles the cost-utilization dilemma by only reserving moderate computing resources in SSDs while achieving satisfactory burst I/O performance through inter-SSD resource sharing (cf. Figure 1c). Our key insight is that the high-speed and cache-coherent *Compute eXpress Link (CXL)* interconnections [19, 58, 109] can be harnessed to facilitate fine-grained, high-profit, and low-overhead SSD harvesting. Specifically, recognizing the black-box limitation of conventional SSDs, Espresso first disaggregates the SSD architecture into two parts, *compute-end* and *data-end*, based on their functionality. Compute-end encloses computing resources, such as ARM processor and onboard DRAM, which are responsible for executing firmware tasks (e.g., address translation [16, 35]). Data-end comprises flash resources (e.g., flash channels) and data-related components (e.g., DMA engine), which are in charge of data transfer and flash I/O. Espresso exposes them separately to the host and peer SSDs via the high-speed CXL interconnection. This design enables fine-grained resource management and promises to mitigate the resource stranding issues.

With the disaggregated SSD architecture, Espresso can benefit both read and write requests by harvesting idle compute-end to alleviate burdens of the SSDs, which are busy with firmware tasks. This idea is facilitated by the cache-coherent feature of CXL, with which the harvested compute-end can precisely operate the essential metadata of busy SSDs (e.g., FTL mapping table [16]) for I/O request handling. Moreover, this design avoids detrimental copyback because it harvests only the stateless computing resource to expedite metadata processing while keeping the data path on the stateful flash memory unchanged. In addition, Espresso employs a holistic I/O redirection design and a miss-ratio-curve-based scheme to deliver reasonable performance isolation for harvested SSDs. Considering the overhead of centralized resource management, Espresso first leverages the global coherent memory constructed by CXL to enable inter-SSD communication. Espresso then implements decentralized and self-governing resource management in SSDs to relieve host CPU burdens. Comprehensive evaluation results demonstrate that Espresso outperforms existing JBOF designs, improving SSD resource utilization by 50.4%, saving 19.0% BOM costs while having negligible performance loss.

Our main **contributions** can be summarized as follows:

- We deeply review the cost-utilization dilemma of JBOF and reveal that the black-box constraint of conventional SSD designs can lead to severe resource stranding issues.
- We propose a novel SSD architecture that disaggregates SSD internal resources into compute-end and data-end based on their functionality. This design lays the foundation for fine-grained and efficient SSD resource harvesting.
- We propose a cost-efficient JBOF design that reserves moderate computing resources in each SSD at low BOM costs while achieving demanded I/O performance by leveraging CXL to facilitate inter-SSD resource sharing.

2 Background and Motivation

2.1 JBOF and NVMe SSD

JBOF architecture. Just a bunch of flash (JBOF) is a type of storage server that can incorporate multiple high-performance SSDs as a whole, thereby satisfying the ever-increasing performance demands in a scale-out manner. As shown in Figure 2a, a JBOF comprises CPU, DRAM, NIC, and tens of SSDs, connected via PCIe interconnections. For high cost and energy efficiency [34, 75, 108], recent advanced JBOF products typically equip Data Processing Units (DPUs) to replace separated CPU, DRAM, and NIC, serving as the *host*. For example,

[1] Espresso is accessible at https://github.com/ChaseLab-PKU/Espresso.

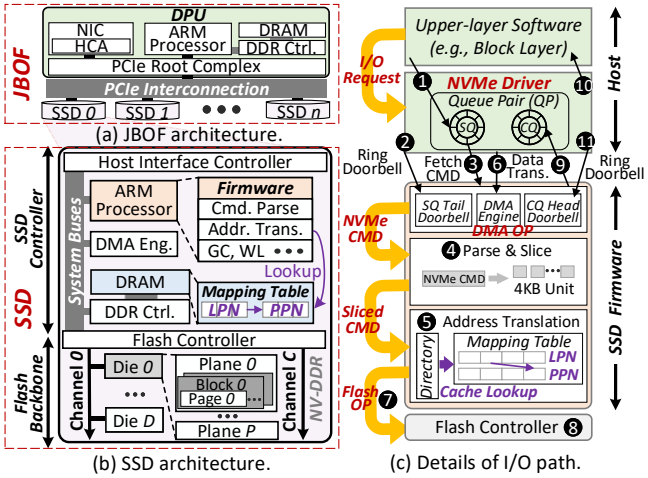

Figure 2: Details of the traditional JBOF system.

SuperMicro SSG-229J-5BU24JBF [110], one of the up-to-date JBOF products, supports 24 SSDs with two BlueField-3 DPUs [78], each containing a 16-core ARM processor and 16 GB DRAM. In the following, we mainly focus on DPU-based JBOF to enjoy its superior cost and energy efficiency, which aligns with the target of this paper. Nevertheless, our designs are also applicable to conventional JBOF products.

SSD architecture. Figure 2b presents a typical architecture of modern SSDs [91]. The SSD controller connects to the host through PCIe lanes and a host interface controller. Moreover, it integrates an ARM processor, a DDR DRAM controller, and some specialized processing elements (e.g., DMA engine). The ARM processor is mainly responsible for performing firmware tasks (e.g., command parsing, address translation, and garbage collection). These components are coupled with a flash backbone through the flash controller. The flash backbone consists of 8 to 16 flash channels, each enclosing several flash dies. A flash die can be further divided into multiple flash planes, blocks, and pages.

I/O path. Figure 2c illustrates the I/O path in JBOF systems. When I/O requests arrive, the NVMe driver in the host submits NVMe commands to submission queues (SQ, ❶). It then notifies the SSD of the command arrivals by ringing the SQ doorbells corresponding to the queues (❷). Afterward, the SSD firmware operates the host interface controller to fetch NVMe commands from SQ (❸). SSD firmware then parses these commands, slices them into unit size (e.g., 4 KB, ❹), and translates the host *logical address (LPN)* to the flash *physical address (PPN)* by referring to the *mapping table* in *flash translation layer (FTL,* ❺*)*. The mapping table is persisted in the flash backbone for crash consistency and cached in onboard DRAM for high performance. A *mapping directory* is used to locate cached mapping table entries. SSD firmware also needs to orchestrate the host-SSD data transfers by issuing host *DMA operations* to the DMA engine (❻). Subsequently, the SSD firmware sends *flash operations* to the flash controller (❼), which performs flash I/O following the Open NAND Flash interface (ONFi) protocol [82] (❽). In the backward, the firmware writes the results to the completion queues (CQ) and then notifies the host by generating MSI-X interrupts [26] (❾). Finally, the NVMe driver reports request completions to upper-layer software (❿) and acknowledges interrupts by updating the CQ doorbell (⓫).

2.2 Motivation: Cost-Utilization Dilemma

High cost of SSD. An obvious trend in SSD advancement is that SSD manufacturers tend to integrate numerous computing resources within SSDs to conduct firmware tasks rapidly, thereby boosting I/O performance. Figure 3a presents the computing power of embedded processors in varied SSD controllers on Dhrystone v2.1 benchmark [120]. The results show that the computing power of embedded processors has increased exponentially over the last decade. Moreover, enterprise SSDs [73, 91] typically demand 1 GB onboard DRAM per TB flash capacity to accommodate their entire metadata (mainly the FTL mapping table) for fast access. These abundant computing resources cause high *bill of material (BOM)* costs of SSDs. For instance, the computing resources (i.e., SSD controllers and DRAM) account for 23.2% and 31.8% of BOM costs to manufacture 4 TB PCIe 4.0 SSDs and PCIe 5.0 SSDs [27, 67, 113, 114] (cf. `Compute` in Figure 3b).

Low utilization of JBOF. Contrary to the continually increasing burst performance demands and BOM costs, SSD utilization in JBOF remains low due to the sporadic nature of I/O bursts. Quantitative analysis reveals that in any uptime of a Tencent storage server equipped with 25 drives [134], the probability of at least 20 drives being underutilized (i.e., under 75% bandwidth utilization) is 94.6% (cf. Figure 3c). This is because in modern cloud platforms, especially the Infrastructure-as-a-Service (IaaS) cloud [66, 86], storage drives are commonly allocated (or sold) to different tenants. These tenants utilize their own drives to serve varied applications with diverse I/O patterns, which experience I/O bursts at different times [99, 107]. This phenomenon also exists in other storage servers over diverse storage service providers. As depicted in Figure 3d, the average drive bandwidth utilization is only 8.0%, 27.8%, and 15.3% in Alibaba [2], Tencent [134], and Fujitsu [56] clusters, respectively.

3 Preliminary Study

3.1 Simple Solution and Challenge

The cost-utilization dilemma inspires future SSD and JBOF designs to be cost-efficient. Ideally, future SSDs may only reserve moderate hardware resources at low BOM costs while achieving required I/O performance by harvesting underutilized resources within the same JBOF.

JBOF consisted of host-managed SSDs. *Host-managed SSD (HMSSD)*, such as open-channel SSD (OCSSD) [12,

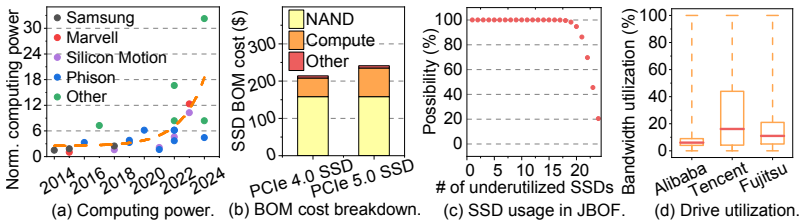

Figure 3: Analysis of the cost-utilization dilemma.

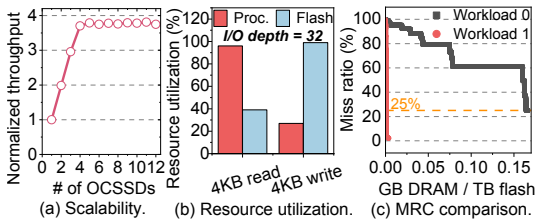

Figure 4: Preliminary study.

86, 87, 107], zoned-namespace (ZNS) SSD [11], and DirectFlash [105], is a representative SSD architecture that retains minimum hardware (e.g., flash controller and flash backbone) in SSD while relying on host computing resources and user-specified driver to conduct firmware tasks and cache metadata. Although HMSSD is superior in low cost, it, unfortunately, hampers scalability and compatibility. To be specific, the tens of HMSSDs in JBOF cause substantial computing overhead, compelling the centralized and limited host resources to become the performance bottleneck. Here we take OCSSD-based JBOF as an example, for its mature software support (i.e., Linux LightNVM [63]). Figure 4a shows the aggregated throughput of a 16-core-DPU-enabled JBOF with varying numbers of OCSSDs (cf. § 5.1 for experimental setups). The performance of the JBOF gets saturated with only 4 SSDs, because of the limited host resources. Note that, even for other JBOF products equipping costly x86 CPUs, the average resource for each OCSSD is also restricted (e.g., two 24-core CPUs for 97 SSDs in Dell PowerStore 500T [22]). In production environments, applications also compete for the essential host resources, further exaggerating the scalability crisis. Moreover, HMSSD-based JBOF faces severe compatibility issues as it requires huge manpower for OS and application adaptation to explicitly conduct firmware tasks, preventing it from wide deployment [4].

SSD virtualization and harvesting. A more scalable and compatible solution is SSD virtualization [7, 21, 75, 88, 126] and harvesting [5, 58, 86, 96, 107, 119]. Specifically, although SSDs in JBOF are logically allocated to different tenants for separate use, an extra storage virtualization layer in hypervisor [86, 107] can harvest the resources of idle SSDs by dynamically grouping busy SSDs (named *borrower*) and several idle SSDs (named *lenders*) as virtual SSDs. Thereafter, user write requests originally targeting the borrower can spread across both the borrower and lenders through the virtual SSD abstraction, thereby achieving higher burst write performance and SSD utilization. Note that the written data is temporarily stored in the storage space of the lenders. Once the burst period concludes, data should be copied back to the borrower to restore space ownership of the lenders [86].

Challenges. While this approach succeeds in harvesting idle resources, it unfortunately faces prominent challenges:

• *Coarse-grained SSD harvesting causes resource stranding issues* ***(Challenge 1)***. We analyze the pressure of different I/O tasks on SSD internal computing (i.e., ARM processor and DRAM) and flash (i.e., flash channels) resources, the results of which are shown in Figures 4b and 4c. 4 KB sequential reads on a real DaisyPlus SSD (cf. § 4.6 for details) consume 96% of the processor clocks while merely utilizing 39% of flash clocks (cf. Figure 4b). In comparison, 4 KB sequential writes are flash-intensive (99%), while leaving the processor underutilized (27%). Moreover, Figure 4c illustrates the *miss ratio curve (MRC)* [95, 117] of LRU-based metadata (i.e., FTL mapping table) cache in onboard DRAM. `Workload 1` [134] only consumes 0.001 GB DRAM (per TB flash) to achieve a 25% miss ratio, while that is 0.17 GB for `Workload 0`. In conclusion, different I/O tasks can impose varying levels of pressure on computing and flash resources within SSDs. Unfortunately, upper-layer software treats SSDs as monolithic black boxes, which leads to resource stranding issues. For example, when the flash backbone of an SSD is heavily engaged in 4 KB write bursts, its computing resources may remain idle. These idle resources cannot be lent to other SSDs in the simple approach because the entire SSD is considered busy.

• *Limited profit in read-dominated workloads* ***(Challenge 2)***. Our evaluation reveals that the simple virtualization and harvesting approach only brings 0.5% and 0.8% throughput improvements in Tencent [134] and Alibaba [2, 23] workloads, respectively, where read requests dominate the I/O (cf. § 5.2). This is because the target data of read requests is exclusively stored in the borrower's flash backbone. Lenders cannot assist the borrower in serving read requests due to the lack of the target data in the lenders' flash backbone.

• *High overheads brought by written data copyback* ***(Challenge 3.1)*** *and resource management* ***(Challenge 3.2)***. In our tests, the simple approach causes 0.29 more drive writes per day (DWDP) on Tencent traces [134]. This is because, when lenders are reclaimed, the hypervisor must copy the written data back to the borrower for availability [86]. These extra writes lead to 22.5% shorter SSD lifetime for enterprise SSDs [91] typically with 1 DWDP endurance. Moreover, the centralized virtual SSD management in hypervisor can introduce substantial software overhead [52, 86], which compels the host CPU to become the performance bottleneck and causes severe throughput loss (e.g., 21.4% in Tencent [134]).

3.2 Key Insight: Compute Express Link

CXL outline. *Compute eXpress Link (CXL)* [19] is an advanced interconnect standard designed to facilitate high-performance and cache-coherent communication among the

host and various peripheral devices (e.g., SSD) [42, 59, 131]. CXL comprises three sub-protocols: *CXL.io* undertakes PCIe backward-compatible operations; *CXL.cache* empowers cache coherence in CXL fabric; *CXL.mem* enables device memory to be accessed by the host and other devices via `load/store` instructions. For higher scalability, CXL 3.0 [20] introduces port-based routing and multi-level switching. These new features extend CXL fabric to rack-level and enable cache-coherent peer-to-peer communication among up to 4096 points (i.e., hosts or devices). In this work, we conform to CXL 3.0 standard and equip SSDs with all three sub-protocols (i.e., as CXL Type-2 devices [39]), enabling cache-coherent memory access within the entire JBOF.

Opportunities. Recognizing the black-box constraint of conventional SSDs, we can first disaggregate the hardware resources of SSDs into multiple disjoint parts and then expose these parts separately to the host and other SSDs through the high-speed CXL interconnection. This design facilitates fine-grained resource management, laying a foundation to tackle the resource stranding issues (solution of ***Challenge 1***). Additionally, with the support of cache-coherent memory access, the lender's processor can help the borrower handle I/O requests (e.g., command parsing and address translation) by directly operating the borrower's metadata stored in its onboard DRAM through CXL fabric. Moreover, the borrower can cache parts of its mapping table in the lender's DRAM for a lower miss ratio. This method benefits both reads and writes and avoids data copyback overhead (solution of ***Challenges 2 and 3.1***), as it only harvests the stateless computing resources (i.e., processor and DRAM) to accelerate metadata processing, without redirecting data. Finally, we can exploit the cache-coherent memory to facilitate efficient inter-SSD communication. Thereafter, a self-governing and decentralized SSD resource management scheme can be implemented to alleviate the CPU burden imposed by the centralized virtualization and harvesting (solution of ***Challenge 3.2***).

4 Design and Implementation

Inspired by the aforementioned preliminary analysis, we propose *Espresso*, a novel JBOF design that facilitates fine-grained, high-profit, and low-overhead inter-SSD resource sharing to tackle the cost-utilization dilemma.

4.1 Overview

Target scenarios. Espresso is designed for DPU-based JBOF (cf. § 2.1) to enjoy its extraordinary energy and cost efficiency, aligning with the objective of this paper. In such systems, SSDs are typically allocated to different tenants for separate use and accessed as raw devices. Simultaneously, an elastic resource management mechanism is required to achieve higher utilization [86]. Espresso designs can also benefit high-performance storage servers by enabling resource sharing

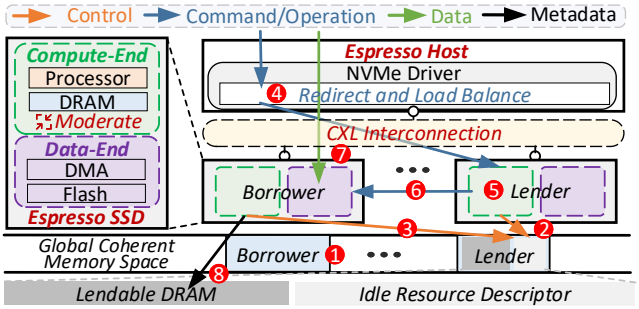

Figure 5: Overview of Espresso.

at the SSD level, thereby simplifying upper-layer software implementations and freeing host computing resources for other components of the storage stack.

Base components. Figure 5 illustrates the overview of Espresso. Compared with existing JBOF designs, there are four main differences: (1) Espresso replaces conventional PCIe interconnections with CXL to enjoy its high performance and cache coherence; (2) Espresso breaks the black-box constraint of traditional SSDs and enables fine-grained management of SSD internal resources (§ 4.2); (3) Espresso only reserves moderate computing resources (i.e., weaker processor and smaller DRAM) within each SSD at low BOM cost while satisfying burst I/O performance demands via resource harvesting; (4) Espresso makes a minor modification to the host NVMe driver for I/O redirection and load balance. For simplicity, we assume SSDs in Espresso are homogeneous (i.e., equipping the same hardware and running the same firmware), matching the common practice in JBOF markets [110]. We will discuss heterogeneous scenarios in § 6.

Workflows. During device initialization (e.g., system reboot [80]), each SSD exposes portions of its onboard DRAM via CXL interconnections. These exposed DRAM make up a global coherent memory space, facilitating inter-SSD communication (❶). Afterward, if an SSD is idle (i.e., *lender*), it calculates how many computing resources (i.e., processor and DRAM) can be lent out and announces this availability by writing its *idle resource descriptors* (❷, § 4.3). When the computing resources in one SSD (i.e., *borrower*) are in short supply (e.g., an I/O burst comes or a high DRAM miss ratio occurs), it searches all other SSDs' idle resource descriptors and chooses a lender for resource harvesting (❸, § 4.3). This step can be repeated multiple times to borrow more resources from multiple SSDs. For processor harvesting (§ 4.4), the host NVMe driver redirects portions of NVMe I/O commands originally targeting the borrower to the lender (❹). The lender then assists in serving I/O commands with its idle processor by operating the borrower's metadata (❺). Subsequently, the lender sends DMA and flash operations to the DMA engine and flash controller of the borrower (❻). The borrower then executes these operations to transfer data **directly** between the host and its flash backbone, without passing through the lender (❼). For DRAM harvesting (§ 4.5), the borrower can directly cache parts of its mapping table in the lender's

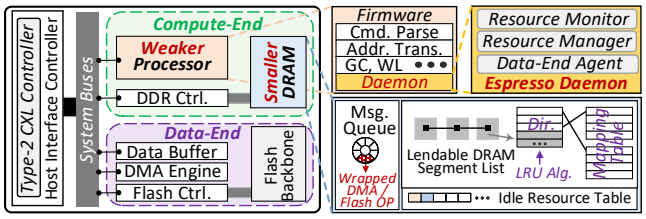

Figure 6: Disaggregated SSD architecture.

DRAM (❸). This harvested DRAM improves the cache hit ratio and reduces access to the slow flash backbone for the mapping table, leading to a higher I/O performance. SSD internal housekeeping tasks (e.g., garbage collection [123] and bad block management [47]) occur infrequently and consume fewer computing resources than I/O handling. Therefore, in Espresso, these tasks are executed by the borrower itself without resorting to the lender. However, when an SSD is busy with housekeeping, it can borrow computing resources for I/O handling, mitigating performance impacts.

4.2 Disaggregated SSD Architecture

Conventional SSDs are black boxes in which the onboard computing and flash resources are tightly coupled and invisible to external systems. This agnostic causes resource stranding issues (cf. § 3.1). Tackling this challenge, Espresso employs a disaggregated SSD architecture that decouples SSD into two disjoint parts: *compute-end* and *data-end*, as shown in Figure 6. Compute-end comprises computing resources, such as ARM processor, DDR controller, and onboard DRAM. It is responsible for executing SSD firmware tasks (e.g., I/O parsing and address translation). Data-end encloses flash resources (e.g., flash controller and backbone) and data-related components (e.g., DMA engine and data buffer). This part is in charge of data transfer and flash I/O. Moreover, a Type-2 CXL controller [39] is employed to facilitate CXL-related operations, such as exposing onboard DRAM to the host and peer SSDs in Espresso and operating the exposed DRAM of other SSDs coherently. Specifically, during system initialization, the CXL controller of each Espresso SSD registers its local DRAM as *global fabric-attached memory (G-FAM)* to the CXL fabric manager (FM) [20]. Afterward, SSD processor can access peer SSDs' G-FAM via `load/store` instructions (e.g., `LDR/STR` in `aarch64` ISA [25]), which will be interpreted as CXL `MemRd/MemWr` requests and then executed by the CXL controller. Moreover, the CXL controller is responsible for maintaining the coherence of the SSD's local DRAM with `BISnp` and `BIRsp` requests (i.e., in HDM-DB mode [20]).

In the compute-end, an *Espresso daemon* is implemented in SSD firmware and runs on the ARM processor. It contains three components: (1) A *resource monitor* is deployed to monitor the resource utilization of both compute-end and data-end. Specifically, for compute-end, the resource monitor periodically (e.g., 10 ms) polls the Performance Monitor Unit (PMU) [17, 24] of the ARM processor to track its utilization (i.e., busy clocks). DRAM resource is measured by the miss ratio of mapping table lookup. For data-end, the resource monitor gets utilization from the embedded flash monitor module, which is typically implemented as channel-level hardware busy clock counters in existing flash controller designs [51, 104]. Espresso takes the average utilization across all flash channels; (2) A *resource manager* is employed to borrow or lend computing resources based on the current utilization reported by the resource monitor; (3) A *data-end agent* bridges lender's compute-end with borrower's data-end. To be specific, the borrower's data-end agent maintains portions of onboard DRAM as globally visible message queues [94]. Thereby, the lender's compute-end can access the borrower's data-end by enqueueing wrapped DMA and flash operations (cf. § 2.1) to the borrower's message queues. The borrower's data-end agent then dequeues and unwraps these operations and sends them to the DMA engine and flash controller for data transfer and flash I/O.

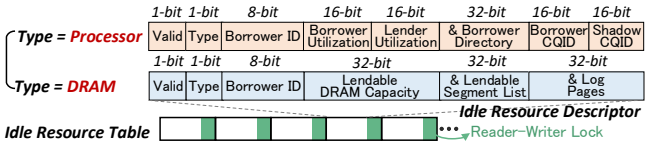

Figure 7: Data structures for resource management.

4.3 Decentralized Resource Management

As shown in Figure 7, each Espresso SSD maintains portions of its onboard DRAM as *idle resource table*, consisting of multiple *idle resource descriptors*. These data structures are visible to the host and all peer SSDs in Espresso and are synchronized with reader-writer locks [13] (i.e., a `pthread_rwlock_t` for each idle resource descriptor in C program). There are two formats of idle resource descriptors used to describe idle processor and DRAM resources, respectively. Both contain five messages: (1) One valid bit points out whether this descriptor is valid; (2) One type bit presents the type of idle computing resources (i.e., processor or DRAM); (3) 8 bits record the identification of the borrower (0xFF means that the resource has not been borrowed). Espresso assigns a unique identification to each SSD during device initialization [80]; (4) 32 bits depict the amount of idle resources. Specifically, for idle processor, these 32 bits are used to indicate the current processor utilization of both the borrower and the lender (16 bits for each) for load balance (cf. § 4.4). Both the lender and the borrower will update this field periodically (e.g., 10 ms) after harvesting begins. For idle DRAM, these 32 bits indicate the capacity of the lendable DRAM, maintained by the lender; (5) 64 bits record the essential information for resource sharing. In particular, for idle processor, 32 bits indicate the address of the borrower's mapping table directory, while the other 32 bits record the CQIDs of borrower CQ and shadow CQ (16 bits for each) for I/O redirection (cf. § 4.4); For idle DRAM, 32 of the 64 bits

point to the header of the lendable DRAM segment list, while the other 32 bits point to the start address of log pages for crash consistency (cf. § 4.5).

With the aforementioned data structures, Espresso enables decentralized resource management. Specifically, SSDs in Espresso can lend out their idle resources by writing the idle resource descriptors with writer locks. Moreover, resource borrowing is facilitated by searching the idle resource tables of all peer SSDs with reader locks and choosing one (or more) idle SSD based on best-fit algorithm [98] to harvest (i.e., writing the borrower identification of the chosen idle resource descriptor with writer lock). If the borrower no longer requires the borrowed resources (e.g., I/O burst completes), it sets the borrower identification of the idle resource descriptors to 0xFF. In turn, if the lender no longer wants to lend resources, it tags the valid bit of the descriptor as invalid. The lender, borrower, and host need to periodically check and update the idle resource descriptor according to current resource utilization and take corresponding actions to start and end harvesting (cf. § 4.4 and § 4.5). Note that Espresso does not require accurate clock synchronization among lender, borrower, and host. However, if the synchronization period is too long, Espresso may suffer from delays in the start and end of harvesting, thereby affecting performance (e.g., when a lender stops lending resources due to bursts, if the borrower and host fail to synchronize in time, some borrower's requests will still be redirected to the lender, causing resource contention). We empirically set the period as 10 ms with a trade-off between this performance loss and the synchronization overhead.

4.4 Transparent Processor Harvesting

Trigger conditions. Espresso SSD triggers processor resource harvesting based on the busy status of both the processor and data-end, as summarized in Table 1. They are regarded as busy if their current utilization exceeds a configurable watermark (e.g., 75%), otherwise considered underutilized. If both the processor and the data-end are busy (❶), the SSD does nothing as it has no available processor for sharing. Also, borrowing extra processor yields minor as the data-end has been exhausted. In comparison, whenever the processor is underutilized (❷ and ❸), the SSD can lend out this resource. This can happen when the SSD is bottlenecked by the flash backbone (❷) or the whole SSD is idle (❸). Lastly, if only the processor is busy (❹), the SSD can borrow processor resources to maximize the I/O parallelism of the data-end, achieving a higher throughput. Correspondingly, SSDs cancel borrowing or lending when the status of their resources no longer satisfies the above trigger conditions.

Transparent I/O redirection. Espresso harvests idle processors by redirecting parts of the borrower's NVMe I/O commands to the lender. The lender then locates the borrower's mapping directory and table with the address recorded in the idle resource descriptor (cf. § 4.3). Afterward, the lender can

ID	Processor	Data-end	Action	Possible reason
❶	Busy	Busy	None	Mixed I/O burst
❷	Underutilized	Busy	Lend out	Write burst (cf. § 3.1)
❸	Underutilized	Underutilized	Lend out	No I/O arrives
❹	Busy	Underutilized	Borrow in	Read burst (cf. § 3.1)

Table 1: Trigger conditions of processor harvesting.

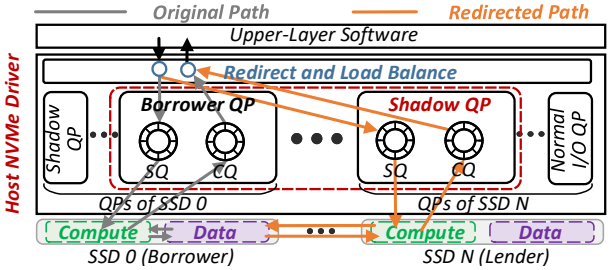

Figure 8: Transparent I/O redirection.

access the borrower's mapping tables and help serve I/O commands with its idle processor. Espresso SSD employs fine-grained locks to enable efficient inter-SSD synchronization of the mapping table, inheriting from prior multi-core SSD designs [133]. Espresso realizes I/O redirection by slightly modifying the host NVMe driver, which is the unique entrance of NVMe SSDs. This modification is transparent to the upper-layer applications (e.g., file system), ensuring compatibility. As shown in Figure 8, when initializing NVMe SSDs [80], Espresso reserves a few NVMe I/O queue pairs (QPs, each enclosing an SQ and a CQ) of each SSD as *shadow QPs*. When lending processor resources, the lender points out the identification (e.g., CQID [79]) of one of its shadow QPs in the idle resource descriptor. Subsequently, the borrower chooses one of its normal I/O QPs (named *borrower QPs*) for I/O redirection and also records its identification in the idle resource descriptor (cf. § 4.3). Thereafter, the host NVMe driver binds the borrower QP with the shadow QP, and submits parts of NVMe I/O commands targeting the borrower SQ to the shadow SQ. Following this, the lender fetches NVMe I/O commands from the shadow SQ and helps handle these commands. In the backward, the NVMe driver collects results from both borrower CQ and shadow CQ and then commits I/O completions to upper-layer software. When ending harvesting, the host NVMe driver no longer redirects I/O commands to the shadow SQ. Once all I/O commands within the shadow QP are completed, the host unbinds the shadow QP from the borrower QP, leaving them for future resource harvesting.

Holistic load balance. The host NVMe driver selectively redirects I/O commands to the lender with a holistic load balance algorithm. This algorithm is two-fold. On the one hand, the NVMe weighted round-robin (WRR) feature [80, 121] enables setting a weight for each NVMe I/O SQ, which indicates the priority of command fetching. For example, if the weights of two SQs are 2 and 1, respectively, the SSD serves two I/O commands from the former SQ and then serves one command from the latter. With this feature, Espresso can assign the shadow SQ of the lender with a low weight if it wants to minimize the performance impact on the lender's

own I/O. On the other hand, the host reads the idle resource descriptor periodically (e.g., 10 ms) to figure out the current processor utilization of both the borrower and lender (cf. § 4.3). Then, it controls the number of NVMe I/O commands sent to the borrower and lender with the following formula:

$$\frac{N_{borrow}}{N_{lend}} = \frac{U_{lend}}{U_{borrow}} \times \frac{\sum_{lend} W}{W_{shadowSQ}} \times \frac{W_{borrowSQ}}{\sum_{borrow} W}$$

N_{borrow} and N_{lend} represent the numbers of I/O commands sent to the borrower and lender, respectively. U_{borrow} and U_{lend} are the processor utilization of the borrower and the lender. $W_{borrowSQ}$ and $W_{shadowSQ}$ represent the weights of the borrower SQ and the shadow SQ. Lastly, $\sum_{borrow} W$ and $\sum_{lend} W$ are the total weights of all NVMe I/O SQs in the borrower and the lender. With this formula, Espresso can balance processor utilization by selectively redirecting I/O commands. For example, if N_{borrow}/N_{lend} is 3, Espresso redirects I/O commands to the lender with a 25% probability.

4.5 Persistent DRAM Harvesting

Trigger conditions. Espresso SSD manages DRAM resources in *segments* (2 MB by default) and caches mapping table with LRU replacement algorithm. Espresso SSD decides whether to borrow or lend DRAM based on the miss ratio curve (MRC) of current mapping table lookup patterns. Specifically, Espresso SSD adopts SHARDS [117], a lightweight and efficient algorithm, to predict MRC online. Based on the predicted MRC, SSD can lend out all the spare DRAM segments, which has no help on a lower miss ratio (i.e., the cached mapping table will not be accessed in the near future), minimizing the effect of cache pollution from the borrower. Moreover, SSD tries to borrow sufficient DRAM that reduces its miss ratio to below a given threshold (e.g., 10%). Correspondingly, lender reclaims DRAM when it predicts more DRAM in need to achieve a lower miss ratio. In turn, borrower returns DRAM when its local DRAM is sufficient to keep the miss ratio within the given threshold.

Crash consistency. Borrower harvests DRAM by temporarily caching parts of its mapping table in lender's lendable DRAM segments (i.e., as recorded in the idle resource descriptor, cf. § 4.3). In turn, borrower needs to read back the *offsite metadata* (i.e., the mapping table cached in the lender's DRAM) to its flash backbone when ending harvesting. While this idea can be facilitated by the cache-coherent capability of CXL, there still remains an open question in practice, that is, how to guarantee crash consistency of the off-site metadata. To be specific, for high availability, enterprise SSDs are typically demanded to deliver *power loss protection (PLP)* [80]. When an SSD suddenly loses power [77, 116, 135], the power hold-up circuit and capacitor in the SSD (e.g., the 2.3 mF tantalum capacitor in Samsung 845DC SSD [89]) immediately flushes the data and metadata buffered in the processor cache and onboard DRAM to the persistent flash backbone. This design ensures crash consistency of the SSD. However, if the borrower's dirty mapping table is exclusively cached in lender's DRAM, the borrower cannot provide PLP to the offsite metadata. For instance, if the lender SSD is permanently unplugged from the JBOF, the borrower cannot recover its mapping table to locate data and thus suffers from data loss (or needs sophisticated reconstruction through special hardware [37, 138]).

Tackling this issue, Espresso deploys a log-based crash consistency mechanism to protect the offsite metadata. In particular, when DRAM harvesting begins, the borrower vacates a 4 KB log page in its local DRAM for each harvested DRAM segment. Afterward, whenever modifying offsite metadata in the harvested segment, the SSD, either borrower or lender, needs to commit a log (e.g., redo log [33]) to the log page associated with the segment. Moreover, lenders need to ensure the log has been written back to the borrower with cacheline flush instructions. When the log page of a harvested DRAM segment is full, the segment will be flushed back to the borrower's flash backbone, after which the corresponding log page can be cleared and reused. Note that while the log operation introduces extra memory write overhead, it is relatively minor (i.e., hundreds of *ns*) compared to the flash I/O (i.e., tens of μs) caused by DRAM miss. If the lender fails (e.g., multiple I/O timeouts occur [80]), the host NVMe driver first notifies the borrower to recover its offsite metadata by replaying the logs in the local log pages. Afterwards, NVMe driver resubmits in-flight NVMe I/O commands in the shadow SQ to the borrower and then unbinds the borrower QP with the shadow QP. If the borrower fails, the host NVMe driver first notifies the lender to recycle the lent resources by clearing the harvested DRAM segments and resetting the corresponding idle resource descriptors. Subsequently, NVMe driver clears the corresponding shadow QP, leaving it for future harvesting.

4.6 Implementation

Cache coherence region. In Espresso, data are transferred without cache coherence using CXL.io sub-protocol [20]. However, Espresso does necessitate cache coherence among the host and SSDs for the following metadata: (1) the message queues within the data-end agent (cf. § 4.2), accounting for 128 KB per SSD by default; (2) the idle resource table (cf. § 4.3), which takes 256 B per SSD; (3) the cached mapping table and its auxiliary structures (e.g., locks). As will be shown in § 5.4, 0.25 GB per TB flash capacity is sufficient (i.e., 12 GB for twelve 4 TB SSDs).

Note that CXL standard does not mandate a specific implementation of hardware-managed cache coherence. Espresso employs a directory-based approach [1], in which the hardware overhead primarily depends on the number of cachelines that need to be tracked simultaneously. This is proportional to the number of in-flight requests of the borrower in Espresso, rather than the total metadata size. Our default setting employs 1 K directory entries to track 64 KB cache per SSD.

Prototype. We implement the host-side design of Espresso (e.g., I/O redirection and load balance, cf. § 4.4) in the NVMe driver of Linux kernel v5.15 [62], following the NVMe specification [80]. Due to the lack of publicly available CXL 3.0 hardware, we validate the firmware-side modification of our disaggregated SSD designs on DaisyPlus OpenSSD board [51, 112], a PCIe-based SSD development platform. This board integrates a quad-core ARM Cortex-A53 processor, 2 GB DRAM, and adequate FPGA resources. SSD firmware runs on the ARM processor, while the host interface controller and flash controller are implemented on the FPGA part. We inherit the core functionalities (e.g., garbage collection) of the SSD firmware (in C language) from DaisyPlus, but modify the I/O path to realize Espresso daemon. The data-end agent takes 114.2 ns, on average, to dequeue and unwrap a DMA/flash operation from the message queue in local DRAM (cf. § 4.2). Also, it takes 321.9 ns to commit a redo log to the local log pages for crash consistency (i.e., prepare and flush a log to the local DRAM, cf. § 4.5). We cross-validate the performance model used in our simulator and emulator with these results.

Simulator. We use SimpleSSD [100], a popular full-stack simulator, to evaluate Espresso. Prior studies [32, 43] have demonstrated that SimpleSSD can accurately model the performance of host (e.g., CPU and DRAM) and modern SSD components (e.g., embedded ARM processor, DRAM, and flash backbone). We also extend SimpleSSD with our industrial collaborators by 18 K LOC to support lots of detailed SSD techniques, such as incremental step pulse programming [106], SLC cache [115, 130], and read retry [127]. These efforts ensure the accuracy of the simulator. To evaluate the CXL fabrics, we integrate Xerxes [6], a cycle-accurate CXL simulator, which can accurately model the features defined in CXL 3.0 standard [20]. We use McPAT [60] and DRAMPower [14] to examine energy consumption.

Emulator. For cross-validation, we also port Espresso to a NUMA-based emulation platform. As recommended by prior work [58, 59, 83, 132], we mimic CXL fabric with cross-NUMA access and emulate each SSD with a dedicated socket (i.e., Intel Xeon 8562Y+ CPU [38]) running NVMeVirt [49], a popular SSD emulator. However, constrained by the number of sockets (e.g., 2), such an emulation platform cannot accurately mimic the tens of SSDs in JBOF. Therefore, we opt to conduct most of our evaluation on the simulator, while taking a NUMA emulation in § 5.6.

5 Evaluation

5.1 Experimental Setup

System configurations. As listed in Table 2, we configure the simulated JBOF system based on SuperMicro SSG-229J-5BU24JBF [110], one of the up-to-date JBOF products, which supports at most 12 SSDs per DPU. The simulated DPU contains a 16-core 2.1 GHz ARM processor and 16 GB DRAM, aligning with BlueField-3 [78], and acts as JBOF host (cf. § 2.1). The simulated SSD follows the configuration of commodity storage device [18, 71, 91], which delivers 14 GB/s and 10 GB/s peak read and write bandwidths. The SSD's processor encloses 6 ARM cores with `aarch64` ISA [25] running at 1 GHz frequency. In addition, its onboard DRAM can accommodate entire mapping table (i.e., 1 GB per TB flash). DPU and SSDs are connected with CXL fabric in tree topology (cf. Figure 9).

Host	16-core 2.1 GHz ARM processor and 16 GB DDR5-5600 DRAM		
SSD	**Performance**	**ARM processor**	**Flash backbone**
	Read/Write: 14/10 GB/s	6 Cores @ 1 GHz ISA: aarch64 (ARMv8)	8 Channel (2400 MT/s, 8-bit) / 8 Die / 4 Plane / 1024 Block / 1024 Page / 16 KB, 4TB in total

Table 3: Workload characteristics.

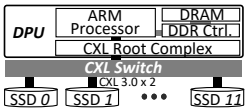

Figure 9: Topology.

JBOF platforms. We compare Espresso with six other designs. (1) `Conv`: conventional JBOF design, in which all SSDs equip abundant computing resources (i.e., 6 ARM cores and 1 GB DRAM per TB flash) for high I/O parallelism; (2) `OC`: OCSSD-based JBOF design that reserves minimum computing resources in SSDs but utilizes host resources to execute firmware and cache metadata (cf. § 3.1); (3) `Shrunk`: compared to `Conv`, it **shrinks** the computing resources in each SSD. By default, it halves the resources (i.e., 3 ARM cores and 0.5 GB DRAM per TB flash). We also evaluate different reservation settings in § 5.4; (4) `VH`: based on `Shrunk`, it uses the simple virtualization and harvesting approach (cf. § 3.1) to improve I/O performance; (5) `VH(ideal)`: an ideal variant of `VH`, in which no copyback is required; (6) `ProcH`: `Shrunk` with our processor harvesting designs (cf. § 4.4); (7) `Espresso`: a cost-efficient JBOF design that includes all the techniques proposed in this paper. It reserves the same amount of computing resources in each SSD as `Shrunk` (i.e., **half** of the computing resources in each SSD of `Conv`).

Workloads. We conduct evaluations with both microbenchmarks and various real workloads collected from production environments [3, 45, 56, 102, 122, 134]. Table 3 lists their key characteristics. To intuitively demystify the interactions between borrowers and lenders, we run workloads on 6 of the 12 SSDs (i.e., `borrowers`) by default, while keeping the other

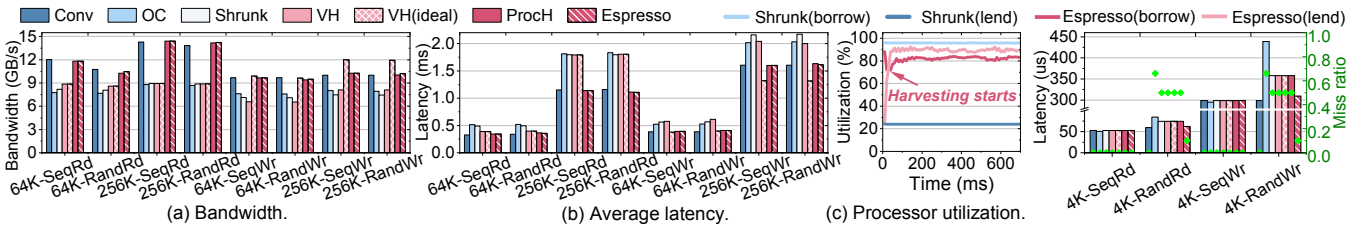

Figure 10: Performance benefits of processor harvesting.

Figure 11: DRAM harvesting.

6 SSDs idle (i.e., `lenders`). We also take sensitivity studies on varied numbers of borrowers and lenders in § 5.4 and examine complex scenarios where all 12 SSDs have different workloads in § 5.5. To demonstrate end-to-end performance improvement brought by our designs, we conduct comparisons on varied application instances in § 5.6.

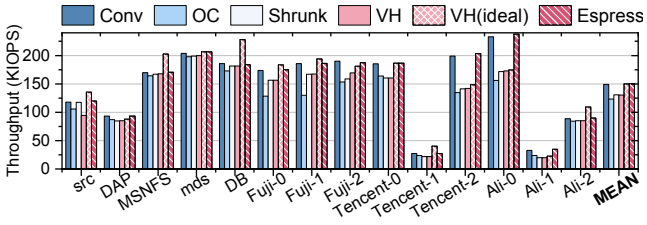

Figure 12: Throughput comparison in real workloads.

5.2 Benefit Analysis

Processor harvesting. Figure 10 illustrates the throughput and average latency comparison in microbenchmarks. For simplicity, we present the average performance of the 6 SSDs that run workloads (i.e., `borrowers`). We set the I/O depth as 64 to mimic the throughput-intensive scenarios and examine different I/O sizes from 64 KB to 256 KB. In comparison to `Conv`, `OC` and `Shrunk` suffer 27.8% and 29.2% throughput loss in all workloads, on average. Similar deterioration can also be observed in the latency comparison (i.e., 44.1% and 46.4% higher). This is because the insufficient processor resources in `OC` and `Shrunk` cannot afford such intensive I/O patterns and become the performance bottleneck. `VH` and `VH(ideal)` also lag far behind `Conv` in read workloads, as the simple virtualization and harvesting approach has no help to read requests (cf. § 3.1). Compared with `Shrunk`, `VH` and `VH(ideal)` succeed in improving write performance by redirecting parts of write requests to `lenders`. VH(ideal) can even outperform `Conv` by 10.2%. This can be attributed to the harvested flash resources of `lenders`, as data is temporarily stored in the `lenders'` flash backbone via their flash channels. However, such gains are swept out after copyback occurs. As a result, `VH` still falls behind `Conv` by 25.6%. On the contrary, `Espresso` achieves comparable performance to `Conv` in all workloads with only half of the computing resources. This is because `Espresso` can harvest idle processors of `lenders` for I/O serving. Figure 10c shows the average processor utilization of `borrowers` and `lenders` in 256 KB sequential read test. `Espresso` achieves 50.4% higher utilization than `Shrunk`.

DRAM harvesting. To evaluate how much Espresso can benefit from DRAM harvesting, we set an experiment to analyze the I/O performance in latency-sensitive scenarios (i.e., 4 KB reads and writes). We set the I/O depth to 1 in this test. Figure 11 illustrates the average latency and mapping table miss ratio of different JBOF settings. Without sufficient DRAM to buffer the entire mapping table, `OC`, `Shrunk`, and `ProcH` experience 66.2%, 49.7%, and 49.7% miss ratios in random read workloads, thereby causing 41.4%, 24.7%, and 24.7% higher latencies, compared to `Conv`. Similar degradation also exists in random write tests. The virtualization and harvesting approach (`VH`) does not work for DRAM harvesting. This is because even if redirecting write requests to `lenders`, `lenders` still suffer from the miss penalty due to insufficient DRAM. In contrast, the DRAM harvesting designs (cf. § 4.5) in `Espresso` enable `borrowers` to borrow idle DRAM resources from `lenders` to buffer mapping table. As a result, `Espresso` achieves comparable latencies to `Conv`.

Improvements in real workloads. Figure 12 presents the throughput comparison in diverse real workloads collected from production environments. Compared with `Conv`, `OC` and `Shrunk` suffer 16.2% and 13.4% throughput loss in all workloads, on average, owing to the stressed computing resources. `VH(ideal)` outperforms `Shrunk` in write-dominated workloads (e.g., 15.5% in `src`) via write request redirecting. However, the substantial overhead of data copyback dispels such a mirage. Consequently, `VH` still lags behind `Conv` by 14.0%. In contrast, `Espresso` can aid all workloads with diverse I/O types, eliminating the copyback overhead. Specifically, although employing the same amount of computing resources, `Espresso` outperforms `Shrunk` and `VH` by 19.2% and 20.0%. Moreover, `Espresso` performs better than `VH(ideal)` in some workloads (e.g., `Ali-0`). This is because, in these read-dominated workloads, the requested data resides exclusively in the borrower's flash backbone. Without our harvesting design, lenders cannot assist the borrower in serving read requests due to the lack of the target data in the lenders' flash backbone. `Espresso` also achieves comparable throughput to `Conv` even with only half the computing resources (cf. § 5.1), which proves that our design can satisfy demanded performance targets via inter-SSD resource sharing. Note that in some I/O-intensive workloads, `Espresso` slightly outperforms `Conv` (e.g., 2.0% in `Ali-0`). We attribute this minor difference to the doubled CXL lanes for NVMe command

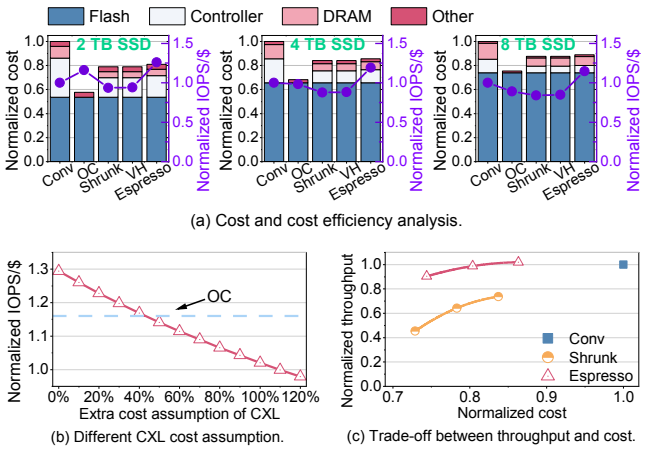

Figure 13: BOM cost evaluation normalized to `Conv`.

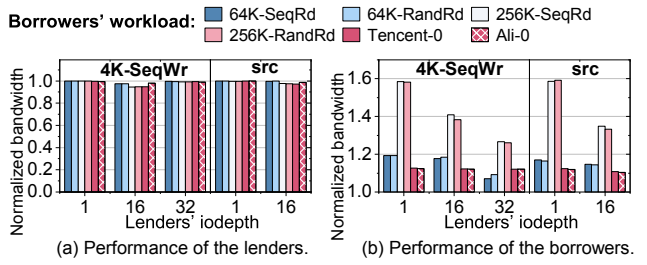

Figure 14: Interaction between lenders and borrowers.

fetching (i.e., `lenders` and `borrowers` in `Espresso` can concurrently fetch commands with their own CXL lanes).

BOM cost saving. We further evaluate the BOM costs of SSDs in different JBOF platforms. According to the current prices on the market [27, 65, 67, 74, 101, 113, 114], we identify the costs of NAND flash, DDR4 DRAM, enterprise SSD controller, and other expenses (e.g., PCB board and packaging) as $4.95 per 128 GB, $7.2 per GB, $48, and $6, respectively. We assume the halved computing resources (i.e., SSD controller and DRAM) in `Shrunk` and `VH` consume halved costs. According to prior work [111], we estimate the prices of CXL-enabled SSD controller and DRAM in `Espresso` are 10% higher than those in `Shrunk` by default. As shown in Figure 13a, `Espresso` succeeds in saving BOM cost by 19.0% for 2 TB SSDs, compared with `Conv`. Although SSDs in `Espresso` are more expensive than those in `OC` and `Shrunk`, such expenses are worth given the improved performance. Figure 13a also depicts the normalized cost efficiency (i.e., IOPS/$) in `Ali-0` workload. `Espresso` outperforms all other designs (e.g., 19.7% higher than `OC`) in this metric. Figure 13b further shows the cost efficiency of `Espresso` under different CXL cost assumptions (i.e., how much more expensive the CXL-enabled SSD controller and DRAM are than those in `Shrunk`). `Espresso` outperforms `OC` as long as the extra BOM costs brought by CXL do not exceed 40%. Figure 13c illustrates the trade-off between throughput and cost of different designs (cf. § 5.4 for how to vary these two parameters). We assume there is a sufficient number of idle SSDs for harvesting. `Espresso`

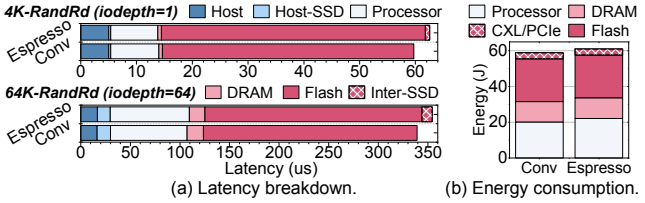

Figure 15: Overhead analysis (latency and energy).

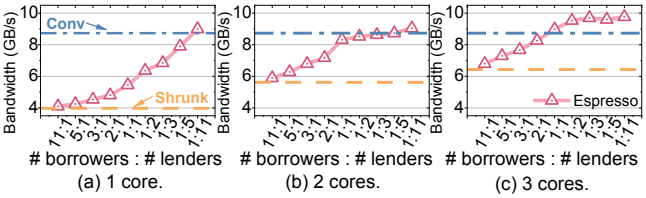

Figure 16: Sensitivity study on different processor resources.

demonstrates better balance between these two metrics than `Conv` and `Shurnk` (i.e., the curve of `Espresso` is more toward the upper-left corner).

5.3 Overhead Analysis

Performance impact on lenders. In this test, we run varied I/O-intensive workloads on `borrowers`, while `lenders` serve moderate I/O requests. We set the I/O depth as 64 for `borrowers` while varying the I/O depth from 1 to 32 for `lenders` to mimic different degrees of I/O pressure. Note that `lenders'` processors are too busy to be lent when running `src` workload in 32 I/O depth. Therefore, we omit this result. Figure 14 presents the throughput of `lenders` and `borrowers` in `Espresso`. We have normalized the results to that of `Shrunk`, where no resource is lent out (i.e., best case for `lenders`) or borrowed in (i.e., worst case for `borrowers`). Resource lending causes negligible performance loss (1.3% on average, cf. Figure 14a) for `lenders`. This is because, with our holistic load balance algorithm (cf. § 4.4), `lenders` can reserve sufficient computing resources to handle their own I/O commands. The throughput of `borrowers` improves 15.5%, 23.3%, and 30.0%, when the `lenders` serve 4 KB sequential writes in I/O depths of 32, 16, and 1 (cf. Figure 14b). This is because, with lighter workloads, `lenders` can lend out more resources to help `borrowers` serve I/O commands.

Extra latency. Espresso designs (e.g., remote metadata access and synchronization) can introduce extra latency. To understand such overhead, we break down the latency of 4 KB and 64 KB random reads into six parts, as shown in Figure 15a. `Host` is the time consumed by the host I/O stack (e.g., NVMe driver). `Host-SSD` is the time for data and NVMe command transfer between the host and SSD. `Processor` is the time consumed to execute SSD firmware (e.g., I/O parsing and address translation). `DRAM` encloses the time of onboard DRAM accesses (e.g., reading mapping table). `Flash` represents the time of flash operations (e.g., flash read). Finally,

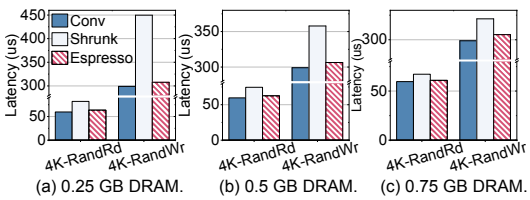

Figure 17: Analysis of varied DRAM resources.

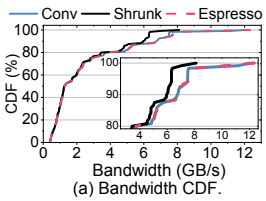

Figure 18: Comparison in complex scenarios.

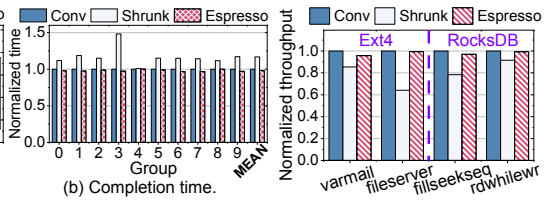

Figure 19: NUMA test.

`Inter-SSD` includes the time taken on the CXL interconnection. In both `Conv` and `Espresso`, `Flash` dominates the latency. Compared with `Conv`, `Espresso` causes 3.3% more `Flash` overhead because of the sporadic DRAM miss (cf. § 5.2). `Espresso` also takes 3.1% more `Processor` time for inter-SSD synchronization. There is no obvious difference in terms of `Host` overhead, thanks to our decentralized resource management scheme (cf. § 4.3). Moreover, Espresso only takes 20 ns more amortized host CPU time for each I/O command to compute the load balance formula for redirecting (cf. § 4.4). `Espresso` takes minor `Inter-SSD` overhead (up to 2.9%), because CXL interconnection has extremely high speed and delivers sub-microsecond remote access.

Energy consumption. Figure 15b illustrates the energy consumption to conduct `Fuji-0` workload of different designs. Compared with `Conv`, `Espresso` takes 3.5% more energy, because of the added Espresso daemon and CXL-enabled inter-SSD communication (cf. § 4.2). However, this minor overhead brings huge rewards, as it allows resource sharing to exploit the idle SSDs in JBOF, thereby achieving required I/O performance with reduced resources and costs (cf. § 5.2).

5.4 Sensitivity Study

Different processor resources. We examine the benefits brought by our designs in different processor resource configurations. For fair comparisons, we equip SSDs in `Shrunk` and `Espresso` with the same capacity of DRAM as SSDs in `Conv`. We vary the number of ARM cores in each SSD of `Shrunk` and `Espresso` from 1 to 3. We also change the ratios of numbers of `borrowers` and `lenders` from 11:1 to 1:11. Figure 16 shows the throughput in `Ali-0` workload. Without inter-SSD resource harvesting, the throughput of `Shrunk` decreases with fewer cores (up to 54.6% degradation in the 1-core setting, cf. Figure 16a). In contrast, `Espresso` achieves comparable throughput to `Conv` when there are enough `lenders` for harvesting. For example, in 2-core tests, `Espresso` achieves 97.7% performance of `Conv` when each `borrower` harvests two `lenders` (i.e., `1:2`). Note that, with excessive `lenders` for harvesting (e.g., when ratio is `1:11`), `Espresso` cannot further boost performance, owing to the limited throughput of flash backbone and overwhelming synchronization overhead.

Different DRAM resources. We reserve different capacities of DRAM in the SSDs within `Shrunk` and `Espresso`. For fair comparisons, we equip SSDs in all JBOF platforms with 6 ARM cores. We assume there is enough number of idle SSDs for DRAM harvesting, which has been witnessed in production environments (cf. § 2.2). Figure 17 illustrates the latency comparison. `Shrunk` experiences 44.0%, 22.3%, and 10.0% higher latency with 0.25, 0.5, and 0.75 GB DRAM per TB flash capacity, respectively. On the contrary, benefiting from our DRAM harvesting designs (cf. § 4.5), `Espresso` only introduces negligible latency increases (3.4% on average).

5.5 Complex Scenario

We examine complex scenarios where all SSDs have their own workloads. We randomly select 12 workloads from Tencent traces [134] as a group, and assign each workload to each of the 12 SSD. We repeat the experiment 10 times. Figure 18a presents the cumulative distribution function (CDF) of throughput across all 120 workloads. Echoing our findings in the previous tests, `Espresso` succeeds in fulfilling the burst I/O performance demands, even with only halved computing resources. To be specific, SSDs in `Espresso` achieve 12.3 GB/s peak throughput, while this value is only 8.1 GB/s in `Shrunk`. Figure 18b shows the workload completion time comparison. `Espresso` shortens at most 34.3% time than `Shrunk`, thanks to our inter-SSD resource sharing designs.

5.6 Application Test on NUMA Platform

We now evaluate Espresso designs on a 2-socket NUMA-based emulation platform (cf. § 4.6). We use one socket to mimic the borrower SSD, while the other socket acts as the lender SSD and the host. We choose Ext4 filesystem [68] and RocksDB [30] as the representative applications of JBOF and run them with `filebench` [31] and `db_bench` [29], respectively. Figure 19 shows the throughput comparison of different designs. Similar to our previous tests, `Espresso` outperforms `Shrunk` by 24.8% and achieves comparable throughput to `Conv` even with reduced computing resources, cross-validating the superiority of our designs.

6 Related Work and Discussion

SSD architecture. Multiple studies [28, 42, 47, 48, 76, 83, 124, 133] have been proposed to renovate SSD architectures. Decoupled SSD [47] decomposes SSD architecture into front-end (i.e., SSD controller) and back-end (i.e., flash backbone) and introduces a network-on-chip to facilitate communication among flash controllers. It improves the efficiency of

SSD internal data movement (i.e., garbage collection). In contrast, Espresso disaggregates SSD components based on their functionalities to enable fine-grained resource management and sharing. XHarvest [83] renovates SSD architecture and achieves high I/O performance through secure host resource harvesting. On the contrary, Espresso satisfies performance requirement via inter-SSD resource sharing.

Communication protocol. NVMe is the de facto communication protocol for most high-performance SSDs. We opt to implement I/O redirection and load balance on NVMe protocol to be compatible with existing I/O stacks, avoiding excessive software modification. To adapt to prior works [42,54,59,124,131] that access SSDs via `load/store` instructions, a similar I/O redirection and load balance mechanism can be implemented in the memory access path (e.g., the memory management subsystem of Linux kernel [64]).

Storage virtualization. Great efforts [36, 75, 86, 107] have been taken to virtualize storage devices and improve their utilization. BlockFlex [86] and FleetIO [107] enhance SSD utilization by harvesting idle flash resources, thereby facing critical challenges, such as limited read profit and huge data copyback overhead (cf. § 3.1). In contrast, Espresso focuses on the stateless computing resources and enables general and lightweight inter-SSD resources sharing with CXL fabric.

RAID. RAID [15] is a storage organization scheme that distributes I/O requests across multiple SSDs to improve utilization. However, RAID also treats SSDs as black boxes, which prevents fine-grained utilization of SSD internal resources, leading to stranding issues (cf. § 3.1). Moreover, RAID has been widely criticized for its substantial software overhead on the centralized host, resulting in poor scalability [41,128,129]. In contrast, Espresso enables fine-grained resource harvesting and supports decentralized and SSD-governing resource management, achieving high scalability. Additionally, Espresso is aimed to maximize the utilization of the underlying storage hardware (i.e., JBOF), which are effective to any types of software storage organizations (e.g., RAID) that users adopt.

JBOF with heterogeneous SSDs. Our design can be adapted to JBOFs comprised of heterogeneous SSDs (i.e., equipping different firmware and computing resources) with minor revisions. Specifically, the borrower can expose its firmware tasks as non-decompilable executable files [55, 125] in trusted execution environments (TEE) [8, 44, 83]. Therefore, the lender can seamlessly execute the borrower's firmware tasks with its general-purpose ARM processor while ensuring security. Considering the computing power disparity of varied SSDs, Espresso can replace the busy indicator (which is processor utilization now, cf. § 4.4) with a more general and absolute metric (e.g., current waiting queue depth) for load balance. Similar designs can also be applied in scenarios where SSD manufacturers are reluctant to expose SSD firmware details. Note that Espresso host only needs to know the current status of SSDs (e.g., idle resource table), which can be exposed via standardized specifications (e.g., NVMe Telemetry logs).

Espresso with future CXL. Considering the hardware cost, the trend of CXL evolution is toward supporting coherence over only portions of the memory region [9,57,136,137]. The limited coherence requirements of Espresso (cf. § 4.6) are aligned with this trend. One can further shrink the cache coherence region by dividing the tens of SSDs in Espresso into multiple groups and only allowing harvesting within the same group. In scenarios without hardware-supported cache coherence, software-based coherence mechanisms are required, albeit with significantly high synchronization overhead.

Practicality and compatibility. The main hardware modifications of Espresso are only the CXL interconnections and reduced SSD computing resources, while the other innovations (e.g., Espresso daemon) are implemented as software/firmware. Thanks to the backward-compatibility of CXL to PCIe and our support to NVMe protocol, Espresso SSD can act as a conventional SSD and adapt to existing I/O stacks and applications without violating compatibility. SSD industry [10, 50, 53, 72, 81, 103] is also actively exploring to evolve SSDs with CXL (e.g., Samsung CMM-H [103]) and decouple SSD architectures (e.g., Samsung AM9C1 [92, 93]). Espresso aligns with this trend and holds the promise.

7 Conclusion

While the numerous computing resources significantly elevate the BOM costs of SSDs to satisfy the performance requirement of burst I/O, the sporadic nature of I/O bursts causes severe SSD underutilization in JBOF scenarios. Tackling this issue, we propose Espresso, a novel JBOF design that reserves moderate computing resources in SSDs at low costs while achieving demanded I/O performance by employing CXL to facilitate fine-grained inter-SSD resource sharing. Our evaluation results reveal that Espresso improves SSD resource utilization by 50.4% and saves 19.0% BOM costs with negligible performance loss, compared to existing JBOF designs.

Abstract

Disaggregated Memory (DM) architectures offer caching systems the potential for elastic scaling and improved resource utilization by decoupling compute and memory. However, this advantage is undermined by costly cross-node synchronization, which exacerbates the overheads of critical cache operations, including hotness tracking, eviction coordination, and memory defragmentation. To address this challenge, we present FORGE, a caching system tailored for DM that prioritizes synchronization efficiency. FORGE groups cached objects based on similarity and performs group-level synchronizations to amortize overheads. It evicts cold groups via a contention-free and hotness-aware FIFO queue, efficiently sustaining high hit ratios while mitigating memory fragmentation. Leveraging the predictability of FIFO evictions, FORGE adopts a lazy synchronization strategy that updates hotness metrics just-in-time for eviction and offloads this process to on-chip memory in RDMA NICs for acceleration. Extensive evaluations on YCSB and real-world workloads demonstrate that FORGE achieves up to 4.5× higher throughput, 4.0×/7.5× lower P50/P99 latency, and an average of 1.14× higher cache hit ratio compared with state-of-the-art systems.

1 Introduction

In-memory caching systems like Memcached [3] and Redis [4] are fundamental infrastructure in cloud datacenters [6, 17, 18, 54, 75]. They accelerate data access for various applications, including web services [14], machine learning [55], and serverless computing [37]. These applications often exhibit highly dynamic and bursty workloads [58, 60, 65, 72], making it crucial for caching systems to elastically scale resources to ensure both high performance and utilization. However, traditional caches run on monolithic servers where compute and memory resources are tightly coupled, preventing independent scaling of compute and memory and often leading to resource overprovisioning and underutilization.

To improve resource utilization and scalability, Disaggregated Memory (DM) architectures [42, 61] decouple compute and memory from monolithic servers into separated pools. Compute Nodes (CNs) in compute pools provide abundant CPU cores, while Memory Nodes (MNs) in memory pools offer large memory capacity. CNs access remote memory on MNs via high-speed interconnects like Compute Express Link (CXL) [1] and Remote Direct Memory Access (RDMA) [2], bypassing limited compute units on MNs. This allows caching systems to independently scale compute (via CNs) for high throughput and memory (via MNs) for large capacity, aligning resources more closely with application demands.

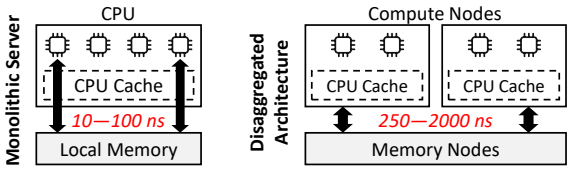

Figure 1: Memory access latencies in different architectures.

Despite the advantages of DM, caching systems face a critical new challenge: **synchronization amplification**. While prior work has extensively optimized key-value indexing for DM [43, 45, 46, 63, 71, 85], the efficiency of essential housekeeping tasks, including hotness tracking, eviction, and garbage collection, remains largely unaddressed. In monolithic servers, these tasks are lightweight, leveraging low-latency (10–100 ns), cache-coherent CPU load/store to access compact metadata. However, in disaggregated architectures (Fig. 1), where MNs lack computational capability [42, 43, 45, 62, 79], housekeeping must be offloaded to CNs. This shift introduces **cross-node synchronizations** over high-latency interconnects like CXL (∼350 ns [78]) or RDMA (∼2,000 ns [34]), incurring delays at least 20× higher than monolithic setups. Consequently, the housekeeping synchronization overheads become severe performance bottlenecks, directly interfering with latency-sensitive `Get`/`Set` operations. To fully exploit DM's potential, caching systems need to rethink how to efficiently coordinate housekeeping synchronizations across nodes in DM by overcoming three key challenges:

1) Efficiency–Effectiveness Trade-off in Eviction. While evicting groups of cold objects appears promising for amortizing synchronization costs, its efficacy heavily depends on grouping strategies and workload characteristics. In skewed workloads [7, 12, 13, 75], groups often contain a mix of hot and cold objects, resulting in aggregated group-level hotness metrics that obscure fine-grained object popularity. This can mislead CNs into retaining cold objects grouped with hot ones while evicting uniformly warm groups, degrading cache hit ratios and undermining benefits of batched eviction.

2) Accuracy–Overhead Dilemma in Hotness Tracking. Group-level hotness tracking mitigates synchronization overhead by aggregating metadata updates, but leads to misleading coarse-grained metrics under skew. On the other hand, object-level tracking ensures accuracy but demands frequent fine-grained updates across distributed CNs, reintroducing prohibitive synchronization costs. While First-In-First-Out (FIFO) replacement avoids hotness tracking altogether by enforcing a static eviction order, it ignores access patterns and often results in suboptimal hit ratios [20, 77].

3) Timeliness–Cost Conflict in Synchronization. For hotness-aware eviction to be effective, MNs need to hold up-to-date hotness metrics that accurately reflect dynamic access patterns. In DM, achieving this timeliness demands frequent synchronizations from distributed CNs, incurring substantial network overhead. While delaying synchronizations for batching can amortize costs, it introduces staleness in hotness metrics, causing misidentification of hot/cold objects and ultimately degrading cache performance.

As a result, these fundamental trade-offs leave caching systems struggling to balance management granularity, synchronization efficiency, and eviction effectiveness, remaining open and critical problems in DM environments.

To address these challenges, we present FORGE, a **F**IF**O**-based g**r**oup-level caching system on disa**g**gregated m**e**mory. By organizing objects into groups sharing similar access patterns, FORGE coalesces the accuracy of object-level tracking with the efficiency of group-level coordination. Specifically, CNs execute `Get`/`Set` operations and track fine-grained object hotness to ensure precision, while synchronizing metrics to MNs only in coarse-grained groups to amortize network overheads. Leveraging these fine-grained metrics during group eviction, a lightweight regrouping scheme extracts and consolidates hot objects while filtering out cold ones, ensuring high adaptivity. To enable scalable eviction, FORGE transforms the standard FIFO policy into a contention-free, hotness-aware mechanism via ring-array-based virtual segmentation. By mapping groups to distinct virtual segments based on their hotness, FORGE accelerates the eviction of cold groups while preserving hot ones, effectively improving hit ratios without the synchronization bottlenecks of traditional priority queues.

Our co-design of group-level caching and FIFO replacement introduces a novel lazy synchronization scheme tailored for DM. We observe that *synchronized object hotness metrics are not needed immediately upon cache hits but can be deferred until predictable group evictions, triggered as groups approach the head of the FIFO queue*. CNs monitor FIFO queue metadata to identify groups nearing eviction and initiate just-in-time hotness flushing, ensuring accuracy while minimizing synchronization frequency. Furthermore, despite the large cache capacity of MNs, the number of objects evicted concurrently remains small, enabling CNs to efficiently leverage the fast on-chip memory of RDMA NICs (RNICs) in MNs as synchronization destinations. This strategy significantly reduces synchronization overhead and mitigates interference with performance-critical `Get`/`Set` operations, balancing timeliness, efficiency, and effectiveness.

In summary, this paper makes the following contributions:

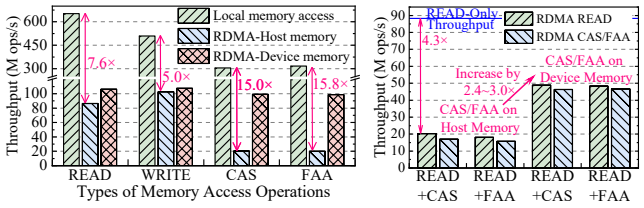
- We identify and analyze the critical challenge of synchronization amplification in DM caching systems, where housekeeping synchronizations become a major bottleneck.
- To address this challenge, FORGE introduces three key innovations: 1) DM-tailored group-level management to amortize synchronization overheads; 2) fine-grained object hotness tracking combined with hotness-aware FIFO queue to enhance hit ratios despite group-level eviction; 3) a lazy synchronization mechanism that exploits predictable eviction timing to defer and batch hotness updates, accelerated by RNIC on-chip memory, ensuring both efficiency and timeliness.
- We implement FORGE and perform extensive experiments that show the performance advantages of FORGE over state-of-the-art systems. The source code of FORGE is publicly available at https://github.com/cszjyang/forge.

2 Background and Motivation

2.1 In-Memory Caching Systems

In-memory caching systems store frequently accessed (hot) objects in fast but limited-size memory and serve `Get`/`Set` requests from applications, reducing access latency and offloading backend storage. When the cache is full, replacement algorithms evict less accessed (cold) objects to make room for new ones, maximizing the cache's utility [20, 38].

Traditional caching systems scale at the granularity of instances on monolithic servers, where compute and memory resources are tightly coupled. This rigid bundling prevents independent scaling of individual resources and often leads to overprovisioning and underutilization. For example, during peak demand, the system launches additional instances to handle the increased load. The new instances bring both compute and memory, even if only one resource type is the bottleneck, leaving the other resource underutilized. Moreover, instance-based scaling often requires expensive data repartitioning and cache warming [5, 21, 23], discouraging frequent resizing.



(a) Performance: Local memory access vs. RDMA in Host/Device memory (b) Performance interference between RDMA verbs

Figure 2: Performance characteristics of RDMA-based DM.

Figure 3: Traffic breakdowns of conventional queue-based (LRU [20] and SIEVE [82]), sampling-based (Ditto [62]) and our (FORGE) caching systems.

2.2 Adapting Caching Systems to DM

To improve resource utilization in datacenters, Disaggregated Memory (DM) architectures [42, 61] deconstruct monolithic servers by decoupling compute and memory into distinct resource pools. Compute Nodes (CNs) offer abundant CPU cores and limited local memory for temporary buffering, while Memory Nodes (MNs) provide large memory capacity but limited compute power for control-plane operations (e.g., connection management). These pools are interconnected via high-speed links such as CXL [1] and RDMA [2], enabling CNs to directly access remote memory on MNs without involving the MNs' weak compute units. This decoupled design allows independent scaling of compute and memory by adding CNs or MNs. Moreover, since MNs are shared across all CNs, scaling does not necessitate data repartitioning, simplifying resource management and load balancing.

The demand for elastic scaling makes caching systems ideal for DM. CNs handle compute-heavy tasks including `Get`/`Set` requests, hotness tracking, and eviction, while MNs store the cached objects and hotness metrics such as access timestamps (for LRU [20]) and frequency counters (for LFU [38]). The systems independently scale the CNs and MNs on demand, improving performance and resource efficiency.

However, DM introduces fundamental performance challenges. As shown in Fig. 2a, RDMA throughputs are lower than local memory by 5.0–15.8×. Atomic `RDMA_CAS/FAA` (compare-and-swap/fetch-and-add) operations are particularly costly due to RNIC serialization: they incur 4–5× higher overhead than basic reads/writes and degrade concurrent `RDMA_READ` throughput by 4.3× due to interference (Fig. 2b). Although using RNIC on-chip memory as the `RDMA_CAS/FAA` destination can shorten the serialization critical path, improving atomic throughput by 4.9× and reducing interference by 2.4–3.0×, this memory's scarce capacity (e.g., 256 KB in a Mellanox ConnectX-5 RNIC) limits broader applicability.

These hardware constraints pose a critical challenge for caching systems, which continuously perform housekeeping tasks (hotness tracking, eviction, and garbage collection) to maintain high hit ratios. In DM, ensuring coherence and correctness for these tasks necessitates frequent cross-node synchronization. This requirement transforms housekeeping from lightweight local operations into heavy network burdens that interfere with performance-critical `Get`/`Set` operations, severely undermining overall system efficiency.

Hotness Tracking and Eviction. Existing replacement algorithms broadly fall into two main categories: queue-based and sampling-based. Traditional queue-based schemes (e.g., LRU [20], LFU [38]) maintain a global priority queue (often a linked list). On cache hits, CNs promote accessed objects within the queue; for eviction, CNs remove cold objects at the queue tail. However, such queue manipulations under exclusive locks necessitate a sequence of `RDMA_CAS`, `RDMA_READ`, and `RDMA_WRITE`. For consistency, only one CN can update the queue at a time, forcing other CNs to block and retry under contention. Exacerbated by DM's high latency [44, 84], such blocking severely degrades concurrency and performance.

Recent algorithms for monolithic servers, like SIEVE [82], mitigate the hit-path overhead of traditional queue-based schemes. Specifically, on every cache hit, a thread checks and sets the object's visited bit using an atomic operation (e.g., `RDMA_CAS` in DM), bypassing the overheads of promoting the object within the queue. However, for eviction, a thread still needs to lock the queue and move a global pointer to sequentially scan the linked objects, reading and clearing their visited bits until an unvisited cold object is found. Although fast in a monolithic server, this scanning is expensive in DM, since it triggers serialized RDMA operations with multiple network round trips while holding the lock, severely inflating eviction latency and blocking other CNs' concurrent evictions.

To quantify these synchronization overheads, we evaluate LRU and SIEVE on RDMA-based DM using YCSB [19] and real-world Twitter traces [75], with 16 threads on CNs and a 10% cache ratio on MNs. The experimental setup is detailed in § 6. To reduce blocking contention, we partition the queues of both LRU and SIEVE into 32 shards, allowing different CNs to simultaneously operate on different shards. Despite this synchronization optimization, the RDMA traffic in LRU remains overwhelmingly dominated by hotness tracking (57.4%) and eviction (29.2%), vastly exceeding the mere 13.4% consumed by actual `Get`/`Set` operations, as shown in Fig. 3a. While SIEVE reduces the hotness tracking traffic (37.7%), it shifts the synchronization bottleneck to the blocking eviction path (47.6%). These findings demonstrate

that conventional queue-based policies, though effective in monolithic systems, incur synchronization overheads that are severely amplified into major performance bottlenecks in DM.

To avoid the costly blocking overhead of global queues, state-of-the-art DM systems like Ditto [62] employ sampling-based algorithms [10, 56]. On cache hits, CNs locally accumulate hotness metrics and periodically flush them in batches to MNs using `RDMA_WRITE` (for access timestamps) and `RDMA_FAA` (for frequency counters). To select eviction candidates, CNs read a random sample of objects via `RDMA_READ`, compare their (potentially stale) hotness metrics, and evict the coldest ones using `RDMA_CAS` to ensure consistency [62, 81]. Consequently, Ditto eliminates blocking among CNs during synchronization for hotness tracking and eviction, achieving 3.1–5.0× higher throughput than SIEVE in DM.

However, these benefits come with two critical trade-offs. First, while the periodic and batched hotness flushing reduces network traffic, it creates a dilemma: short flushing intervals maintain metric accuracy but limit traffic reduction, whereas long intervals reduce traffic but risk stale metrics leading to erroneous eviction of hot objects. Second, the sampling-based eviction introduces another trade-off: limited sampling may overlook colder objects and reduce hit ratios, while extensive sampling increases `RDMA_READ` traffic and overhead. Consequently, these mechanisms struggle to balance synchronization efficiency, metric freshness, and eviction effectiveness. In Fig. 3a, our evaluation of Ditto reveals that hotness tracking and eviction still consume 45.9% and 18.0% of total RDMA traffic, respectively, exceeding the 36.1% for `Get`/`Set` executions. These synchronization overheads significantly hinder the scalability and efficiency of state-of-the-art DM systems.

Garbage Collection (GC). In dynamic workloads, object size distributions fluctuate over time [75]. The frequent insertion and eviction of variably-sized objects lead to memory fragmentation, where free space becomes divided into small, non-contiguous fragments dispersed across multiple CNs, making each CN struggle to allocate contiguous space for large objects. Consequently, fragmentation diminishes effective memory utilization and cache hit ratios. To mitigate this, caching systems leverage GC [57] for defragmentation. However, GC in DM necessitates costly cross-node coordination using `RDMA_READ` and `RDMA_CAS` to track and reclaim fragments. As shown in Fig. 3b, while GC mitigates eviction costs by reclaiming space for new objects, it consumes 31.9%, 38.2%, and 18.3% of traffic respectively in LRU, SIEVE, and Ditto. In contrast, for YCSB workloads with uniform object sizes, GC is unnecessary. These results highlight the persistent tension between fragmentation management and synchronization efficiency in DM caching systems.

2.3 Towards Efficient Synchronization

To overcome synchronization bottlenecks, caching systems in DM need to rethink the coordination of housekeeping tasks across distributed CNs. A promising approach involves organizing cached objects into groups, enabling group-level hotness tracking and eviction to amortize synchronization overheads across multiple objects. Moreover, fixed-size group allocation can mitigate memory fragmentation [36]. However, despite these potential benefits, critical challenges remain in realizing practical group-level caching for DM.

C1: Efficiency–Effectiveness Trade-off in Eviction. Despite efficiency, coarse-grained group eviction can be ineffective at retaining hot objects and evicting cold ones. For example, in skewed access patterns [41, 83], aggregated group-level hotness metrics (e.g., access timestamps and frequency counts) often mislead CNs to mistakenly retain skewed groups containing both hot and cold objects, while evicting more uniformly warm groups, thereby reducing hit ratios.

C2: Accuracy–Overhead Dilemma in Hotness Tracking. To avoid inaccurate group-level hotness metrics, caching systems employ accurate object-level tracking. But this requires fine-grained updates of hotness metrics from distributed CNs, reintroducing prohibitive synchronization overheads. Another method is to evict groups in FIFO order, thus avoiding expensive hotness tracking. However, FIFO eviction is unaware of object hotness and often yields low hit ratios [20, 77].

C3: Timeliness–Cost Conflict in Synchronization. For hotness-aware eviction to be effective, the hotness metrics on MNs need to be timely, which requires frequent costly synchronizations from distributed CNs, as analyzed in § 2.2. Delaying and batching synchronization reduces cost but results in stale metrics, leading to misidentification of hot objects.

3 FORGE Overview

To address these challenges, FORGE coalesces the strengths of group-level caching and FIFO eviction, and introduces novel DM-friendly designs. Fig. 4 shows the overview of FORGE. To serve application `Get`/`Set` requests, CNs access and manage the cached objects on MNs via one-sided RDMA. The MN hash table indexes the cached objects, which are organized into groups based on access patterns (§ 4.1). FORGE decouples operation granularity: performance-critical `Get`/`Set` requests operate on individual objects to avoid read/write amplification, while housekeeping tasks are performed at the group level to amortize synchronization overheads.

For a `Set` request, a CN inserts the object into an allocated group and updates the hash table (§ 4.2). Each group occupies a fixed-size memory chunk to prevent external fragmentation. When a group becomes full (i.e., reaching chunk capacity or a configurable maximum object number such as 256 [74, 76]), the CN pushes the group pointer into the tail of the contention-free FIFO queue (§ 5.1) on an MN. Upon exhausting groups with available space for insertion, the CN dequeues and evicts cold groups from the queue head to reclaim their space for new allocations. This group-level eviction removes overheads from the critical path of latency-sensitive `Get`/`Set` operations,

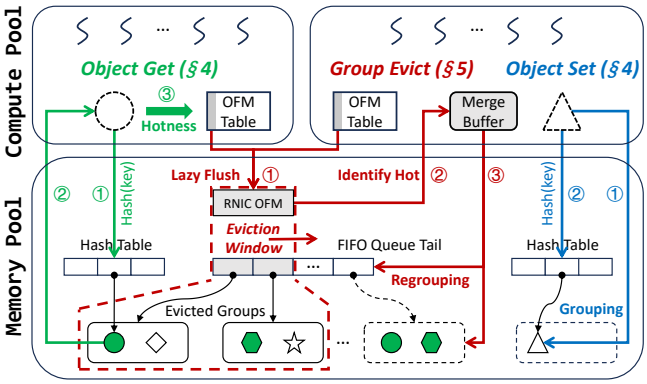

Figure 4: The overview of FORGE.

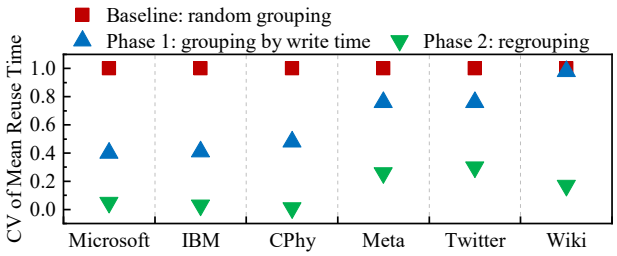

Figure 5: Similarity of objects grouped by different schemes.

amortizing synchronization costs across multiple objects.

For `Get` requests, all CNs can read objects from any groups (full or partially filled) via the hash table. On cache hits, CNs increase the objects' frequency counters in their local fine-grained Object Frequency Maps (OFMs). These updates are buffered and lazily flushed to MNs at the group level to track global hotness of objects (§ 4.3). This design directly addresses **C2**: object-level tracking guarantees accuracy, while group-level flushing amortizes synchronization overheads.

To tackle **C1**, FORGE significantly enhances basic group-FIFO eviction through two key techniques. First, it integrates a lightweight regrouping mechanism. During eviction, CNs fetch synchronized OFMs from MNs to identify hot objects. FORGE's Two-Way Index Map (§ 5.3) allows CNs to efficiently extract and consolidate only the hot objects for reinsertion, bypassing the overheads of scanning entire groups and querying hash tables. Second, FORGE introduces virtual segmentation (§ 5.4) to infuse the FIFO queue with hotness-awareness, assigning hotter groups to deeper segments within the queue to systematically delay their eviction and prioritize the removal of colder groups. Together, these strategies effectively improve cache hit ratios with minimal coordination.

To resolve **C3**, FORGE introduces a novel lazy-yet-timely hotness synchronization strategy (§ 5.2) that leverages the predictable, sequential eviction order of the FIFO queue. By anticipating which groups are nearing the queue head and thus imminent eviction, distributed CNs defer flushing fine-grained object hotness metrics (OFMs) until groups enter the eviction window, effectively eliminating unnecessary synchronization traffic. This approach ensures metrics are updated precisely when needed for eviction decisions, balancing freshness and efficiency. Moreover, FORGE directs this synchronized traffic to the fast on-chip memory of RNICs in MNs, which is small but sufficient for handling the limited number of groups within the eviction window, further reducing latency and overhead.

As previewed in Fig. 3, FORGE drastically reduces synchronization overheads, thereby achieving significantly higher throughput and lower latency while improving the cache hit ratio compared with state-of-the-art systems [62].

4 Grouping Management for Cached Objects

4.1 Object Grouping Scheme

FORGE groups cached objects with similar access patterns to enable effective group-level eviction. The rationale is that by collectively evicting groups of cold objects while preserving hot ones, the system can maintain high hit ratios while amortizing synchronization overheads. To enhance intra-group similarity, FORGE adopts a two-phase grouping scheme.

Phase 1: Write-Time Grouping. During `Set` operations, each CN exploits temporal locality by sequentially inserting newly written objects into a group with available space, ceasing additions once the group reaches capacity. This approach leverages empirical findings that objects written contemporaneously often exhibit correlated access patterns [59, 74, 76]. Moreover, this method remains application-agnostic by relying exclusively on object write time, a universally available and lightweight attribute. This design ensures broad generalizability without requiring prior knowledge of object semantics or access characteristics.

Phase 2: Hotness-Based Regrouping. When a group reaches eviction, the hotness metrics accumulated over its lifecycle serve as a robust indicator of object access patterns. FORGE leverages these metrics to identify and extract hot objects from the evicted group, merging them into a new hot group for reinsertion. This strategy effectively consolidates frequently accessed objects while filtering out colder ones, thus enhancing cache efficiency with minimal synchronization overhead.

To validate the grouping effectiveness, we measure intra-group similarity using the real-world workloads in §6. We calculate the coefficient of variation (CV, standard deviation divided by the mean) of object reuse times within the same group, where a lower CV indicates higher similarity. Fig.5 reports the average CV of 10,000 groups of 256 objects under three schemes: 1) random grouping, 2) Phase-1 write-time grouping, and 3) Phase-2 hotness-based regrouping. The results show that Phase-1 grouping improves intra-group similarity over random grouping, while Phase-2 regrouping further refines it. Similar trends hold for the other group sizes (16–1024 objects), but the results are omitted due to space limitation. As a result, the two-phase grouping scheme enables FORGE to evict cold objects in batches while preserving the

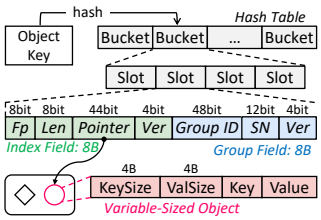

Figure 6: The data structures of the hash table and object.

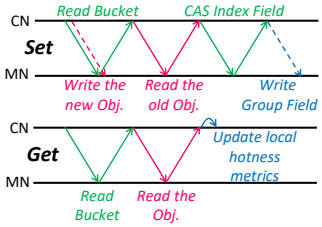

Figure 7: The workflows of Set and Get operations.

hot ones with similar access patterns for future reuse.

4.2 Grouping-Aware Caching Operation

To ensure low latencies and high throughputs for caching systems in DM, FORGE proposes performance-critical `Get`/`Set` operations to become lock-free and non-blocking, while supporting efficient group-level management.

As shown in Fig. 6, each slot in the hash table in MNs contains two atomic 8-byte fields, i.e., the index field and group field. The atomic index field contains a 1-byte fingerprint (*fp*) of the object key for quick filtering, a 1-byte object length in the granularity of fixed-size memory blocks (e.g., 256 bytes), and a pointer to an object in MNs. The atomic group field contains the object's group ID, and an intra-group sequence number (*SN*). The group ID is the unique key of the group determined at group allocation time, while intra-group *SN* indicates the object's insertion order within the group.

Lock-free insertion typically uses pointer swapping: CN writes an object to MN and then atomically installs the pointer into the index using `RDMA_CAS` [46, 52, 62, 85]. But since `RDMA_CAS` works on 8-byte granularity, it cannot update both the index and group fields simultaneously. A naive solution, i.e., locking the slot to atomically update both fields, would block concurrent accesses and degrade `Get`/`Set` performance.

FORGE employs lightweight versioning to ensure non-blocking progress and consistency without locks. Each slot in the system includes a 4-bit version number for both its index and group fields. During a `Set` operation, the CN first updates the index field with an incremented version number and later updates the group field to match the version. This two-phase versioning mechanism guarantees that subsequent `Get` operations can safely read consistent group information by verifying version matches, eliminating the need for locks while maintaining data integrity and high concurrency.

Version-Assisted Lock-Free Set. Fig. 7 shows the processing of `Set` operations. In the first Round Trip Time (RTT), a CN issues an `RDMA_READ` to fetch the hash bucket that the object key corresponds to, and in parallel writes the object to a group with available space in MNs (Phase-1 grouping in § 4.1). The CN then scans *fp*-matched slots in the fetched bucket and follows pointers to read objects and identify a key match. If a key-matched slot is found, the CN sends `RDMA_CAS` to update the slot's index field with the new object pointer and an incremented version number. If not matching, an empty slot is selected and updated in a similar manner. Upon a successful `RDMA_CAS`, the CN asynchronously issues an `RDMA_WRITE` to update the group field with the object's group ID, *SN*, and a version number matching the index field. Since the CN does not need to wait for the final asynchronous `RDMA_WRITE` to complete, the group-level management does not cause additional RTTs to the critical path of `Set` operations.

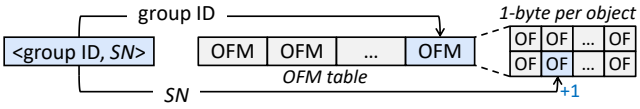

Figure 8: Object hotness tracking in the CN-side OFM table.

Version-Assisted Lock-Free Get. As shown in Fig. 7, the workflow of `Get` is similar to `Set` when locating the object with the target key, except that `Get` does not write a new object or update the slot. Since the `Set` operation atomically updates the index fields using `RDMA_CAS`, the `Get` operation can always follow the pointer to read the consistent and up-to-date object data without blocking. Upon locating a target object (i.e., a cache hit), the CN verifies that the version numbers of the object's index and group fields match, ensuring both correspond to the same atomic `Set` operation. In rare cases where a `Get` operation races with a concurrent `Set`, it may transiently observe a stale version in the group field, when the `Set` has updated the index field via `RDMA_CAS` but its asynchronous `RDMA_WRITE` to the group field is still in flight. This timing window is inherently brief (spanning one RDMA RTT of a few μs) and does not compromise correctness, since the index field that is updated first always references consistent object data. When versions match, the CN extracts the object's group ID and intra-group *SN* from the group field to accurately track hotness, maintaining integrity without locking.

4.3 Group-Based Object Hotness Tracking

As shown in Fig.8, a CN tracks object hotness by increasing access counters in a local Object Frequency Map (OFM) table. Specifically, each OFM corresponds to a group, structured as a compact 1-byte-per-object frequency array indexed by the intra-group *SN*. This layout ensures that the *i*-th counter directly maps to the *i*-th object within the group. Prior to group eviction, OFMs buffered across distributed CNs are flushed to MNs to synchronize global hotness metrics. The OFM design offers the following key advantages in DM architectures.

CN-Side Memory Efficiency. CN local memory is scarce, necessitating efficient utilization [43, 45, 46]. Existing object-level systems [62] waste limited CN memory by storing object keys to index buffered hotness metrics, which is inefficient given that real-world keys are often long (e.g., $\geq$38 bytes for 50% of objects at Twitter [75]). FORGE addresses this

inefficiency via its OFM table, which indexes metrics using compact group IDs and intra-group *SNs*. Since *SNs* serve as implicit offsets within arrays, they require no explicit storage, eliminating key-induced memory bloat. This design dramatically reduces the metadata footprint: a mere 1GB table can track hotness for one billion objects, maximizing CN memory efficiency while maintaining full hotness tracking capability.

Network Efficiency. Since the 1-byte-per-object frequency counters within a group are stored contiguously, the counters for 8 objects can be flushed in a single 8-byte `RDMA_FAA`, significantly reducing synchronization traffic.

In DM caching, timely synchronization of hotness metrics from distributed CNs to MNs is critical. Without this, stale metrics on MNs cause hot objects to be misidentified as cold, inducing erroneous evictions and degraded hit ratios. State-of-the-art systems [62] rely on random sampling to select eviction candidates, which makes future metric needs unpredictable and forces periodic synchronization, resulting in a dilemma: short intervals increase overhead, while long intervals risk staleness. In §5.2, FORGE resolves this dilemma by leveraging the predictable FIFO eviction order to enable low-overhead lazy synchronization of hotness metrics precisely when needed, ensuring accuracy without unnecessary traffic.

5 FIFO-Based Replacement for Groups

FORGE adopts a group-level FIFO replacement to overcome the synchronization amplification in DM. First, evicting groups in FIFO order avoids inefficient random sampling and expensive per-object evictions in DM. Moreover, the strict FIFO order prevents unfair group evictions misled by highly aggregated group-grained hotness metrics. Furthermore, the predictability inherent in FIFO eviction unlocks novel and efficient synchronization schemes in DM.

5.1 Contention-Free FIFO Management

Conventional FIFO queues structured as linked lists [8, 31, 82] require exclusive locks to serialize concurrent operations. Akin to LRU as analyzed in § 2.2, this serialization imposes a severe bottleneck in DM by allowing only a single CN to progress while others are blocked. FORGE eliminates this contention by structuring the queue as a lock-free ring array.

As shown in Fig. 9, the FIFO queue on an MN is organized as a ring array of N contiguous nodes. For convenience, we denote the i-th node in the ring array as $A[i]$. The 4-byte head cursor points to the FIFO head node $A[head \bmod N]$, which becomes the oldest in the queue and will be dequeued next. The tail cursor points to $A[tail \bmod N]$ where the next FIFO node will be enqueued. Crucially, the two cursors are packed into an 8-byte aligned word on the MN to enable `RDMA_FAA`-based contention-free FIFO enqueue and dequeue as follows.

When a group reaches capacity, the CN filling it enqueues a FIFO node referencing the group by first performing an

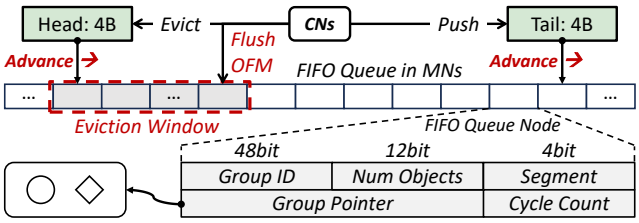

Figure 9: The CN-driven FIFO queue management.

`RDMA_FAA` to atomically advance the tail cursor by one and retrieve the *oldTail* value. The CN then issues an asynchronous `RDMA_WRITE` to populate the FIFO node at $A[oldTail \bmod N]$ with the queue cycle count ($\lfloor oldTail/N \rfloor$), the group's unique ID, the number of grouped objects, and a pointer to the group's location, thereby efficiently linking the group to the queue.

When a cache is full, a CN evicts cold groups in the eviction window starting from the FIFO queue head. Specifically, the CN dequeues FIFO nodes by advancing the head cursor by k (e.g., 4) with `RDMA_FAA` and reads the k FIFO nodes starting at $A[oldHead \bmod N]$ via `RDMA_READ`. To ensure consistency, the CN verifies whether the fetched FIFO nodes belong to the current queue cycle by comparing their cycle counts against the expected cycle. Any mismatch indicates an unfilled or stale node from the last cycle, prompting the CN to retry the fetch. Once consistency is ensured, the CN uses the metadata in the fetched FIFO nodes to conduct group-level evictions. A `Segment` field in the FIFO node enables hotness-aware optimizations during eviction to improve hit ratios (§ 5.4).

In state-of-the-art systems [62], multiple CNs can independently sample and then race to evict the same cold objects using `RDMA_CAS`, where only one CN succeeds while the others suffer failed attempts and retry overhead under contention. In contrast, our `RDMA_FAA`-based management is contention-free. Each atomic `RDMA_FAA` on the cursors succeeds without retries and returns a unique old value, ensuring that multiple CNs can concurrently and safely enqueue and dequeue groups without locks or `RDMA_CAS`-retry loops. This design substantially reduces atomic operation overhead, thereby mitigating interference with performance-critical `Get`/`Set` executions.

5.2 Lazy Hotness Synchronization

To maintain high hit ratios, accurate hotness metrics (tracked via OFMs in § 4.3) are important for identifying hot objects during eviction. However, synchronizing OFMs from distributed CNs to MNs eagerly upon every cache hit incurs significant overheads. To achieve high efficiency, we observe that *the synchronized hotness metrics are not necessary right away upon cache hits, but only later during evictions, whose timing is predictable in the FIFO-based replacement.*

Our key insight is that, under FIFO-based replacement, a group only becomes eligible for eviction once its corresponding FIFO node enters the eviction window near the queue

head (Fig. 9). For groups outside this window, CNs track OFMs locally without synchronization, avoiding unnecessary DM traffic. When a group's FIFO node enters the eviction window, CNs proactively flush their buffered OFM updates for that group to MNs using efficient batched operations, i.e., one RDMA_FAA per 8 counters. This flush-on-entry strategy ensures that by the time a CN dequeues the FIFO node to evict the target group, the group's OFM on MNs has been globally synchronized across all CNs, providing accurate hotness metrics for informed eviction decisions.

However, if the eviction window is too small, a group may be quickly evicted after entering the window, before CNs can timely detect its entry and flush the buffered OFMs. FORGE prevents this detection failure by determining a safe eviction window size that guarantees CNs have sufficient time to detect new groups and flush their OFMs before eviction.

Robustness via Physical Bounds. To determine the window size, we analyze the maximum eviction rate under a worst-case write-miss workload (i.e., 0% hit ratio), where each operation is a cache-miss Set involving at least 2 RDMA_WRITE, 1 RDMA_READ, and 1 RDMA_CAS. As shown in Fig. 2a, RNIC throughput limits are 107 Mops/s for WRITE, 88 Mops/s for READ, and 20 Mops/s for CAS. Consequently, the throughput bottleneck of cache-miss Set becomes: $\frac{1}{\frac{2}{107}+\frac{1}{88}+\frac{1}{20}} \approx 12\,\text{Mops/s} = 12\,\text{ops/}\mu\text{s}$. Thus, in each μs, at most 12 new objects are inserted and the other 12 are evicted. Suppose the eviction window holds 16 groups and each group contains 256 objects, evicting them all consumes at least $\frac{16\times256}{12} \approx 341\,\mu$s. Therefore, CNs only need to check the eviction window every 100 μs, providing a 3.4× safety margin over the maximum eviction rate, to ensure timely OFM flushing before group eviction. In practice, real-world workloads [9, 53, 69, 75] exhibit higher hit ratios than this worst case and consequently lower eviction rates, permitting even more relaxed detection intervals. For system configurations (e.g., more RNICs per MN) that sustain higher maximum eviction rates, FORGE dynamically adjusts both the eviction window size and detection intervals to ensure robust and timely synchronization.

In every detection interval (e.g., 100 μs), each CN issues one probing RDMA_READ to fetch the current FIFO head value *headNow*, in parallel with normal Get/Set RDMA RTTs to minimize detection overhead. The CN compares *headNow* with the previous value *headLast* from the last detection interval. If $headNow > headLast$, $headNow - headLast$ new FIFO nodes have entered the eviction window. In this case, the CN issues another RDMA_READ to fetch these FIFO nodes in the eviction window, extracts their group IDs, and flushes the corresponding buffered OFMs from the CN to MNs using one RDMA_FAA per 8 bytes. This design ensures each CN incurs negligible detection overhead, while all groups' OFMs are lazily yet timely synchronized before evictions.

Acceleration via RNIC Device Memory. Our analysis of the maximum eviction rate reveals an insight: *although the cache capacity in MNs could be large, the number of objects concurrently evicted by CNs remains small*. Our FIFO-based replacement further confines concurrent evictions to a limited number of objects within the eviction window. This eviction locality enables FORGE to leverage the fast yet limited (256KB) on-chip device memory of RNICs in MNs to accelerate synchronization of hotness metrics (OFMs).

Based on this insight, CNs direct their synchronization traffic to a dedicated region (e.g., 16 KB) in the on-chip memory of the RNIC in MNs. This region is organized as an OFM Ring Array (short for *RA*) and consists of M contiguous OFMs. The value of M is configured to exceed the number of groups in the eviction window. This is highly practical, since a 16KB buffer can accommodate 1-byte-per-object OFMs for up to 16K objects, which are 4× more than the 16 groups of 256 objects in the eviction window. When the FIFO node $A[i \bmod N]$ enters the window, CNs flush the buffered OFM of the corresponding group to $RA[i \bmod M]$ via RDMA_FAA. Furthermore, the head and tail cursors of the FIFO queue, occupying only 8 bytes, are also maintained in RNIC on-chip memory to accelerate RDMA_FAA-based enqueue and dequeue.

As shown in Fig. 2, this on-chip synchronization reduces RDMA_FAA overhead by up to 5× and alleviates performance interference with concurrent Get/Set executions. Importantly, while most commodity RNICs provide such on-chip memory, this acceleration is an optimization, not a dependency. If on-chip memory is unavailable, FORGE seamlessly places the OFM Ring Array and cursors in MN host memory while preserving correctness and the benefits of lazy synchronization.

5.3 Lightweight Object Regrouping

When a CN evicts a batch of k (e.g., 4) groups by advancing the FIFO head (obtaining $oldHead$), it fetches the corresponding k FIFO nodes starting from $A[oldHead \bmod N]$ and their fully synchronized OFMs starting from $RA[oldHead \bmod M]$. The CN then zeroes out these OFM locations in RA via RDMA_WRITE, initializing them for future reuse in the ring.

Guided by the access frequencies in the fetched OFMs, the CN ranks the objects across the k evicted groups and consolidates the hottest objects into a new group until it becomes full (Phase-2 regrouping in § 4.1). As shown in Fig. 10, this process entails a sequence of parallelized operations: reading hot objects from their original locations, compacting them into a consolidated buffer, writing the new group to the MN, and updating the corresponding hash table slots to reference the objects' new locations.

However, this process faces a critical performance challenge: locating specific objects and their hash table slots is prohibitively expensive without fine-grained indexing. A straightforward approach would be to read the entire group chunk via RDMA_READ, scan it sequentially to extract object keys, and then perform a hash table lookup for each key. Such a strategy is impractical due to generating excessive network traffic, fundamentally undermining FORGE's efficiency.

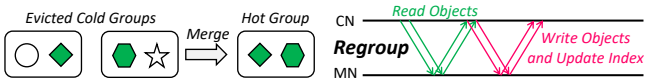

Figure 10: Regrouping hot objects from evicted groups.

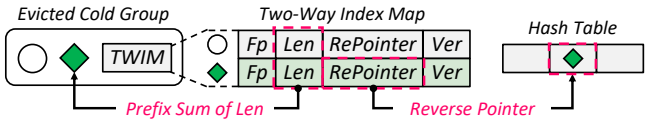

Figure 11: The Two-Way Index Map for regrouping.

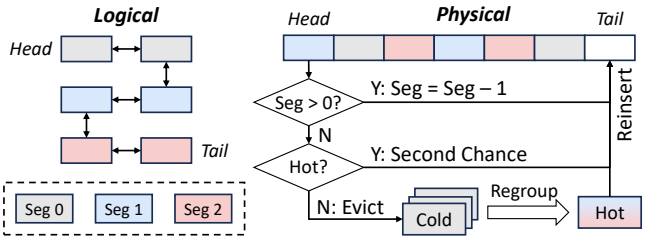


(a) Queue segmentation (b) Ring-array-based segmentation

Figure 12: The virtual segmentation of the FIFO queue.

To enable lightweight regrouping, FORGE introduces a Two-Way Index Map (TWIM) embedded at the tail of each group's chunk. As shown in Fig. 11, the TWIM is an array where each 8-byte entry corresponds to an object indexed by its intra-group *SN*. Each TWIM entry mirrors the object's index field in the hash table but replaces the object pointer with a reverse pointer to the object's hash table slot. The TWIM is constructed by the CN that populates the group, allowing object start offsets within the group to be calculated by summing preceding object lengths stored in the TWIM.

With the aid of TWIM, regrouping becomes highly efficient. When evicting a group, the CN uses FIFO node metadata to derive the TWIM address ($GroupPointer + ChunkSize - NumObject \times 8$) and fetches the OFM and TWIM in parallel. The OFM identifies the *SNs* of hot objects, while the TWIM provides their exact data locations and index slot addresses. This allows the CN to only read the necessary hot objects and update their index slots with minimal RDMA operations, eliminating costly full-group scanning and hash table lookups.

5.4 Hotness-Aware FIFO Queue

Although the contention-free FIFO queue minimizes synchronization overheads for replacements, its assumption that older objects are colder does not always hold. Many real-world workloads exhibit skewed access patterns [7, 12, 13, 75]: older objects can remain frequently accessed, while newly inserted ones are often short-lived [77]. As a result, plain FIFO often achieves lower hit ratios than adaptive schemes like LRU [20].

To improve adaptability, FORGE partitions the FIFO queue into segments to prioritize evicting cold objects. Groups are inserted into different segments based on their hotness: the hotter a group is, the farther from the head it is placed. For example, groups in Phase-1 containing likely-cold new objects are inserted into the first segment (i.e., Segment 0 in Fig. 12a), near the head and thus evicted quickly. In contrast, a merged group in Phase-2 is likely hotter and thus inserted into the deeper segments (e.g., Segments 1 or 2) according to its aggregated access frequency, delaying their eviction. Consequently, the groups with colder objects are evicted sooner than hotter ones, thus increasing the proportion of hot objects retained in the cache. However, this segmented FIFO queue requires a linked-list-based structure that allows random insertion, limiting only one CN holding the lock to modify the queue, while other CNs are blocked. This conflicts with FORGE's contention-free ring-array design.

To avoid this conflict, FORGE adopts virtual segmentation on top of its contention-free ring array by embedding a *Segment* field in each FIFO node. As shown in Fig. 12b, CNs simulate segment-based insertion by assigning *Segment* values to FIFO nodes while physically enqueuing them at the queue tail. Phase-1 groups are enqueued with *Segment = 0*, and Phase-2 merged groups are enqueued with *Segment > 0*.

When a FIFO node with *Segment > 0* is dequeued, its group is not evicted. Instead, the CN decrements its *Segment* value and reinserts it into the queue tail. Only nodes with *Segment = 0* are considered for eviction. Before eviction, the CN inspects the group's OFM: if most objects are active (e.g., over half the counters are non-zero), the group is reinserted rather than evicted, and the CN proceeds to the next candidate. This reinsertion avoids unnecessary regrouping for hot objects already co-located in one group, and speeds up the eviction of subsequent groups with more cold objects. Moreover, since the OFM is zeroed out upon fetch (§ 5.3), the reinsertion restarts the group's hotness tracking from zero for the next eviction cycle, preventing stale metrics from accumulating indefinitely. Overall, virtual segmentation enables hotness-aware eviction while preserving FORGE's ring-array structure for efficient synchronization.

5.5 Discussions

Support for multi-queue designs. Prior work [22, 28, 32, 33, 77] employs multiple queues to filter out unpopular objects and mitigate cache pollution. As an orthogonal optimization, FORGE also incorporates this approach by maintaining a 20% small FIFO queue and an 80% main FIFO queue. Each queue is independently managed with our virtual segmentation and lazy hotness synchronization, accelerated via RNIC on-chip memory. New groups first enter the small queue. When the *small* queue is full, its head group is either promoted and reinserted into the *main* queue if hot, or evicted and merged if cold. The main queue applies the same policy when full.

Considerations for tiered caching. In addition to MN-tier

caching, CNs can leverage their limited local memory to cache objects, thereby accelerating `Get`/`Set` operations. However, hotness tracking, eviction, and GC in the MN tier still require cross-CN synchronization to ensure coherence and consistency. Therefore, the relative synchronization cost can become even higher in systems with CN-tier caching, further highlighting the motivations and benefits of FORGE's synchronization-efficient mechanisms for managing the global tier on MNs. FORGE currently does not employ CN-tier caching, aligning with state-of-the-art systems [62] for fair comparisons.

Adaptability to CXL-based DM. While FORGE primarily focuses on RDMA-based DM and assumes one-sided RDMA verbs, its design principles are potentially applicable to CXL-based DM using memory-semantic instructions. Recent research [29, 30] indicates that CXL shared memory pools introduce new architectural constraints for cross-CN coherent synchronization. As a result, caching systems like Ditto [62], which rely on fine-grained synchronization for object-level housekeeping, may encounter scalability bottlenecks due to excessive synchronization traffic. In contrast, FORGE significantly reduces cross-node synchronization demand through coarse-grained group management and lazy hotness flushing, making it highly adaptable to the architectural constraints of future CXL environments.

6 Performance Evaluation

6.1 Experimental Setup

Testbed. We conduct our evaluation on a cluster of 6 machines (3 CNs and 3 MNs), each with two Intel Xeon Gold 6230R CPUs, 256 GB DRAM, and a 100Gbps Mellanox ConnectX-5 RNIC connected to a 100Gbps InfiniBand Switch.

Comparisons. We compare FORGE with three state-of-the-art systems, Ditto [62], S3-FIFO [77], and GL-Cache [74].

Ditto [62] represents the state-of-the-art in DM caching systems, employing sophisticated object-level hotness tracking and sampling-based eviction. Similar to LeCaR [68], CNs utilize multiple eviction policies (e.g., LRU and LFU), select the highest-weight policy to predict the utility of sampled objects, and evict the lowest-utility objects. CNs maintain a history of recently evicted objects, which they use to adjust policy weights to correct mispredictions. **S3-FIFO** [77] is the latest object-level replacement algorithm. It uses multiple FIFO queues to filter out unpopular objects and promote hot objects through the queues. **GL-Cache** [74] is an efficient group-level caching system. It uses decision trees to predict the utility of sampled groups based on their group-level hotness metrics and evicts those with the lowest predicted utility.

However, S3-FIFO and GL-Cache are designed for traditional monolithic servers and cannot directly work on DM. Thus, based on their original papers [74, 77], we faithfully re-implement them on RDMA-based DM (i.e., S3FIFO-DM and GLCache-DM). For fair comparisons, we further enhance them with DM-relevant designs proposed by FORGE, including lock-free `Get`/`Set` operations, contention-free FIFO management, asynchronous and batched RDMA for hotness flushing, and lightweight object regrouping. In GLCache-DM, CNs periodically flush collected training data (e.g., group hotness metrics and utility scores) to MNs, where decision trees are asynchronously retrained to avoid blocking CNs. Although SIEVE [82] is another prominent FIFO-based algorithm for monolithic servers, our analysis in § 2.2 demonstrates its severe synchronization bottlenecks in DM due to serialized doubly-linked queue scanning. As a result, SIEVE-DM delivers 3.1–5.0× lower throughput than Ditto. In contrast, our enhanced S3FIFO-DM leverages a contention-free ring-array to mitigate these synchronization bottlenecks, making S3FIFO-DM a much stronger and robust representative for object-level FIFO schemes throughout our evaluation. All the evaluated systems are implemented in C/C++. Since Ditto's open-source prototype only supports a single MN, we use one MN for fair comparisons across all four systems, and further evaluate the other three systems with multiple MNs in §6.5.

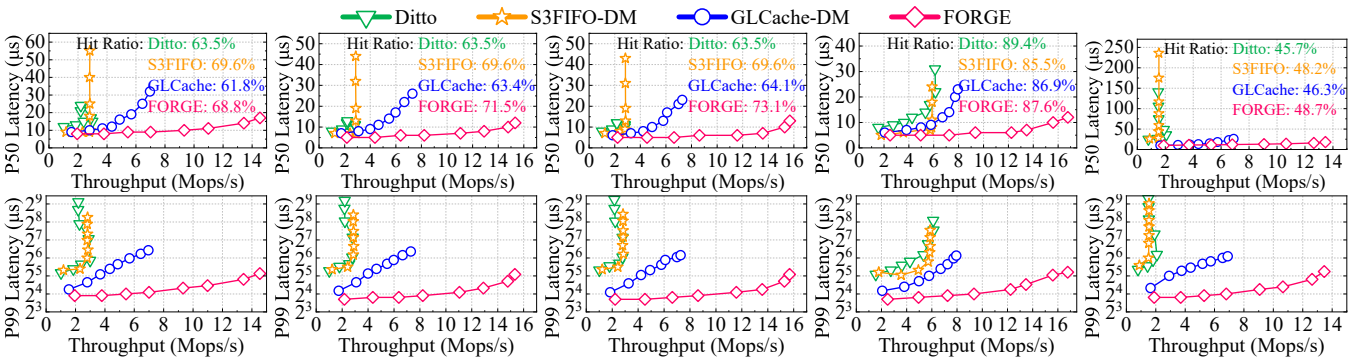
Configurations. We use the recommended configurations of all baselines, e.g., a sample size of 5 and a history size of 1024 for Ditto [62], a 10% small queue and an object frequency ceiling of 3 for S3-FIFO [77], 7-dimensional group-level hotness metrics and XGBoost-based [16] decision trees for GL-Cache [74]. For FORGE and GLCache-DM, the group size is 64 objects, and each eviction merges 8 groups. We analyze the sensitivity of FORGE to group sizes in §6.6.

Workloads and Methodology. The YCSB [19] workloads with a Zipfian distribution ($\theta = 0.99$) include: A (50% GET, 50% UPDATE), B (95% GET, 5% UPDATE), C (100% GET), D (95% GET, 5% INSERT), and E (95% SCAN, 5% INSERT). The real-world workloads cover object stores from Wikimedia [64] and IBM [25], block I/O from CloudPhysics [69] and Microsoft Research Cambridge [53], and key-value caches from Twitter [75] and Meta [9]. Each workload comprises up to 100 million requests, while the IBM workload contains 10–40 million requests due to trace limitations. Before evaluation, we warm up the cache with the first 20% of requests. Following state-of-the-art methodologies [62, 74, 77, 82], we evaluate the cache as a closed system with on-demand fill, where each `Get` miss includes the overhead of an uncounted `Set`. This setup provides performance isolation and generality across storage backends. We further analyze the sensitivity of system performance to different miss penalties in §6.6.

6.2 Performance in YCSB Workloads

We evaluate the four systems under YCSB workloads with 256-byte objects and a 20% cache size, a standard setting in DM caching [62]. The performance trends and bottlenecks remain consistent with the smaller 10% cache ratio in Fig. 3. We vary the number of threads across 3 CNs from 16 to 256.

As shown in Fig. 13, Ditto and S3FIFO-DM exhibit the



(a) YCSB A-20% (b) YCSB B-20% (c) YCSB C-20% (d) YCSB D-20% (e) YCSB E-20%

Figure 13: Throughputs, 50th (upper) and 99th (lower) percentile latencies of systems in YCSB workloads at 20% cache sizes.

worst throughputs and latencies, bottlenecked by the costly object-level synchronizations. Their CNs frequently synchronize object hotness updates to MNs when cache hits, creating significant RDMA traffic (corroborating the traffic breakdown in Fig. 3) that interferes with `Get`/`Set` and inflates P50 latencies. Ditto embeds the hotness metadata in hash buckets to facilitate tracking and sampling, but the enlarged hash buckets increase the RDMA payload of each index lookup. Moreover, on cache misses, their object-level eviction mechanisms lie on the critical path and lead to high P99 latencies. In Ditto, the random sampling and `RDMA_CAS`-based eviction incur large overheads and contention-induced retries. S3FIFO-DM, despite being improved by using our contention-free FIFO queue, still suffers from high eviction overheads because its policy requires intensive RDMA operations to demote cold objects and promote hot ones through multiple queues.

GLCache-DM and FORGE remove the group-level hotness tracking and eviction from `Get`/`Set` critical paths and significantly reduce synchronization traffic. Thus, they achieve higher throughputs and lower latencies than Ditto. However, like Ditto, GLCache-DM suffers from inefficient sampling and retry under contention, and the buffered hotness metrics need to be synchronized at intervals to avoid stale metrics on MNs. Moreover, each inference of the decision trees consumes hundreds of microseconds of CN CPU cycles. Consequently, the performance of GLCache-DM is still constrained.

FORGE excels by eliminating synchronization bottlenecks. Its contention-free FIFO management eliminates the inefficient sampling that plagues Ditto and GLCache-DM. Its version-assisted lock-free index and TWIM-based lightweight regrouping overcome the potential inefficiency of coarse-grained group management. More critically, FORGE's lazy synchronization ensures that hotness metrics are flushed just-in-time for eviction, radically reducing synchronization traffic (validating the benefits previewed in Fig. 3) without sacrificing metric accuracy. Consequently, FORGE achieves 2.0–8.7× higher throughput, 1.3–5.9× lower P50 latency, and 3.9–13.3× lower P99 latency than all baselines.

FORGE demonstrates superior cache performance, achieving hit ratios in the top two across workloads. Its lazy synchronization equips CNs with globally accurate hotness information, enabling precise eviction decisions and the effective identification and reinsertion of hot objects. In contrast, the hit ratios of Ditto (and GLCache-DM) are hampered by their dependence on random sampling and stale (or misleading group-grained) hotness metrics, with read-latest YCSB D being an exception where their recency-aware algorithms like LRU align well with the access pattern. Although S3FIFO-DM also benefits from accurate metrics, FORGE maintains a hit ratio advantage in YCSB B–E by augmenting the FIFO foundation with a hotness-aware virtual segmentation that proactively evicts colder groups within the same queues, adapting better to shifting access patterns. The write-intensive YCSB A proves challenging for all grouping methodologies, yet FORGE sustains a highly competitive stance. These collective results validate that FORGE's synchronization efficiency delivers comprehensive system improvements, boosting not only throughput and latency but also enhancing hit ratios.

6.3 Performance in Real-World Workloads

We evaluate the four systems with real-world workloads from CloudPhysics (CPhy), Wikimedia (Wiki), Microsoft Research Cambridge (MSR), and IBM, using 128 threads across 3 CNs. Aligned with the setup in Ditto's paper [62], object sizes are fixed at 256 bytes, while cache sizes are varied among 5%, 10%, and 20% of the trace footprints.

As shown in Fig. 14, the performance of both Ditto and S3FIFO-DM remains constrained by their costly object-level synchronization mechanisms. In particular, S3FIFO-DM delivers the lowest throughput and highest latency in most cases. Its eviction policy necessitates frequent object demotion and promotion across multiple queues. Such frequent queue management triggers a high volume of atomic `RDMA_FAA` operations, which are especially expensive and significantly interfere with performance-critical `Get`/`Set` as shown in Fig. 2.

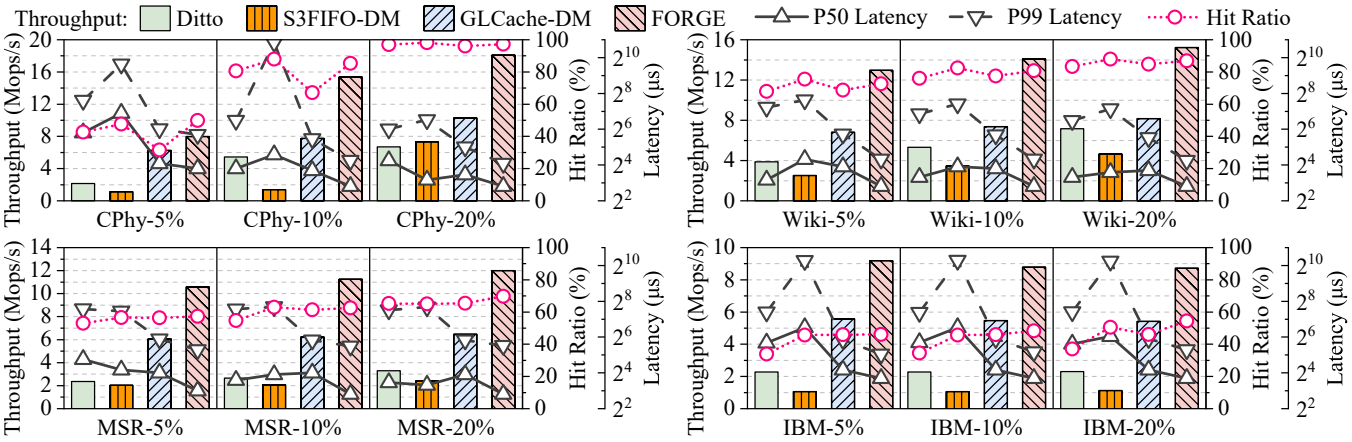


Figure 14: Throughputs, latencies, and hit ratios in real-world workloads at 5%, 10%, 20% cache sizes with fixed object sizes.

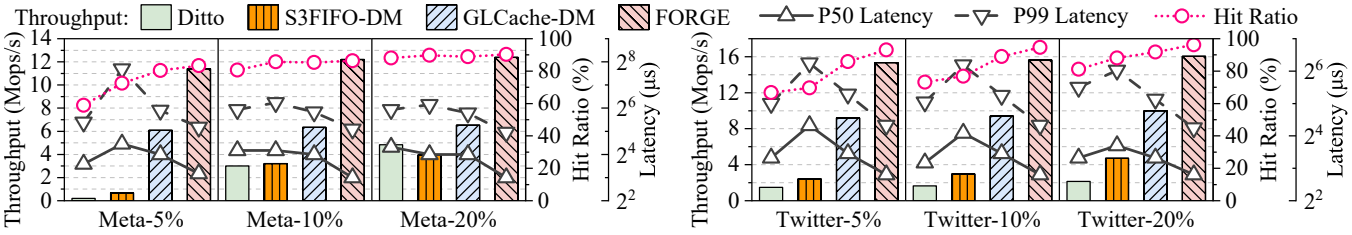

Figure 15: Throughputs, latencies, and hit ratios in real-world workloads at 5%, 10%, 20% cache sizes with variable object sizes.

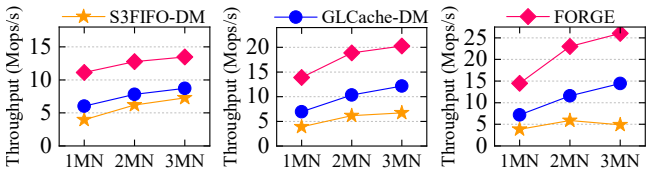
In CPhy with a 5% cache size (short for CPhy-5%), the small cache cannot hold enough groups for GLCache-DM to train reliable decision trees, impairing the model's robustness and reducing eviction effectiveness and hit ratios. In CPhy-20%, the large cache and skewed access pattern lead to high hit ratios (≈96%) for all systems. Higher hit ratios reduce eviction frequency and overhead, thereby improving the throughputs and latencies of all systems. However, despite lower rates of eviction and random sampling, the eviction timing of any specific object (and group) in Ditto (and GLCache-DM) remains unpredictable. Therefore, CNs in both systems still need to periodically flush buffered hotness metrics to MNs, incurring DM traffic and limiting performance.

In contrast, FORGE synchronizes hotness just-in-time for eviction, thereby adapting to dynamic hit ratios. Leveraging this lazy mechanism, CNs flush metrics only when a new group enters the eviction window. Under high hit ratios in CPhy-20%, evictions are rare, and new groups enter the eviction window slowly. Consequently, the lazy synchronization is infrequent, improving the throughput and latency of FORGE. On the other hand, under low hit ratios in workloads like IBM, evictions occur more frequently to make room for new objects, triggering more rapid hotness synchronization to maintain metric accuracy. This adaptive approach, combined with efficient FIFO-based hotness-aware group eviction, drastically reduces synchronization overheads while maintaining high hit ratios. As a result, compared with Ditto and GLCache-DM, FORGE achieves 1.3–4.5× higher throughput, 1.2–4.0× lower P50 latency, and 1.2–7.5× lower P99 latency across workloads, with an average 1.14× improvement in hit ratios.

6.4 Robustness to Memory Fragmentation

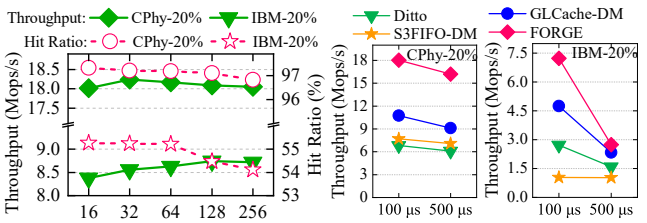
We evaluate the systems in real-world workloads from Meta and Twitter with their dynamic object sizes, using 128 threads across 3 CNs. To establish a stringent baseline for comparison, we enhance the object-level systems (Ditto and S3FIFO-DM) with a slab-based allocator that organizes object blocks into 24 size classes, a standard technique to mitigate external fragmentation [11, 24]. Even with this enhancement, Fig. 15 shows that their performances sharply degrade under small cache sizes (e.g., Meta-5% and Twitter-5%). This is because object-level evictions divide free memory into small, disjoint fragments reclaimed by multiple CNs. Each CN struggles to allocate contiguous memory for large objects, reducing effective memory utilization and lowering hit ratios. With larger cache capacities (e.g., Meta-20% and Twitter-20%) mitigating fragmentation, the performances of Ditto and S3FIFO-DM recover but remain fundamentally constrained by their costly object-level hotness tracking, evictions, and GC.

In contrast, GLCache-DM and FORGE perform evictions and space reclamation at group granularity, avoiding external fragmentation and achieving robustness under dynamic object sizes. Furthermore, FORGE's enhanced FIFO eviction



(a) 100 CN threads (b) 200 CN threads (c) 300 CN threads

Figure 16: The scalability of systems with CNs and MNs in the Meta workload at 20% cache sizes.



(a) Group size (objects) (b) Miss penalty (μs)

Figure 17: The sensitivity analysis of system performance.

and lazy synchronization mechanisms give it a performance advantage. Compared with GLCache-DM (the best baseline), FORGE achieves 1.61–1.93× higher throughput, and reduces P50 and P99 latency by 1.43–2.00× and 1.67–1.95× respectively, with 1.02–1.09× improvements in hit ratios. Since the workloads contain large objects, both systems are ultimately bottlenecked by the single MN's finite network bandwidth.

6.5 Scalability Analysis

Our scalability evaluation employs the Meta workload with a 20% cache size, scaling MNs from 1 to 3 and varying the thread count across 3 CNs from 100 to 300; Ditto is excluded as its open-source prototype lacks multi-MN support, and its CN scalability was previously assessed in §6.2. As depicted in Fig. 16, both FORGE and GLCache-DM demonstrate excellent scalability, where adding MNs increases aggregate network bandwidth, alleviating the network bottleneck and boosting throughput. This improvement is marginal under low thread counts (e.g., 100) where systems are compute-bound, but becomes pronounced with abundant CN threads (e.g., 300) where network bandwidth is the primary constraint. The non-linear compute scaling with thread count stems from overheads and resource contention in Hyper-Threading [48]. S3FIFO-DM scales poorly due to exacerbated memory fragmentation under scale. Ultimately, FORGE's highly efficient synchronization design enables it to outperform GLCache-DM (the best baseline) by 1.54–2.02× across configurations.

6.6 Sensitivity Analysis

We evaluate FORGE's sensitivity to group size and cache miss penalty in CPhy-20% and IBM-20%, the workloads with the highest and lowest hit ratios in § 6.3, respectively.

Group Size. As shown in Fig. 17a, in the low-hit-ratio IBM workload, where evictions occur frequently, larger groups better amortize eviction overheads and thus yield higher throughput. Conversely, smaller groups can maintain higher intra-group access similarity, leading to slightly better hit ratios. In the high-hit-ratio CPhy workload, where evictions are rare, performance is largely insensitive to group size. These results show that FORGE is robust across different group sizes.

Miss Penalty. For each `Get` miss, CN threads are stalled for 100 μs or 500 μs before inserting the missed object into the cache, emulating the realistic latency of fetching objects from distributed storage [35, 47]. As shown in Fig. 17b, the impact of this penalty is highly workload-dependent: in the high-hit-ratio CPhy workload, misses are rare, minimizing the penalty's effect and allowing FORGE to outperform all baselines by 1.68–2.64× and 1.78–2.66× under the 100 μs and 500 μs penalties, respectively. Conversely, the low-hit-ratio IBM workload triggers frequent miss penalties, leading to substantial thread stalls that limit overall throughput and leave the network significantly underutilized, thereby diminishing the relative advantage of FORGE's synchronization efficiency; despite this, FORGE still maintains a clear superiority with performance gains of 1.52–6.94× (100 μs) and 1.17–2.68× (500 μs). More importantly, in datacenters, a large number of concurrent application clients [54] would sustain network saturation despite such stalls, thus giving FORGE's efficient synchronization a decisive performance advantage.

6.7 Contributions of Different Techniques

Fig. 18 presents an ablation study of FORGE on YCSB workloads with a 20% cache size. Starting from a baseline with group-level FIFO eviction, we apply each proposed technique one by one. We use 256 CN threads across 3 CNs.

+ Lock-free Index. Our version-assisted lock-free index eliminates serialization on hash table slots during `Set` operations. This is especially critical for the write-heavy YCSB A, where it improves the throughput by 21.5× and P50 latency by 6.7×.

+ Contention-free FIFO Management. By minimizing the synchronization overheads of FIFO enqueuing and dequeuing, this technique excels on workloads with low hit ratios that trigger frequent evictions. It boosts the throughput by 23.1%–57.5% and reduces P99 latency by 1.25–10.36× across all workloads, with peak gains observed in YCSB E.

+ Lightweight Regrouping. Leveraging TWIMs for object regrouping, CNs efficiently read only the necessary hot objects and update their pointers with minimal RDMA operations. This improves throughput by 32.6%–55.8%, and cuts P50 and P99 latency respectively by 20.0%–65.2% and 45.2%–61.0%.

+ Hotness-aware FIFO Queue. This design enhances FIFO queues through virtual segmentation, effectively retaining hot

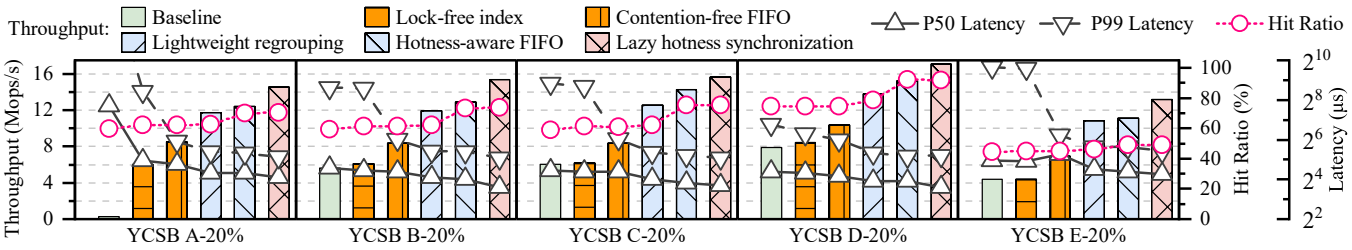


Figure 18: Performance contributions of different techniques across YCSB workloads at 20% cache sizes.

groups longer while prioritizing the eviction of cold ones. Built upon the multi-queue scheme, it yields a substantial 1.12–1.21× improvement in cache hit ratios for YCSB A–D. The gain is more modest (1.06×) in the scan-heavy YCSB E.

+ Lazy Hotness Synchronization. Leveraging the predictability of FIFO evictions, distributed CNs wait until a group nears the queue head to flush its hotness metrics, eliminating unnecessary synchronization traffic. FORGE further accelerates the traffic via RNIC on-chip memory to minimize interference with performance-critical `Get`/`Set` operations. Even on a baseline already heavily optimized by the preceding techniques, this lazy synchronization further improves the throughput and P50 latency by up to 18.9% and 33.3%, respectively.

7 Related Work

Memory Disaggregation. To improve resource utilization, existing studies leverage memory disaggregation across various domains, including indexes [43, 45, 46, 85], key-value stores [26, 39, 52, 63, 67], transaction processing [29, 79, 80], and memory management [15, 40, 42, 49, 61, 70, 83]. Unlike them, FORGE focuses on caching systems in DM. Its closest competitor, Ditto [62], employs an eager object-level housekeeping mechanism that introduces substantial synchronization overhead and undermines overall caching efficiency. In contrast, FORGE pioneers an innovative lazy hotness synchronization mechanism integrated into a DM-tailored group-level framework and enhanced-FIFO replacement strategy, which fundamentally reduces synchronization demands through coordinated eviction of groups rather than individual objects.

Group-based Cache and Storage Management. Grouping objects to amortize operational overheads has been widely explored across various storage tiers. In distributed file systems, SmartStore [27] aggregates correlated files into semantic-aware groups via latent semantic indexing to optimize complex metadata queries. For local flash storage, Kangaroo [50] and RIPQ [66] group small objects into large writes to mitigate flash write amplification. In monolithic in-memory caches, Segcache [76] groups objects with similar lifecycles to enable efficient bulk expiration, whereas GL-Cache [74] clusters objects to amortize machine-learning overheads for eviction. In contrast, FORGE introduces group-level management specifically for DM architectures to resolve the unique bottleneck of cross-node synchronization amplification.

Replacement Algorithms. Prior research [8, 22, 28, 31, 33, 51, 59, 73, 77] focuses on sophisticated eviction algorithms to optimize hit ratios and throughputs in monolithic servers, but fundamentally overlooks the critical challenge of synchronization amplification in DM. For instance, recent algorithms like SIEVE [82] achieve efficiency via simplified structures in monolithic environments. However, as demonstrated in § 2.2, applying SIEVE directly to DM still incurs prohibitive object-level synchronization overhead, especially due to the eager checking and setting of visited bits upon cache hits, and the blocking queue scans during eviction. In contrast, FORGE lazily defers hotness metric flushing until object groups enter the eviction window, bypassing unnecessary DM traffic for hotness tracking upon cache hits. Moreover, FORGE performs group-level eviction using a contention-free and hotness-aware FIFO design, eliminating the costly blocking overhead while maintaining high hit ratios. Overall, FORGE enables a high-performance DM caching system via a holistic redesign with DM-friendly data structures, efficient eviction schemes, and novel synchronization mechanisms.

8 Conclusion

DM amplifies the synchronization overheads in crucial cache housekeeping, creating a critical bottleneck that undermines the benefits of resource disaggregation. FORGE addresses this challenge through a synergistic design with DM-tailored group-level management, a contention-free hotness-aware FIFO policy, and a lazy-yet-timely hotness synchronization mechanism. This cohesive approach minimizes unnecessary cross-node synchronization while preserving accuracy, enabling FORGE to significantly outperform state-of-the-art DM caching systems. The source code of FORGE is publicly available at https://github.com/cszjyang/forge.

Abstract

Confidential databases (CDBs) enable secure queries over sensitive data in untrusted cloud environments using confidential computing hardware. While adoption is growing, widespread deployment is hindered by high overheads from frequent synchronous cryptographic operations, which cause significant computational and I/O bottlenecks.

ZENO is a novel CDB design that removes cryptographic operations from the critical path. It introduces crypto-free mappings that maintain data-independent identifiers within the database while securely mapping them to plaintext secrets in a trusted domain. This paradigm shift yields substantial performance gains across industry-standard benchmarks (TPC-C, TPC-H) and a real-world industrial workload. Specifically, ZENO speeds up TPC-H queries by up to 53.1× on ARM S-EL2 and 94.7× on x86 TDX compared to HEDB. ZENO's optimization techniques have been integrated into GaussDB.

1 Introduction

Cloud databases have become the backbone of modern digital infrastructure, with organizations increasingly outsourcing their data management to Database-as-a-Service (DBaaS) providers [7, 10, 14]. However, this convenience comes with a critical security risk: cloud administrators have unrestricted access to all tenant data, leaving opportunities for both malicious and accidental exposure. Recent breaches, such as the Allianz Life exposure of 1.1 million personal records [20], underscore this threat. For sensitive databases regulated by laws such as HIPAA [5] and PCI-DSS [4], entrusting cloud infrastructure with plaintext data is untenable.

Confidential databases (CDBs) have emerged as a compelling solution. By leveraging trusted execution environments (TEEs), CDBs enable secure data upload and query execution while keeping data encrypted from the cloud provider. Over the past two decades, researchers have explored various CDB designs [25, 28, 42, 65, 73], and major cloud providers have deployed CDB systems [24, 45, 56, 74, 77].

Despite this industry momentum, CDB systems face a critical barrier to widespread adoption: severe performance degradation compared to plaintext databases, with analytical queries experiencing up to 79.5× higher latency [56]. This gap arises from a deliberate system design choice in industry deployments: rather than enclosing the entire DBMS within a TEE, which would prevent database administrators from performing essential maintenance tasks, modern CDBs execute only security-critical operators (e.g., numeric `SUM` operations) inside TEEs. The resulting split architecture necessitates synchronous software-based decryption and encryption for every remote procedure call (RPC) across domains, as illustrated in Figure 1. The computational burden scales linearly with data volume. For instance, a `SUM` aggregation over an N-row table requires $2N$-2 decryptions and N-1 encryptions in total. Even worse, to support arbitrary computation across fields, modern CDBs employ field-level encryption, inflating each 4-byte integer to 32 bytes (8× expansion) due to cryptographic metadata (a 12-byte nonce and a 16-byte authentication tag required by schemes like AES-GCM). This dramatically amplifies cross-domain data movement, memory pressure, and I/O bandwidth demands. These limitations raise a fundamental question: **Is cryptographic overhead inherent to CDB design, or can we achieve equivalent security guarantees with far cheaper alternatives?**

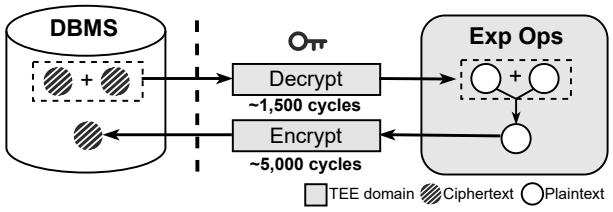

Figure 1: In modern CDBs, a cross-domain invocation involves two decryptions and one encryption, incurring high computational overhead (CPU cycles evaluated on ARM).

Key insight. We argue that the performance crisis stems from an unexamined assumption that has persisted for decades: *any data leaving TEEs must be encrypted.* Modern CDBs store ciphertexts in the DBMS and decrypt them in TEEs for compu-

Table 1: Comparison between modern CDBs and ZENO (CPU cycles evaluated on ARM).

	Modern CDBs	ZENO
Indirection	Ciphertexts	Data-independent FIDs
Protection	Ciphertexts	Encryption at rest
Indirection cost	Decrypt (∼1,500 cycles) Encrypt (∼5,000 cycles)	Get (∼30 cycles) Put (∼200 cycles)

tation. We observe that this is fundamentally a mapping-based protection scheme: the DBMS uses ciphertexts as pointers to reference plaintext data in TEEs. Current practice conflates indirection with protection, encrypting both pointers and data. We decouple these concerns: pointers use lightweight indirection; only data at rest uses encryption. Based on this insight, we aim to replace the costly ciphertext-to-plaintext mappings with highly efficient index-to-plaintext mappings, while preserving both data confidentiality and database correctness.

Our approach. We present ZENO, a CDB system that eliminates compute-intensive cryptography from the critical path without sacrificing security. ZENO introduces *crypto-free mappings* that bind data-independent field identifiers (FIDs) to their corresponding plaintext fields within TEEs. This allows the DBMS to manipulate data as before, while replacing slow per-field en/decryption with ultra-low-latency put/get operations, as shown in Table 1. In addition, to avoid encrypting every field synchronously, ZENO defers encryption: when data must be evicted from TEE memory to untrusted storage, ZENO performs asynchronous block-level encryption rather than fine-grained field-level encryption. In short, crypto-free mappings deliver two key benefits: they remove cryptographic operations from query execution hot paths and reduce metadata overhead via coarser-grained encryption.

Our design brings two main challenges. First, as datasets scale, the mapping lookup time could grow unbounded and ultimately exceed the cost of constant-time cryptographic operations. Second, maintaining transaction semantics and mapping consistency requires new mechanisms because both domains are now stateful, a situation not encountered in conventional CDB systems.

To overcome the first challenge, ZENO introduces a scalable, low-latency data structure called the *mapping store*. This mapping store provides $O(1)$ access complexity by treating FIDs as direct array indices, eliminating the need for tree traversals or hash-table probing. ZENO further preserves data locality across domains through storage-layout-aware mapping store organization. This layout awareness, combined with proactive prefetching, keeps the corresponding data resident in TEE memory when the DBMS accesses an FID block, thereby minimizing additional I/O overhead.

The second challenge requires a subtle observation: the state of the mapping store is internal to the system and invisible to the DBMS. The DBMS observes only the FIDs it maintains—the system's external state. This asymmetry allows us to adopt external synchrony [61]: only FIDs maintained by the DBMS should be mapped to valid, up-to-date plaintexts; the reverse mapping (plaintexts to FIDs) need not even exist. As a result, ZENO only needs to maintain the invariant that every FID in the DBMS has a corresponding valid value in the mapping store. To uphold this invariant across transactions and crashes, ZENO introduces lightweight coordination protocols that ensure cross-domain updates remain consistent and crash-tolerant with minimal overhead.

We evaluate ZENO against HEDB [56], a state-of-the-art modern CDB that achieves the trifecta of functionality, maintainability, and security. Our results across both ARM S-EL2 and x86 TDX show that ZENO achieves substantial performance improvements while preserving all desired properties. On the transactional benchmark TPC-C, ZENO reduces HEDB's throughput loss relative to plaintext PostgreSQL by up to 49.8% on ARM S-EL2 and 73.8% on x86 TDX. On the analytical benchmark TPC-H, ZENO speeds up query execution by up to 53.1× on ARM S-EL2 and 94.7× on x86 TDX over HEDB. On real-world industrial queries, ZENO outperforms HEDB with average speedups of 4.6× on ARM S-EL2 and 2.9× on x86 TDX. Additionally, ZENO reduces storage consumption by 38.9%, 52.8%, and 42.4% across the three workloads, respectively. The main performance techniques of ZENO have been integrated into GaussDB.

Contributions. We make the following contributions:

- We identify and analyze the performance bottlenecks of modern CDBs through comprehensive profiling and empirical analysis.
- We propose a novel CDB design with crypto-free mappings, which remove costly cryptographic operations from the critical path of existing modern CDBs.
- We build and deploy ZENO, which outperforms state-of-the-art modern CDBs across transactional and analytical benchmarks, as well as a real-world industrial workload.

2 Background and Motivation

2.1 Confidential Computing

Confidential computing [9, 12, 16, 17, 22, 41, 47, 52, 55, 57] provides hardware-based trusted execution environments (TEEs) with three security guarantees. First, secure isolation through either enclaves [16, 41, 52] or confidential virtual machines (CVMs) [12, 17, 22] protects against inspection or tampering by untrusted privileged software. Second, hardware root-of-trust enables clients to verify code authenticity via remote attestation. Third, memory encryption and optional integrity checks resist physical attacks. Confidential computing is now widely available on commercial clouds [2, 6, 9, 13, 15].

2.2 Confidential Databases

Database-as-a-Service (DBaaS) [46] offers fully managed databases that handle updates, backups, and maintenance

for users. However, since cloud environments are untrusted, sensitive data like healthcare and financial information requires secure storage and processing. Confidential databases (CDBs) [24, 25, 28, 42, 45, 56, 65, 67, 73, 74, 77] leverage confidential computing to enable SQL query processing over encrypted data without compromising confidentiality.

Existing CDB systems can be broadly categorized into two types. One type [28, 65, 67, 77] places the entire DBMS inside the trusted domain (TEE), where the DBMS processes data in plaintext and encrypts it when interacting with untrusted environments (e.g., network or storage). However, this type imposes an inherent limitation: the black-box TEE hinders DBMS maintainability for database administrators (DBAs) [24, 56]. In contrast, another type [24, 45, 56, 73, 74] adopts a split architecture: only essential expression operators (e.g., arithmetic, comparison[1]) execute inside TEEs, while most DBMS logic (e.g., SQL parsing, planning, buffer management) remains in the untrusted domain. This minimizes the TCB and preserves maintainability: DBAs can inspect query plans and debug DBMS issues. We refer to the latter as *"modern CDBs"* throughout the paper.

To enable flexible computation across arbitrary fields, modern CDBs apply field-level encryption. For example, since all fields from the column `Salary` are encrypted, `"SELECT SUM(Salary) FROM Employee"` requires the DBMS to iteratively call the `addition` operator inside the TEE, which decrypts operands, computes the sum, re-encrypts the result, and returns it to the DBMS. While secure, this design incurs substantial performance overhead, as we will analyze later.

HEDB [56]: a representative modern CDB. Modern CDBs could be vulnerable to *smuggle attacks* [56]: malicious DBAs exploit operator interfaces to construct known ciphertexts (via arithmetic operators, e.g., division yields encrypted "one," addition builds sequences) and compare them against victim ciphertexts (via equality operators), thereby extracting secrets without authorization. HEDB addresses smuggle attacks through a dual-TEE architecture: an *integrity zone* that hosts the DBMS and a *privacy zone* that hosts operators, with a secure channel preventing direct interface access by DBAs. For maintainability, HEDB records cross-zone calls as ciphertext, enabling DBAs to replay and debug queries without plaintext access. Therefore, ZENO builds on HEDB's security foundation. Notably, the performance limitations addressed by ZENO exist across many split-architecture CDBs [24, 45, 73, 74], and its crypto-free mappings generalize beyond HEDB.

2.3 What Makes Modern CDB Systems Slow?

Modern CDBs exemplified by HEDB have demonstrated significant performance overheads. Benchmarks on TPC-H show that HEDB can incur up to a 79.5× increase in latency compared to a plaintext database [56]. These overheads render modern CDBs impractical for latency-sensitive applications, hindering broader industry adoption. Our analysis attributes them to two main factors.

[1]All operators yield encrypted results, except for comparisons (e.g., $<$, $=$, $>$), which output plaintext boolean values for use in indexing ciphertexts.

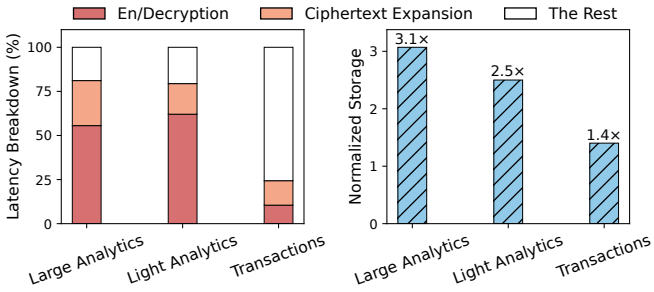

Figure 2: Latency and storage overhead analysis across three typical workloads. **Left (a)**: profiling end-to-end SQL execution time; the rest denotes normal DBMS execution and RPC invocations. **Right (b)**: storage overhead normalized to plaintext databases.

Factor-#1: expensive encryption and decryption. In modern CDBs, each computation on sensitive data requires a cross-domain round-trip, which involves two decryptions and one encryption, each taking thousands of cycles, as shown in Table 1. For an operation like `SUM` on a table with N rows, the computation incurs $N-1$ round-trips, resulting in $2N-2$ decryptions and $N-1$ encryptions. Given that N is often *tens of millions* in real-world scenarios (reported by several CDB vendors we surveyed), this high frequency of expensive cryptographic operations inevitably introduces high overhead on the critical path. While batching multiple RPC invocations into a single round trip (e.g., for aggregation operators such as `SUM`, `AVG`, `MAX`, and `MIN`) can help amortize overhead, the core issue remains that cryptographic operations must still be performed on every single data item.

Factor-#2: ciphertext expansion. Modern CDBs employ field-level encryption with AES-GCM. To guarantee data confidentiality and integrity, each encrypted field requires a nonce (12 bytes) and message authentication code (MAC, 16 bytes), totaling 28 B of cryptographic metadata. This introduces significant ciphertext expansion: a 4-byte integer expands to 32 bytes, an 8× size increase. This expansion creates two performance bottlenecks. First, it enlarges the data transferred during frequent inter-domain RPCs, resulting in higher memory copy latency. Second, it increases the overall storage footprint of the database, leading to more I/O operations between the DBMS buffer pool and storage.

Empirical analysis. We profile HEDB [56] (commit f48742de) using three workloads: (i) TPC-H Q1 with a dataset larger than memory, representing large table computation; (ii) TPC-H Q1 with a dataset fitting in memory, capturing lightweight analytical settings; and (iii) a transactional benchmark with many write-heavy small queries. Despite the batch-

ing optimization, HEDB exhibits significantly higher overhead, with an overall latency slowdown of up to 5.3× relative to the plaintext baseline. As illustrated by the performance breakdown in Figure 2(a), en/decryption operations and ciphertext expansion account for a substantial fraction of the total execution time, contributing 10.5–62.6% and 13.9–25.5%, respectively, across workloads. Specifically, the contribution of I/O amplification is more pronounced in (i) than in (ii). This shift shows that the overhead distribution varies with the workload, particularly with respect to data scale and memory residency. Meanwhile, the storage overhead (Figure 2(b)) reveals that field-level encryption incurs a 1.4× to 3.1× storage expansion relative to the plaintext baseline.

Strawman: a ciphertext-to-plaintext cache. Since confidential VM-based TEEs (e.g., Intel TDX [17], AMD SEV-SNP [22]) provide sufficiently large secure memory, one may consider maintaining a ciphertext-to-plaintext cache within TEEs to remove cryptographic operations from the critical path. However, as the cache scales with the protected dataset, searching a large ciphertext-keyed structure can itself become a bottleneck. As our ablation study shows (§7.2), such a cache helps reduce cryptographic cost but remains limited by the overhead of ciphertext-based lookups.

3 ZENO Overview

Design goals. ZENO has two design goals:

- G1: *Compatibility.* ZENO aims to be compatible with modern CDB designs by preserving their functionality (standard SQL and ACID), while retaining HEDB-level DBA maintainability and security (data confidentiality and database integrity).
- G2: *Efficiency.* ZENO aims to reduce the performance gap between existing modern CDBs and plaintext databases by optimizing the two factors identified in § 2.3.

Threat model. We assume a powerful adversary who controls the entire cloud infrastructure except TEE hardware. This includes compromised server software, rogue cloud and database administrators, and external attackers. Adversaries can read and modify any data outside TEE domains—data at rest, in untrusted memory, and in transit—and observe all network traffic and I/O patterns visible outside TEE domains.

We assume TEEs provide two essential properties: *memory isolation*, preventing external access to TEE-internal state, and *remote attestation*, enabling users to verify code integrity before establishing trust. While TEE-agnostic, ZENO requires these guarantees to ensure sensitive plaintext data remains visible only within TEE domains. We do not consider TEE side-channel attacks (e.g., [36, 69, 72, 76]); these can be addressed by orthogonal hardening techniques [33, 59, 81]. Nor do we consider database vulnerabilities [11], TEE defects [50], physical attacks [51], or denial-of-service.

Functional leakage inherent to split-architecture CDBs is

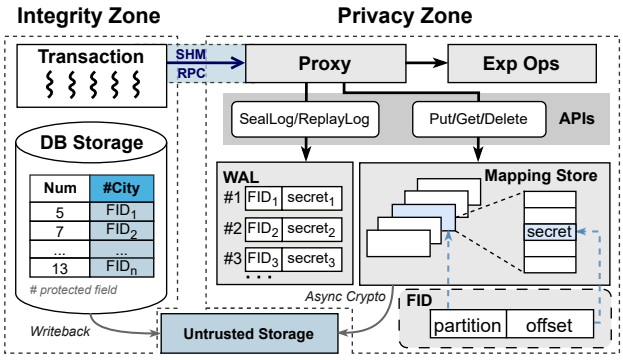

Figure 3: High-level architecture of ZENO.

permitted. This reflects a fundamental trade-off between functionality and privacy: exposing certain metadata is sometimes necessary to support core database functionalities, such as order for index construction [56]. Because our design substitutes ciphertexts with FIDs, we additionally account for any metadata exposed through this indirection mechanism; its security implications are analyzed in § 8.

Insights. Current practice in modern CDBs employs a mapping-based protection scheme, using ciphertexts as pointers to plaintext data in TEEs. This design conflates two orthogonal concerns: *indirection* (cross-domain references) and *protection* (data confidentiality). Because ciphertexts serve both roles, this coupling necessitates expensive en/decryption on every RPC. ZENO decouples them: FIDs provide efficient indirection, while encryption protects data at rest.

In fact, separating indirection from protection is a long-standing systems principle. Capability systems [39, 53] used unforgeable tokens protected by OS confinement, rather than cryptography. Similarly, OSes have long used opaque handles, e.g., Unix file descriptors [21, 68], which are mapped internally by the kernel. In both cases, security comes from address-space isolation, keeping references simple and fast.

Architecture. ZENO's high-level architecture is depicted in Figure 3. Following the security principles of HEDB's dual-zone design, ZENO redesigns how protected values flow between zones. The integrity zone runs a commodity DBMS engine, and the privacy zone comprises four components: (1) a proxy that performs mapping operations and invokes the appropriate operators, (2) expression operators that perform computation over plaintexts, (3) the mapping store that manages the FID-to-secret mappings, and (4) a write-ahead log (WAL) for cross-domain consistency. The mapping store is divided into temporary and permanent partitions for fine-grained management. The proxy interacts with the remaining components through a set of well-defined APIs.

APIs. ZENO provides five APIs to manage the mapping store:

- `Put(partition_num, secret)` → `FID`: Stores the given secret in the specified partition of the mapping store.

Returns an FID with the partition number embedded, as a reference to the stored secret.

- `Get(FID)` → `secret`: Retrieves the secret associated with the specified FID, or returns a null value if the FID has no corresponding mapping.
- `Delete(FID)`: Invalidates the specified FID-to-secret mapping in the mapping store, marking the entry as available for future allocation.
- `SealLog(records)` → `encrypted_records`: Encrypts the given mapping-store WAL records and returns the encrypted records.
- `ReplayLog(encrypted_records)`: Replays the specified encrypted mapping-store WAL records to reconstruct FID-to-secret mappings.

At the operator interface, existing modern CDBs [24, 45, 56, 73, 74] can benefit from ZENO's gains by replacing per-field en/decryption with `Put()`/`Get()` calls (see Listing 1).

```
/* expression operators (unchanged) */
int int_add(int l, int r) { return l + r; }

/* proxy code snippet */
- EncInt enc_int(Ops ops, EncInt left, EncInt right)
+ FID enc_int(Ops ops, FID left, FID right)
{
- int l = Decrypt(left), r = Decrypt(right);
+ int l = Get(left), r = Get(right);
  int result;
  switch (ops) {
      case ADD: result = int_add(l, r); break;
      // other cases...
  }
- return Encrypt(result);
+ // use temporary partitions for intermediate results
+ return Put(TMP_PARTITION_NUM, result);
}
```

Listing 1: Example code for extending the original expression operator using ZENO's APIs.

Workflow. ZENO's query execution follows the workflow of modern CDB architectures. To perform computation, the proxy fetches secrets associated with each input FID from the mapping store via `Get()`, invokes the appropriate expression operator to compute over these retrieved secrets, and then stores the result back to the mapping store via `Put()`, which generates a new FID representing the output. The DBMS proceeds with query execution using this returned FID. Finally, the proxy resolves FIDs back into ciphertexts by calling `Get()` followed by encrypting the retrieved results within the privacy zone before returning them to users. Throughout this process, FIDs remain opaque to users. This design preserves *compatibility* (G1) with the client-side encryption model used by modern CDBs [24, 45, 56, 74].

Challenges. Since ZENO introduces state into the privacy zone, it brings two challenges. First, the lookup latency in the mapping store may grow with dataset size and eventually exceed constant-time cryptographic operations (§ 4). Second, maintaining state consistency between the integrity and privacy zones is necessary for database semantics (§ 5).

4 Achieving Efficiency via Mapping Store

This section details the mapping store, which plays a crucial role in achieving *efficiency* (G2).

4.1 Mapping Management

Data structure design. The mapping store is a linear array of tightly packed fields. Each sensitive field is assigned a unique integer FID that serves as a direct array index, hiding the size of individual fields from the adversary. This design choice offers two advantages. First, employing a compact integer FID effectively restricts the metadata overhead per field to a mere 8 B, representing a 71.4% reduction compared to the 28 B metadata required by modern CDBs. Second, the use of integer-based direct indexing enables $O(1)$, cache-friendly array access to the mapping store, thereby eliminating the pointer-chasing and lookup overhead inherent in tree-based or hash-based key-value stores (e.g., [35, 40, 43]).

Mapping store operations. For fixed-length types (e.g., `FLOAT8`, `TIMESTAMP`), `Delete()` marks the corresponding mapping slots as reusable, and `Put()` either overwrites these invalidated slots or appends to the end. For variable-length types (e.g., `VARCHAR`, `NUMERIC`), the situation is subtle because values cannot be overwritten in place. We therefore maintain two arrays: an *offset array* and a *data array*. The offset array is indexed directly by FIDs and stores pointers into the data array. The data array is inspired by the slab allocator [31]: fields are grouped into size-class buckets, each maintained as a contiguous packed array to minimize fragmentation under frequent allocation and deallocation. Within each bucket, insertions and deletions follow the same overwrite/append logic as the fixed-length case.

Partition-based state management. The mapping store cannot directly infer the lifetime of each field. For instance, when an expression operator produces a result, it is unclear whether the value will be discarded after use or eventually persisted. Careless reclamation risks leaving live FIDs pointing to freed storage, causing data loss. To address this, we classify values into two categories: ephemeral values (e.g., query constants and intermediate results) and persistent values (e.g., data that outlives query completion). We separate their management by mapping them to distinct mapping store partitions: a temporary partition for ephemeral values and permanent partitions for persistent values.

For ephemeral values, reclamation occurs throughout their lifecycle. They are first placed in the temporary partition via `Put()` with the temporary partition identifier `TMP_PARTITION_NUM`. If the DBMS later decides to persist such a value, ZENO intercepts the write path and performs another `Put()` with the permanent partition identifier. During this `Put()` call, ZENO allocates a new persistent FID, copies the value into the permanent partition, and returns the new FID to the DBMS. To avoid accumulating stale values in the tempo-

rary partition, ZENO reclaims ephemeral values in the privacy zone as soon as they are known to be dead, e.g., temporary operands consumed by aggregation or temporary FIDs that have already been migrated to the permanent partition. At the end of each query, any values still remaining in the temporary partition, i.e., ephemeral values whose lifetime extends to the query boundary, can be safely discarded.

For persistent values, reclamation is triggered when the DBMS instructs the proxy to invoke `Delete()` on mappings associated with specific FIDs, e.g., during maintenance operations such as PostgreSQL `VACUUM`, which removes dead tuples.

4.2 Exploiting Data Locality

Mismatches in data access patterns between the DBMS and mapping store can cause *major page faults* on the critical path. For example, when the DBMS accesses an FID whose corresponding secret is not in memory, ZENO must perform an extra I/O in the privacy zone, thereby increasing latency. To reduce such latency, we make the mapping store organization storage-layout-aware and proactively prefetch secrets likely to be accessed by the DBMS. This is achieved by exploiting both temporal and spatial locality.

Exploiting temporal locality. In ZENO, the DBMS first retrieves the FID from storage, and then resolves it through the mapping store to obtain the corresponding secret. This lookup dependency creates a natural temporal alignment in access patterns between the DBMS and the mapping store. For instance, when a query accesses fields associated with $\text{FID}_1, \ldots, \text{FID}_n$ in sequence, the mapping store performs the same sequence to retrieve $\text{secret}_1, \ldots, \text{secret}_n$. This dependency also enables lock-efficient management for the mapping store. Accesses to the same allocated FID do not introduce conflicts, because they are already coordinated by the DBMS's concurrency control. As a result, ZENO synchronizes only during FID allocation, while reads and slot reuse need no additional locking.

Exploiting spatial locality. To further improve performance, ZENO organizes the mapping store into separate partitions based on the storage layout of the underlying database. The partitioning policy is customizable depending on the specific DBMS or storage engine. For example, in PostgreSQL, each table is a separate heap file with unordered field placement and reclamation. ZENO assigns one mapping store partition per heap file to preserve field colocation. In InnoDB, data resides in globally ordered fixed-size pages (e.g., 16 KB) with unordered fields inside each page. ZENO assigns one partition per page to preserve page-level locality. We encode the partition number in the high bits of FID to segment the FID space.

Prefetching. A random lookup in ZENO may involve two serial I/O operations: one for the DBMS to fetch FIDs and another for the mapping store to retrieve secrets. ZENO reduces this overhead by maximizing I/O overlap. Specifically, when the DBMS issues a disk read, ZENO intercepts it and identifies the partition being accessed. Since ZENO uses storage-layout-aware mapping store partitioning, it proactively sends an RPC to the proxy specifying which partition will be accessed. The mapping store then prefetches the corresponding partition concurrently with the DBMS's I/O operation.

5 Ensuring Cross-domain Consistency

Modern CDBs rely on the underlying DBMS to provide ACID properties. ZENO must preserve the same guarantees. However, doing so in ZENO is more subtle because transaction-relevant state now spans two isolated domains, requiring new mechanisms to keep these states consistent throughout the transaction lifecycle.

For cross-domain correctness, the key constraint is that the DBMS interacts with the privacy zone only through FIDs; it cannot directly inspect the mapping store state. Therefore, correctness reduces to a one-way invariant: *every DBMS-maintained FID maps to a valid, up-to-date plaintext in the mapping store*. In contrast, orphan plaintexts in the mapping store are permissible because they are unreachable from DBMS-visible state. This asymmetry naturally aligns with *external synchrony* [61], a consistency model that distinguishes between internal system state and externally visible state. In ZENO, the mapping store constitutes the internal state, while the FIDs maintained by the DBMS constitute the external state with respect to the privacy zone.

This observation pinpoints the moments that require cross-domain coordination: when the set of DBMS-visible FIDs changes, or when such visibility must be preserved across failures. These cases include aborts, where old FIDs become visible again after rollback; commits, where new FIDs become durable; and recovery, where state is restored after failures. Accordingly, ZENO introduces lightweight synchronization between the database and the mapping store at transaction boundaries and during recovery. We describe these mechanisms next.

Handling transaction aborts. When a transaction aborts, rollback may make old FIDs DBMS-visible again. To preserve the invariant, ZENO must keep the mappings for these old FIDs until the DBMS itself determines that they are no longer visible.

To this end, ZENO employs a multi-version concurrency control (MVCC)-like approach: stale values (e.g., logically deleted entries and pre-update versions) are retained at runtime and reclaimed only when the underlying DBMS runs garbage collection (e.g., PostgreSQL's off-path `VACUUM`). For instance, as illustrated in Figure 4(a), when a transaction issues an update, ZENO retains the original mapping entry intact (①) and inserts the new value out-of-place (②). If the transaction is aborted, the DBMS can access the original values as usual (③). The aborted value is eventually reclaimed by the DBMS's off-path garbage collection process (④).

Handling transaction commits. Commits must preserve the external-synchrony invariant across crashes. A privacy-zone crash may lose recently created secrets, while the DBMS can still recover the committed database state. After recovery, the DBMS may contain committed tuples with FIDs whose corresponding secrets are no longer recoverable in the mapping store. To prevent this case, the commit protocol extends external synchrony to crash-recoverable state: if an FID is recoverable after a crash, its corresponding secret must also be. Since both PostgreSQL and the mapping store recover committed state from their WALs, enforcing this invariant reduces to a commit-time WAL-ordering rule: for each transaction, mapping-store WAL updates must be durable before PostgreSQL persists its WAL. A straightforward design would maintain a separate mapping-store WAL and synchronously flush it before PostgreSQL persists its own WAL. Although correct, this design is costly: under synchronous commit, the mapping-store flush becomes an additional serialized I/O on the critical path. This also forces ZENO to track a separate global order for mapping-store WAL records, duplicating PostgreSQL's WAL ordering and increasing commit contention.

To avoid these costs, ZENO co-designs mapping recovery with PostgreSQL's WAL recovery by embedding mapping-store WAL records into the PostgreSQL WAL stream. At commit time, ZENO calls `SealLog()` to generate a block-granular encrypted mapping-store WAL record containing the newly exposed mappings from the transaction. It then adds this record to PostgreSQL's WAL stream before PostgreSQL emits the transaction commit record. Only after this insertion does PostgreSQL continue its normal commit path, placing the resulting WAL records in LSN order and flushing them using its native WAL machinery. To further reduce commit-time overhead, ZENO pipelines and parallelizes block-granular encryption: the privacy zone encrypts full blocks as they accumulate during transaction execution and handles multiple blocks in parallel. This protocol is therefore lightweight, adding only one RPC and residual block-granular encryption to the commit critical path.

Recovering from system crashes. After a system crash, ZENO must restore mappings for all FIDs recovered by PostgreSQL. Recovery is driven by PostgreSQL's standard WAL replay. As PostgreSQL replays the WAL stream, ZENO identifies embedded mapping-store WAL records and then calls `ReplayLog()` to reconstruct the corresponding mappings.

Figure 4(b) illustrates three recovery outcomes. In case ①, the crash occurs before PostgreSQL flushes the WAL stream; both the mapping-store WAL record and the transaction commit record are lost, so no new FIDs become visible after recovery. In case ③, the transaction commit record is durable; by order, the preceding mapping-store WAL record is also durable, so ZENO can reconstruct mappings for all recovered DBMS-visible FIDs. Thus, both cases preserve the external-synchrony invariant. Case ② is the only intermediate case: the

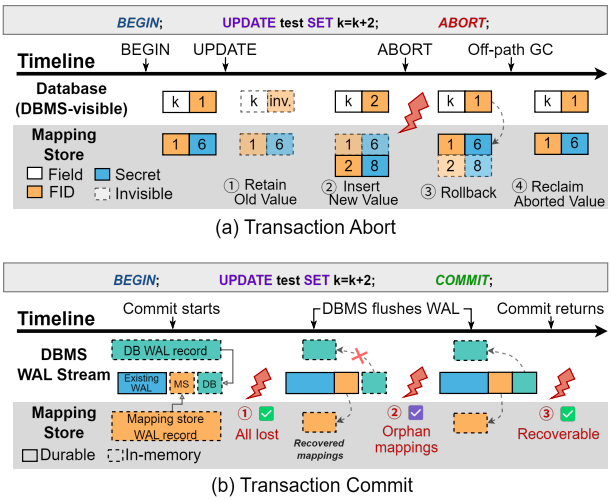

Figure 4: Timeline of a transaction execution in ZENO, illustrating the handling of (a) abort and (b) commit paths.

system crashes during WAL flushing, after the mapping-store WAL record is written back but before the transaction commit record is completely written to disk. WAL replay may reconstruct these mappings, but PostgreSQL will not expose their FIDs in the recovered database state. This is safe because the recovered mappings do not overwrite pre-existing visible data: as described in the abort protocol, ZENO only reuses FIDs after the DBMS has garbage-collected their previous references. Therefore, the reconstructed mappings are merely orphans and do not constitute an inconsistent state. They remain unreachable from DBMS-visible state, preserving consistency; ZENO can reclaim them later via a global scan.

6 Implementation

We implemented ZENO on top of PostgreSQL 15.5 in 6.1K lines of C/C++ code. Table 2 provides a detailed breakdown by component. ZENO runs atop CVMs (i.e., Intel TDX [17] and ARM Secure EL2 [8, 55]) and deploys its integrity and privacy zones in isolated VM domains. To reduce cross-domain RPC overhead, ZENO adopts a context-switchless implementation [24, 26, 75]: the integrity zone sends requests to secure shared memory, while the privacy zone polls the shared memory and dispatches requests for processing. The integrity zone uses dm-integrity [19] for corruption detection, while the privacy zone uses dm-crypt [18] with HMAC-SHA256 for transparent I/O encryption and authentication. The mapping store is backed by `mmap`ed arrays for persistence. Temporal locality is exploited by an LRU cache combined with Linux sequential prefetching; spatial locality is improved by organizing permanent partitions at table granularity. Within each partition, ZENO assigns FIDs by reusing safely reclaimed slots or appending new ones via an atomic monotonic counter. Currently, each 64-bit FID encodes a configurable 16-bit partition prefix and a 48-bit offset. Users can also tune FID length

Table 2: Lines of code for each component in ZENO.

ZENO Components	Language	LoC
Mapping Store	C++	1,074
WAL	C++	461
Commit Protocol (in PostgreSQL source)	C	550
Proxy	C++	2,155
Operators (modified from HEDB source)	C++	1,708
Crypto Library	C/C++	110

and partition-prefix size according to expected data volume: shorter FIDs reduce storage overhead and improve lookup efficiency. An open-source version of ZENO is available at https://github.com/ISCAS-OSLab/ZENO.

7 Performance Evaluation

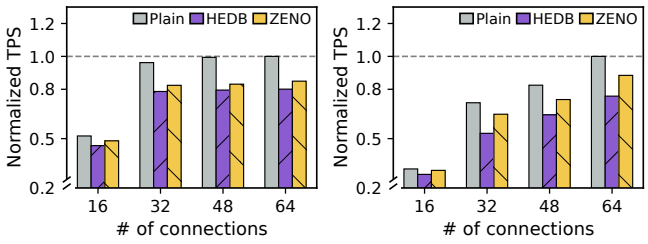
We evaluate ZENO by answering the following questions:

- RQ1: Does ZENO deliver end-to-end performance improvements across platforms and workloads? (§ 7.1)
- RQ2: What are the sources of ZENO's performance gains and consistency overheads? (§ 7.2)
- RQ3: How robust is ZENO under different workloads and resource configurations? (§ 7.3)

Experimental setup. We evaluate ZENO on two platforms. The ARM platform runs on a HiSilicon Kunpeng-920 @ 2.6 GHz server with S-EL2 support, equipped with a 1 TB SSD and Ubuntu 22.04 LTS, hosting two Secure-EL2 VMs running Linux 6.8.0. The x86 platform runs on an Intel Xeon Platinum 8581C @ 4.0 GHz server with TDX support, equipped with a 4 TB SSD and Ubuntu 24.04 LTS.

For both platforms, ZENO and HEDB deploy the integrity and privacy zones in two isolated VM domains with a total resource budget of 32 vCPUs and 64 GB of memory. Under this budget, we sweep several vCPU and memory splits between the two zones for each experiment and use the best-performing split for each system. Both zones disable memory swapping. To ensure resource fairness, baseline plaintext PostgreSQL is deployed in a virtual machine with 32 vCPUs and 64 GB of memory. Across all systems, the benchmark client uses 16 vCPUs and 32 GB of memory. To reduce cross-NUMA RPC latency and hypervisor scheduling noise, we pin all VMs to the same NUMA node when possible, or otherwise to nearby NUMA nodes with low NUMA distance.

For ARM S-EL2, the shared memory for inter-CVM RPCs is protected by the TrustZone hypervisor. For x86 TDX, since no CVM vendors [17, 22] currently provide secure channels between CVMs (their shared memory remains plaintext), we exploit TD Partitioning [3], which allows multiple L2 VMs to run within one CVM. However, TD Partitioning is documented primarily for single-L2-VM deployments, offering little engineering guidance for multi-L2 setups. As such, we adopt a microkernel-inspired deployment: the privacy zone runs in the L1 VM and the integrity-zone DBMS (given its large TCB) runs in an L2 VM managed by the L1, with RPC shared memory controlled by the L1 to prevent malicious host introspection.



(a) ARM S-EL2 (b) x86 TDX

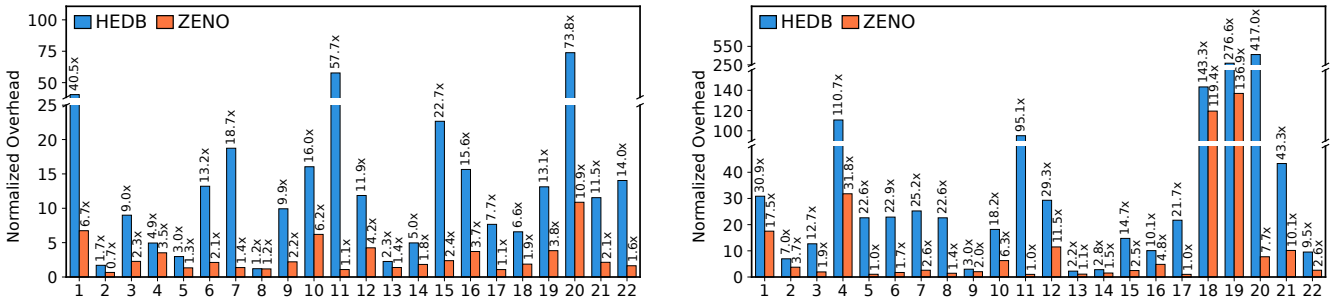
Figure 5: TPC-C throughput with varying numbers of connections at $W = 100$, normalized to the peak plaintext PostgreSQL TPS on each platform (higher is better). ZENO reduces HEDB's throughput loss by up to 49.8% on ARM S-EL2 and 73.8% on x86 TDX.

7.1 End-to-End Performance (RQ1)

We use two standard benchmarks: TPC-C and TPC-H. Since these standard benchmarks are not privacy-oriented, we further use a real-world workload from the industry. For comparison, we include vanilla PostgreSQL as the plaintext baseline and the state-of-the-art HEDB.

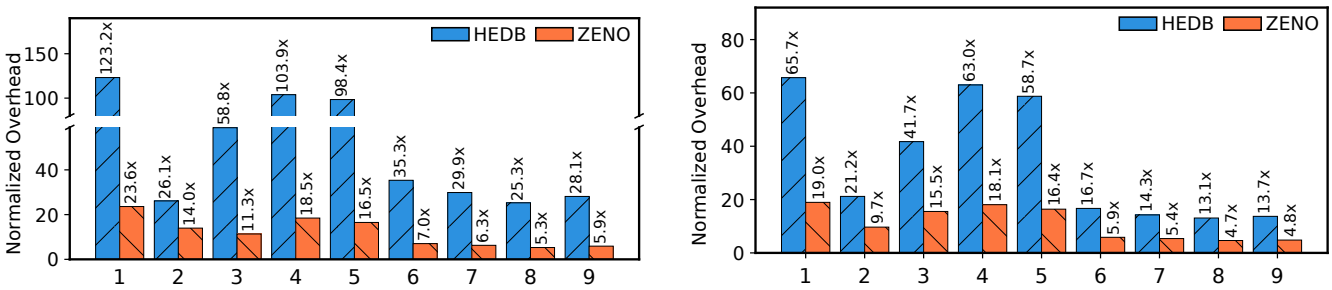
TPC-C. We evaluate TPC-C throughput (transactions per second, or TPS) under varying connection counts using 100 warehouses, treating all non-ID columns as sensitive and placing the database on tmpfs. After a 60-second warm-up, we measure for 300 seconds and normalize TPS to the peak plaintext PostgreSQL throughput across all connection counts. As shown in Figure 5, ZENO narrows the throughput gap between HEDB and plaintext PostgreSQL on both platforms. We report this gap as throughput loss relative to plaintext PostgreSQL at the same connection count. On ARM S-EL2, ZENO reduces HEDB's throughput loss by 18.1–49.8%; on x86 TDX, ZENO reduces HEDB's throughput loss by 51.5–73.8%. The two platforms exhibit different scaling trends due to platform-specific hardware and TEE-stack characteristics.

TPC-H. We use TPC-H (scale factor = 3), a standard OLAP benchmark with large joins, group-bys, aggregations, and arithmetic operations. We make all non-key columns sensitive, as TPC-H does not define security attributes. To evaluate performance under large-dataset execution, we use a 6 GB memory budget. PostgreSQL and HEDB each use the full 6 GB as DBMS-side memory, while ZENO splits the same total budget between the integrity and privacy zones, with 4.5 GB and 1.5 GB, respectively. Results are averaged over 5 runs per query after one warm-up run. Figure 6 shows the slowdown of HEDB and ZENO relative to plaintext PostgreSQL. HEDB incurs an average slowdown of 10.0× on ARM S-EL2 and 23.8× on x86 TDX, driven by excessive cryptographic



(a) ARM S-EL2 (b) x86 TDX

Figure 6: TPC-H execution time of HEDB and ZENO normalized to plaintext PostgreSQL. ZENO substantially reduces HEDB's overhead, achieving speedups of up to 53.1× on ARM S-EL2 and up to 94.7× on x86 TDX.



(a) ARM S-EL2 (b) x86 TDX

Figure 7: Execution time of 9 industrial queries on ARM S-EL2 and x86 TDX, normalized to that of plaintext PostgreSQL. ZENO consistently outperforms HEDB, achieving up to 6.0× and 3.6× speedups on ARM S-EL2 and x86 TDX, respectively.

Table 3: Overall storage usage (in GB) across three workloads. ZENO reduces storage cost by up to 52.8% compared to HEDB.

Database	TPC-C (W=100)	TPC-H (SF=3)	Industrial
Plaintext	10.3	5.2	1.5
HEDB	22.1 (2.1×)	17.8 (3.4×)	3.3 (2.2×)
ZENO	13.5 (1.3×)	8.4 (1.6×)	1.9 (1.3×)

operations and I/O amplification due to ciphertext expansion. In contrast, ZENO restricts the average slowdown to 2.3× on ARM S-EL2 and 4.5× on x86 TDX, outperforming HEDB by 4.4× and 5.3×, respectively. The performance discrepancy is primarily attributable to the Intel TDX implementation, which relies on bounce buffers (i.e., Linux SWIOTLB) for I/O [54]. Consequently, I/O-intensive queries experience higher overhead on x86 TDX compared to ARM S-EL2.

Industrial workload. We evaluate ZENO using 9 real-world complex queries under strict confidentiality constraints. Schemas are anonymized prior to evaluation. We generate synthetic data matching the anonymized schemas at 1 million rows per table, with all columns treated as sensitive. Figure 7 reports the end-to-end execution time normalized to plaintext PostgreSQL. ZENO outperforms HEDB on both ARM S-EL2 and x86 TDX. On ARM S-EL2, ZENO reduces HEDB's 48.4× average slowdown to 10.5× (up to 6.0× speedup); on x86 TDX, it reduces 27.6× to 9.4× (up to 3.6× speedup). These results confirm ZENO's performance gains on real-world industrial workloads.

Storage consumption. As shown in Table 3, ZENO reduces storage consumption by 38.9–52.8% compared to HEDB across all evaluated workloads. This is because ZENO adds an 8-byte FID per value, while existing modern CDBs attach 28 bytes of cryptographic metadata per field.

7.2 Breakdown and Overhead Analysis (RQ2)

To address RQ2, we use TPC-H and TPC-C to isolate different performance factors. TPC-H is ideal for decomposing ZENO's gains; its heavy aggregations and large data volumes expose the specific overheads of cryptographic computation and ciphertext expansion. For aspects not covered by TPC-H, specifically the commit protocol and crash recovery, we use TPC-C to measure their overhead.

Unless otherwise stated, the following experiments use our ARM S-EL2 VM setup. These studies address platform-independent design questions. Fixing one primary platform avoids conflating ZENO's design effects with platform-specific factors such as I/O-path behaviors (e.g., bounce buffers), TEE virtualization overheads, and scheduling.

Factor analysis. We perform a cumulative factor analysis on TPC-H to characterize the sources of ZENO's performance gains. Starting from unoptimized HEDB, we incrementally

enable HEDB's optimization and then introduce ZENO's optimization techniques one by one. Figure 8 reports the geometric mean execution time normalized to plaintext PostgreSQL. Below, all reported reductions and speedups are relative to the preceding variant.

+*Batching* groups aggregation inputs for operators such as `SUM` and `AVG`. Instead of invoking the privacy zone for every intermediate accumulation step, the integrity zone sends a batch of fields per RPC (batch size = 256), reducing RPC frequency and intermediate cryptographic operations. Batching reduces the execution time by 5.8% and speeds up individual queries by up to 1.6×.

+*Decryption cache* represents an optimized version of the ciphertext-to-plaintext cache discussed in § 2. It caches decryption results in the privacy zone, using `boost_unordered_flat_map` [32] with `XXH3_64bits` [37] and a 512 MB cache shared across SQL statements. The decryption cache further reduces the execution time by 21.8% and speeds up individual queries by up to 2.4×. To understand why the gains remain modest, we further instrument per-operation costs under the evaluated workload. A hash-table lookup and an insertion cost 334.9 and 2649.4 cycles on average, respectively, compared with 113.8 and 316.0 cycles for ZENO's direct-indexing `Get()` and `Put()`. Although avoiding repeated decryptions is beneficial, the improvement is bounded by two factors: the relatively high cost of hash-table lookup/insertion operations over ciphertext keys, and the overhead of ciphertext expansion, which remains unchanged.

+*O(1) FID lookup* replaces each ciphertext with a 28-byte padded FID, which is resolved through direct indexing in the mapping store. Together, the padded FID and plaintext value match HEDB's per-field ciphertext footprint, separating the benefit of direct indexing from that of reduced data expansion. O(1) FID lookup reduces execution time by 25.7% and speeds up individual queries by up to 24.7×, confirming that direct indexing substantially lowers privacy-zone processing overhead.

+*Reduced expansion* switches to compact 8-byte FIDs, removing field-level expansion and reducing the data footprint of TPC-H's large, I/O-bound queries. By reducing I/O and memory movement, this step lowers execution time by 53.0% and speeds up individual queries by up to 11.5×.

Finally, +*Partition* enables ZENO's partition-based mapping-store layout. By organizing partitions according to the DBMS storage layout, ZENO improves spatial locality between DBMS-visible FIDs and privacy-zone plaintext values. This optimization further reduces the execution time by 16.6% and speeds up individual queries by up to 6.4×.

Overall, the factor analysis confirms the combined benefits of direct FID lookup, compact field representation, and locality-aware partitioning.

Commit overhead. To capture the runtime overhead of ZENO's commit protocol, we place the database on persistent storage and enable `synchronous_commit`, forcing each transaction commit to wait for WAL durability. We use TPC-C with $W = 100$ and 16 connections for this experiment, and compare ZENO with and without embedded mapping-store WAL records. Enabling mapping-store WAL incurs a modest 2.6% reduction in TPS. To further understand this overhead, we instrument the commit path and directly measure the per-commit cost introduced by ZENO's commit protocol. An invocation producing a 997-byte encrypted payload adds only 18.3 μs to the overall commit latency.

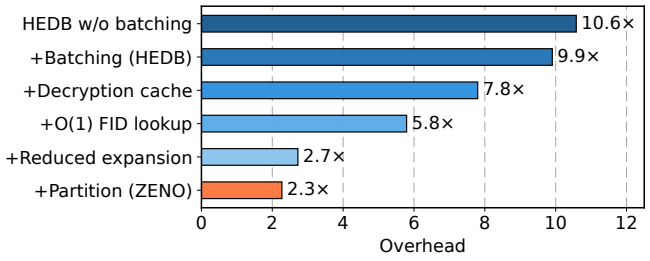


Figure 8: Factor analysis of performance gains across different techniques using TPC-H. Overhead is the execution time normalized to the plaintext baseline.

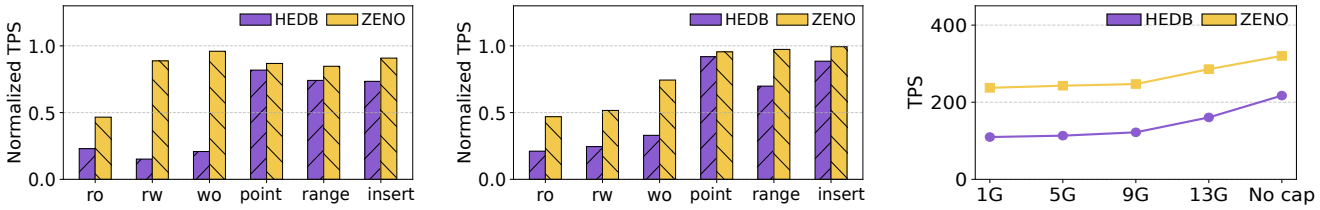
Recovery overhead. During the initial data loading phase of TPC-C (configured with 8 warehouses and 8 threads), we abruptly terminate the process to simulate a crash, leaving 2.6 GB of WAL for recovery. After restart, PostgreSQL replays the WAL stream that contains both database records and embedded mapping-store records. The complete WAL replay takes 26.3 seconds, with mapping-store record replay accounting for 4.1 seconds (15.6%) of the total time.

7.3 Workload and Resource Sensitivity (RQ3)

The performance gain of ZENO depends on both workload characteristics and system configuration. To characterize the impact of these factors, we use Sysbench [62] to issue transactional microbenchmarks with configurable read/write ratios and access patterns. The benchmark runs on a synthetic dataset consisting of 32 tables with 1M rows each, occupying approximately 7 GB in plaintext PostgreSQL, 10 GB in ZENO, and 12 GB in HEDB. To control for other variables, we conduct all experiments entirely in memory, with the exception of the memory-sensitivity analysis. Each experiment includes a 120-second warm-up followed by a 600-second measurement, using 16 connections by default.

Transaction sensitivity. Figure 9(a) presents normalized throughput under Zipfian data distribution (factor = 0.8) across six operation modes: read-only, read-write, write-only, point-select, range-select and insert-only. Overall, ZENO achieves speedups of 1.1–5.8× over HEDB and delivers 46.6–95.0% of plaintext throughput. In write-only mode, ZENO is 4.6× faster than HEDB. This gap arises from frequent `UPDATE` queries such as "`UPDATE test SET`



(a) Transaction Modes (Zipfian, factor=0.8) (b) Transaction Modes (Uniform) (c) Total Memory Size

Figure 9: Microbenchmark performance under different configurations. ZENO consistently outperforms HEDB across all settings.

`k=k+1;`", where ZENO eliminates the cryptographic overhead in HEDB's decrypt-compute-re-encrypt cycle.

Skew sensitivity. We also evaluate a random access pattern generated from a uniform distribution, which exhibits relatively poor locality. As illustrated in Figure 9(b), even under a non-skewed access pattern that yields frequent CPU cache and TLB misses, ZENO still outperforms HEDB by up to 2.3× across all six modes, thanks to its crypto-free mappings.

Memory sensitivity. Both HEDB and ZENO introduce additional metadata overhead (cryptographic metadata and FIDs, respectively) over PostgreSQL, making them more sensitive to available memory size. To quantify this sensitivity, we measure their performance under different total memory sizes. We use a read-write workload with 8 threads and a random access pattern. As illustrated in Figure 9(c), ZENO outperforms HEDB, with an average speedup of 1.9× and a 2.2× speedup even when the total available memory is limited to 1 GB (10% of the dataset for ZENO). This is because ZENO has a smaller storage footprint than HEDB and preserves locality between the mapping store and the database.

8 Security Analysis

This section analyzes ZENO's security guarantees. Following prior modern CDBs [24, 45, 56, 73, 74], we consider two adversary classes: active adversaries can arbitrarily tamper with storage and modify untrusted memory, and passive adversaries (honest-but-curious) do not modify data but attempt to infer sensitive information through observation.

Defense against active attacks. ZENO ensures that sensitive data remains confidential and fresh. First, TEE hardware provides memory encryption and isolation, preventing adversaries from accessing plaintext data during computation. Second, since FIDs are completely opaque to users, a malicious user cannot access others' private data by crafting an FID. Last, ZENO secures untrusted storage against tampering across both zones. In the privacy zone, ZENO uses dm-crypt [18] with HMAC-SHA256 to provide block-level authenticated encryption and detect storage corruption. In the integrity zone, ZENO enforces full-disk integrity [19] to guard against adversaries who may attempt to swap FIDs across records to gain unauthorized access to a victim's secret. Both zones exploit a counter-based freshness mechanism [1] against rollback attacks [23, 34].

ZENO ensures faithful query execution through two mechanisms. First, remote attestation allows users to verify that legitimate ZENO code is running in the TEEs before uploading data. Second, in our implementation based on HEDB, ZENO places both the DBMS (in the integrity zone) and expression operators (in the privacy zone) within trusted domains, with secure channels between TEEs that prevent message injection, replay, man-in-the-middle, and smuggle attacks.

Defense against passive attacks. The primary concern is whether an adversary observing FIDs can learn anything about the corresponding plaintext secrets. We prove that ZENO achieves indistinguishability via a simple observation: FID allocation is *stateful but plaintext-independent*. The allocator maintains internal state that identifies the next available FID and assigns FIDs deterministically from this state, independent of the plaintext m. Consequently, after n prior `Put()` calls, either plaintext m_0 or m_1, when submitted as the $(n+1)$-th item, receives the exact same FID, so the adversary's view of the FID sequence is indistinguishable between the two cases. As a result, ZENO's crypto-free mappings provide confidentiality comparable to *semantic security* [44]: no information about plaintexts is revealed (beyond leakage from other channels, discussed later).

Additionally, because FIDs are assigned independently of plaintext values, the same plaintext may be represented by multiple distinct FIDs, mirroring the behavior of non-deterministic encryption schemes like AES-GCM.

Leakage analysis. While ZENO protects plaintext contents, practical query functionality requires revealing certain metadata to the untrusted infrastructure. We characterize ZENO's leakage profile using the definition of $\mathcal{L}$-security [63, 73], which models security as a leakage function $\mathcal{L}$ that precisely specifies what information an adversary learns. We define ZENO's $\mathcal{L} = (\mathcal{L}_{init}, \mathcal{L}_{query}, \mathcal{L}_{update})$ as follows:

- $\mathcal{L}_{init}(D)$: During database initialization with dataset D, the adversary observes the database storage layout, including its total volume and the number and positions of protected fields. Since these fields are replaced by constant-size FIDs, individual field sizes remain hidden.
- $\mathcal{L}_{query}(q, D)$: For query q over D, the adversary learns:
  1. *I/O access pattern* $ap(q)$: which storage blocks in the

DBMS and mapping store are accessed during query execution.
2. *Search pattern* $sp(q)$: whether two queries access overlapping record sets, revealing query repetition.
3. *Timing* $t(q)$: when and how long the query executes.
4. *Result volume* $|R_q|$: the number of records returned or affected by the query.
5. *Comparison results*: the boolean outcomes (e.g., "$>$") necessary for indexing and filtering, a common trade-off for many enterprise modern CDBs [24, 45, 56, 74].

- $\mathcal{L}_{update}(op, D)$: For an update operation op (i.e., `INSERT`, `UPDATE`, `DELETE`), the adversary learns which storage blocks are modified and the operation type, but not the plaintext values being written or deleted. Since FIDs are allocated monotonically by default, the adversary may also infer the order in which protected fields are assigned FIDs.

This leakage profile provides $\mathcal{L}$*-semantic security*: an adversary observing ZENO's execution learns nothing beyond $\mathcal{L}$ about the underlying plaintext data.

FID metadata discussion. Like ciphertexts in HEDB, FIDs carry observable metadata about protected fields. First, FIDs expose positional information (via embedded partition numbers), analogous to how HEDB leaks ciphertext position through untrusted storage layout. Second, FIDs reveal allocation order, as they are allocated monotonically by default. This information is also observable in HEDB: newly generated ciphertexts are eventually persisted to untrusted storage, and their appearance in logs or batch flushes can reveal generation order, at least at batch granularity. To coarsen this metadata, ZENO could pre-allocate FIDs in batches and assign them via random permutation within each batch, which balances allocation-order confidentiality, allocation efficiency, and spatial locality.

Side-channel discussion. ZENO's stateful privacy zone retains plaintext data in TEE memory for extended periods (until eviction to storage). This residency could increase the attack window for digital side-channels (e.g., cache timing or memory access patterns). However, modern CDBs already face this risk: encryption keys reside permanently in TEE memory; key compromise would breach all sensitive data. Mitigations such as strict resource isolation [33, 81] apply equally to both residual plaintext and long-lived keys.

9 Related Work

Confidential databases (CDBs). To address rising privacy concerns, CDBs on untrusted clouds have long been a goal [58]. TrustedDB [28], EnclaveDB [65], DBStore [67], and SecuDB [77] shield an entire DBMS in TEEs, providing strong security but limiting maintainability. Modern CDBs, such as AlwaysEncrypted [24], GaussDB [45], Operon [74], and HEDB [56], prioritize maintainability by keeping most DBMS logic outside TEEs, but incur severe overhead from per-field cryptography. Other CDB systems take orthogonal approaches: fully cryptography-based databases [29, 30, 63, 64, 66, 71, 78, 79] require no trusted hardware, and oblivious databases [38, 60, 82] hide access patterns.

Motivated by the growing industrial adoption of split-architecture CDBs, ZENO improves their efficiency through crypto-free mappings. Full resistance to active DBAs in this setting further requires defending against smuggle attacks, which HEDB addresses by isolating DBAs from operator interfaces. Systems such as AlwaysEncrypted, GaussDB, and Operon could adopt ZENO's mapping abstraction as a drop-in performance optimization, yet would still need HEDB-style isolation to achieve equivalent security guarantees.

Indirection-protection separation. Separating indirection from protection is a classic systems principle. Capability systems [39, 53] pioneered the use of unforgeable tokens (capabilities) as references to resources protected by OS isolation. Similarly, OSes have long used opaque handles [21, 68]: file descriptors in Unix are integers mapped by the kernel to internal objects. ZENO shares this insight: data-independent FIDs serve as capabilities protected by TEE isolation, removing cryptographic overhead for every reference.

Applicability beyond CDBs. Compartmentalization-based confidential analytics systems [48, 80] encrypt data at TEE boundaries among operators, incurring significant cryptographic overhead. These systems may benefit from the abstraction of crypto-free mappings for better efficiency.

TEE optimizations. Several techniques have been proposed to optimize TEE-based applications, such as context-switchless calls [24, 26, 75], userspace I/O [27, 70], and other optimizations [49, 56].

10 Conclusion

This paper challenges a core assumption in modern CDB design: mappings between untrusted and trusted domains must be cryptographic. Existing CDB systems using ciphertext-to-plaintext mappings suffer from critical performance bottlenecks. ZENO introduces crypto-free mappings, which eliminate costly en/decryption from the critical path and avoid ciphertext expansion. The integration of ZENO's key performance techniques into a production DBaaS system validates the practicality of this approach.

A Artifact Appendix

Abstract

The artifact for this paper contains the source code for ZENO. It also includes scripts for the TPC-C and TPC-H workloads used in the paper, documentation for the two platforms described in § 7, and instructions for building ZENO and running its smoke tests.

Scope

The artifact is intended primarily to support availability and basic functionality checks. It enables users to inspect the ZENO implementation, build the prototype, run the provided

single-machine smoke test, and examine the scripts and documentation for the two evaluated deployment configurations: ARM S-EL2 and x86 TDX. The artifact does not include the proprietary industrial workload used in the paper.

Contents

The artifact has three main parts:

1. The ZENO implementation in `src/`, including the components listed in Table 2. The PostgreSQL integration patch is in `src/integrity_zone/postgresql-patches/` and implements the WAL coordination path used by ZENO's commit protocol. Parts of the protected-operator implementation are derived from HEDB's operator framework.

2. Tests and benchmark scripts. `test/` contains SQL smoke tests; `benchmark/tpcc/` contains plaintext and ZENO TPC-C runners based on sysbench/TPC-C Lua scripts derived from Percona code; and `benchmark/tpch/` contains TPC-H scripts derived from HEDB.

3. Documentation in `README.md` and `doc/`. These files describe the quick-start build, single-machine simulation mode, protected-storage setup, classic two-VM deployment notes, and TD-partitioning deployment notes for x86 TDX.

Third-party code and license notices are summarized in `THIRD_PARTY_LICENSES.md`.

Hosting

The artifact is hosted publicly on GitHub at https://github.com/ISCAS-OSLab/ZENO. The local artifact version used to prepare this appendix corresponds to commit `213036c`.

Requirements

The quick-start configuration requires no special confidential-computing hardware. In this mode, PostgreSQL and the privacy-zone proxy run as two local processes, which is sufficient for build and functional checks.

JANUS: Cross-World, Cooperative Nested Virtualization for Secure Containers

Abstract

Secure containers such as Kata Containers strengthen isolation by running each container inside a lightweight VM. On today's virtualized clouds, this creates an unavoidable form of nested virtualization with dominant cost in memory virtualization. Existing approaches entangle CPU virtualization and three-level page-table management across hypervisors, forcing frequent cross-world synchronization and producing severe overheads for mixed memory-access workloads.

We present JANUS, a cross-world, cooperative nested virtualization architecture that cleanly separates CPU and memory virtualization responsibilities. JANUS performs all guest world switches entirely within the guest hypervisor through a lightweight switcher mechanism, while delegating all memory translation to the host hypervisor. This separation removes the host from the critical path of CPU events and eliminates the intermediate shadow or nested page tables that burden existing designs. JANUS introduces several key techniques, including VMFUNC-based EPTP switching for trap-free transitions between guest and nested-guest address spaces; a shadow-root mechanism that protects world-switch integration while allowing direct updates to the nested guest's page tables; and in-guest virtualization exception handling that enables the guest hypervisor to resolve second-level faults with only a single lightweight host interaction. Evaluations demonstrate that JANUS delivers an average performance improvement of 144% over PVM and 28.6% over KVM-based nested virtualization for real-world applications, and imposes less than 5% overhead compared to native containers in production deployment. JANUS demonstrates that rethinking nested virtualization around cross-world cooperation yields strong isolation with near-native container performance.

1 Introduction

Containers, such as RunC [43] and LXC [15], underpin today's cloud-native software stack by offering portable and efficient isolation to cloud workloads [10]. But their reliance on a shared host kernel [13, 17, 44] exposes applications to kernel-level vulnerabilities and cross-tenant attacks. A single exploited container (e.g. CVE-2025-9074) can compromise the host kernel and cascade across tenants [24]. To mitigate this risk, cloud platforms (e.g., Alibaba MaxCompute [1]) increasingly deploy *secure containers*, such as Kata Containers [25], which place each container inside a lightweight virtual machine (microVM). This design restores hardware-enforced isolation for executing untrusted code (e.g., *user-defined functions* (UDFs) [16]), while preserving the agility of container-based workflows and maintaining high performance under bare-metal deployment [2, 54].

However, provisioning bare-metal instances (for deploying secure containers) remains inefficient and inflexible due to long startup times [28], hindering elastic scale-out under bursty workloads. As a result, platforms must maintain a statically overprovisioned pool of instances to absorb peak demand, leading to substantial resource underutilization during typical steady-state workloads. This has driven platforms to increasingly favor cloud VM instances, which offer greater elasticity by enabling on-demand instance allocation to handle dynamic workload fluctuations [21]. Yet, deploying secure containers on cloud VMs faces a fundamental challenge: secure containers must run within an already virtualized environment, leading to **nested virtualization**, where each container's microVM executes inside a cloud VM. The additional layer of CPU and, especially, memory virtualization introduces substantial overheads that make secure containers slower than their traditional counterparts.

Empirical studies reveal that while CPU-bound workloads exhibit negligible slowdown, memory-intensive workloads can degrade by up to two orders of magnitude under nested virtualization [21]. The primary source of this overhead is the need to reconcile *three* levels of page tables – i.e., the *host page table* (*HPT*) in host (L_0), the *guest page table* (GPT_{L_1}) in cloud VM (L_1 guest), and the nested guest page table (GPT_{L_2}) in secure container (L_2 nested guest) – within the *two-level* hardware translation model commonly supported by modern

* Equal contribution.

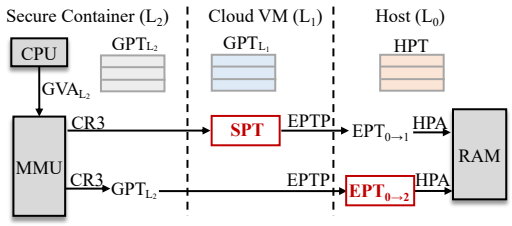

Figure 1: Two approaches for nested memory translation

processors. As illustrated in Figure 1, the hardware MMU traverses two translation structures: the first-level page table (pointed to by CR3) and the second-level extended page table (pointed to by EPTP). With the two-level hardware translation model, nested memory virtualization must compose these three page tables into two to translate a nested guest virtual address (GVA_{L_2}) to the *host physical address* (*HPA*).

More specifically, a classic L_1-dominated approach introduces a *shadow page table* (*SPT*) that merges GPT_{L_2} and GPT_{L_1}, enabling the MMU to perform a two-step translation – from GVA_{L_2} to GPA_{L_1} via *SPT*, and from GPA_{L_1} to *HPA* via $EPT_{0\to1}$[1] [21]. Although straightforward, this approach forces L_1 to constantly synchronize *SPT* with read-only GPT_{L_2}, resulting in high VM exit rates. An alternative L_0-dominated design constructs an $EPT_{0\to2}$ within L_0, directly maintaining the mapping from GPA_{L_2} to *HPA* to complement GPT_{L_2} in supporting two-stage translation [12]. While this design enables L_2 to manage its own page tables, it shifts the synchronization burden to the L_0, which must maintain consistency between the $EPT_{1\to2}$ in the L_1 and $EPT_{0\to2}$.

More recent effort has attempted to circumvent this synchronization bottleneck. CKI [38] constructs GPT_{L_2} to map GVA_{L_2} directly to GPA_{L_1} and leverages Supervisor Protection Keys (PKS) [30] to restrict L_2's memory access, thereby eliminating the need to maintain *SPT*. HyperTurtle [56] takes a different approach by allowing L_1-registered eBPF programs to apply updates directly to $EPT_{1\to2}$ inside L_0, removing the synchronization cost. However, both techniques rely on rigid memory-allocation assumptions, such as preallocation and contiguous allocation, that are difficult to satisfy in dynamic, cloud-native environments.

In this paper, we present JANUS, a cross-world, cooperative nested virtualization architecture that restructures how CPU and memory virtualization are divided across hypervisor layers. As shown in Figure 2, JANUS differs from existing L_0- or L_1-dominated approaches by cleanly separating (nested) virtualization responsibilities: L_1 performs all L_2 world switches (e.g., due to system calls, interrupts, and exceptions) through a lightweight, switcher-based software mechanism, while L_0 exclusively manages nested memory translation via a host-controlled $EPT_{0\to2}$. This division removes L_0 from the critical path of CPU events and hence eliminates the costly cross-world synchronization.

Realizing this architecture requires overcoming several

[1]The notation $0 \to 1$ indicates that the EPT is constructed and maintained by L_0 on behalf of L_1, while $0 \to 2$ and $1 \to 2$ follow analogous semantics.

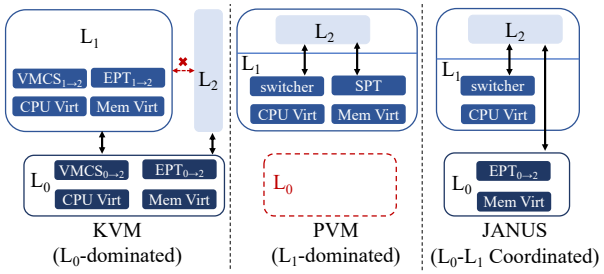

Figure 2: Comparison of nested virtualization approaches among KVM, PVM, and JANUS

challenges in enabling fast and safe cross-world execution. First, JANUS builds upon a software-based CPU virtualization layer, i.e., the *switcher*, that intercepts all L_2 virtualization events within L_1, allowing fast L_1–L_2 world switches without trapping to L_0. Second, seamless transitions between the two worlds require switching not only CPU state but also memory views; JANUS addresses this by using `VMFUNC`-based EPTP switching, allowing the processor to transition between the L_1 view ($EPT_{0\to1}$) and the L_2 view ($EPT_{0\to2}$) entirely within non-root mode (no L_0 participation). Finally, to ensure these transitions remain isolated and tamper-proof, JANUS introduces a shadow-root mechanism that embeds control metadata within the nested guest's page table, preventing a compromised L_2 from subverting world-switch integrity.

Building on this switcher-based CPU virtualization, JANUS realizes nested memory virtualization by using GPT_{L_2} directly as the first-level translation and delegating all second-level mapping to a host-managed $EPT_{0\to2}$, thereby removing the intermediate shadow or nested page tables traditionally maintained in L_1. Making this design both safe and efficient requires addressing two additional challenges. First, writable GPT_{L_2} must not allow a compromised L_2 to remap privileged regions (e.g., the switcher and shadow-root); JANUS enforces this through a *GPA disaggregation* mechanism, which isolates switcher and shadow-root pages from the *GPA* range exposed to L_2. Second, constructing missing $EPT_{0\to2}$ entries must avoid the cascade of exits that plagues prior designs; JANUS achieves this using *in-guest #VE handling*, allowing L_1 to resolve EPT faults locally and issue a single lightweight hypercall to L_0. Together, these mechanisms eliminate costly cross-world synchronization across L_2, L_1, and L_0 and provide fast, secure nested memory management. Beyond basic execution, JANUS extends its design to support key cloud-management operations. For memory reclamation, it provides a lightweight hypercall interface that lets L_1 delegate invalidations to L_0, ensuring coherence across nested translations. For live migration, JANUS 's GPA-disaggregated layout enables hardware *Page Modification Logging* (PML) to track nested-guest dirty pages directly in $EPT_{0\to2}$, eliminating the high overhead of write-protection–based dirty-page tracking.

JANUS delivers system-wide improvements across all layers of the virtualization stack. At the L_2 layer, it enables di-

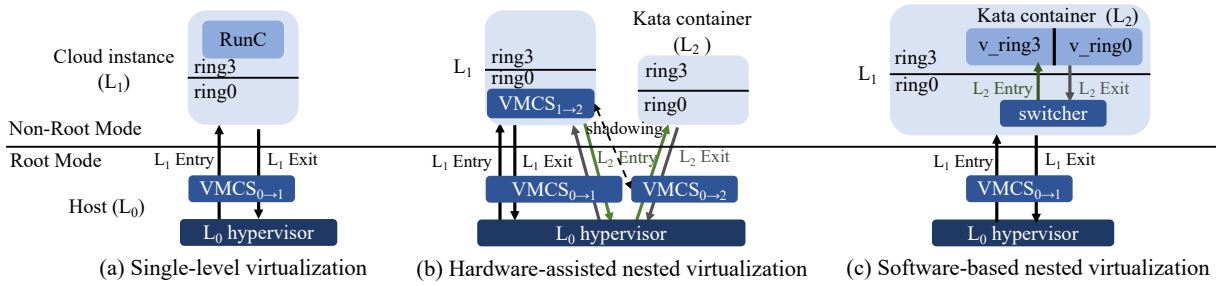

Figure 3: CPU virtualization in single-level virtualization and nested virtualization

rect manipulation of nested guest page tables, allowing fast, trap-free resolution of GPT_{L_2} faults without involving lower layers. The L_1 hypervisor is freed from the burden of maintaining intermediate page tables, effectively eliminating lock contention and frequent VM exits induced by cross-world synchronization. At the L_0 layer, JANUS requires only minimal extensions to deploy $EPT_{0\to2}$, thereby avoiding the complexity and maintenance overhead typically associated with managing $EPT_{1\to2}$. Our evaluation using both microbenchmarks and representative cloud workloads demonstrates that JANUS substantially enhances the efficiency of secure containers on virtualized cloud instances. By eliminating costly cross-world synchronization, JANUS delivers performance gains of up to 3x and 6x over state-of-the-art KVM- and PVM-based nested virtualization approaches.

2 Background

In this section, we provide the necessary background on single and nested virtualization, with a focus on CPU and memory virtualization mechanisms.

As shown in Figure 3, cloud providers deliver virtualized compute instances atop host hypervisors such as KVM [18]. This *single-level* virtualization model is commonly supported by hardware extensions (e.g., Intel VT-x and AMD-V), which enforce a clear division between root and non-root execution modes to isolate host and guest environments. In contrast, containers like RunC [43] rely exclusively on OS-level virtualization techniques, e.g., namespaces [13], control groups (cgroups) [17], and *Linux security modules* (LSM) [44], and thus can operate seamlessly within such virtualized environments with negligible additional complexity.

Recently, the rising demand for stronger isolation guarantees in multi-tenant cloud platforms has driven the adoption of *secure containers*, like Kata Containers [24]. These systems encapsulate conventional containers within lightweight microVMs, retaining container agility while delivering VM-level isolation. At the same time, modern cloud services are commonly provisioned and managed as VM instances, which provide elastic resource allocation, standardized isolation boundaries, and compatibility with existing cloud control planes. To preserve these operational advantages, secure containers are often deployed on top of cloud VMs rather than as a separate bare-metal substrate. In this deployment model, each secure container introduces its own microVM inside an already virtualized cloud instance, resulting in a second layer of virtualization, namely *nested virtualization*, that current hardware does not natively accelerate. This gap exposes severe inefficiencies, particularly in memory management (i.e., the dominant source of overhead in nested virtualization).

2.1 Nested CPU Virtualization

A key challenge in nested virtualization lies in maintaining distinct privilege levels among the host (L_0), guest (L_1), and nested guest (L_2), despite the fact that modern hardware virtualization extensions (e.g., Intel VT-x, AMD-V) expose only a single hardware separation between root and non-root modes. In single-level virtualization, transitions between the L_0 hypervisor and the guest (L_1) are efficiently managed by hardware through the *Virtual Machine Control Structure* (VMCS), which saves and restores processor states across mode switches. However, enabling a second level of virtualization requires these transitions to be emulated entirely in non-root mode, since current hardware lacks native support for an additional privilege boundary [12].

This emulation can be realized in two ways: (1) through hardware-assisted support from L_0 or via (2) software-based mechanisms implemented within L_1. In the hardware-assisted design, as shown in Figure 3(b), L_0 maintains a physical control structure *VMCS* for L_2, synchronizing it with the virtual *VMCS* managed by L_1. Whenever L_1 executes VMCS operations such as VMLAUNCH or VMRESUME (running L_2), the instruction traps to L_0, which must translate virtual *VMCS* into physical *VMCS* and then perform an actual VM entry (on behalf of L_1). Similarly, each VM exit from L_2 first transitions to L_0, which must then reinject the exit event into L_1 to maintain the correct execution semantics. These multi-level transitions introduce high overhead, as every L_2 world switch requires multiple VM exits and reentries involving L_0.

Inspired by paravirtualization techniques such as Xen [11] and Lguest [6], the recent PVM approach [21] introduces a small paravirtualized component called the *switcher*. The switcher implements the minimal subset of VMX state transitions in non-root mode (L_1), allowing efficient world switches between L_1 and L_2 without trapping into L_0.

Specifically, the L_1 hypervisor maps the switcher into both the L_1 and L_2 at identical virtual addresses, allowing control

to transfer seamlessly across world switches. For example, the switcher transitions between worlds by switching the page table and can continue executing the remaining instructions needed to complete the privilege-level transition even after the address space changes. The switcher maintains VMCS-like state structures in per-CPU entry areas and uses them to save and restore processor state during transitions. To enter L_2, the switcher loads the L_2 state (e.g., syscall entry points, IDT, TSS, trampoline stacks, and LDT), switches into the L_2 address space, and issues an `IRET` to drop into the L_2 kernel or user context in non-root ring 3. L_2 kernel and user code remain isolated through separate page tables and a virtual ring hierarchy enforced by L_1. The syscall and IDT handlers installed for L_2 intercept privileged events (syscalls, hypercalls, interrupts, exceptions) and return control to L_1 by restoring its saved state and executing a `RET`. In essence, the switcher implements lightweight VM-entry/VM-exit logic in software, allowing L_2 to reuse the existing *VMCS* of L_1 while providing strong privilege separation via ring 0 and ring 3 state. By localizing VM entry and exit emulation within L_1, such switcher-based CPU virtualization eliminates expensive L_0 traps while preserving correct nested execution semantics.

2.2 Nested Memory Virtualization

Modern processors natively support single-level memory virtualization by performing a two-dimensional page-table walk that translates *guest virtual addresses* (*GVAs*) to *host physical addresses* (*HPAs*): first from *GVAs* to *guest physical addresses* (*GPAs*) using the guest page table, and then from *GPAs* to *HPAs* using a hardware-assisted second-level page table such as Intel's *Extended Page Tables* (EPT) or AMD's *Nested Page Tables* (NPT). Throughout this paper, we refer to EPT as the second-level page table without loss of generality.

In a nested virtualization setting, however, L_0 observes only the mappings from GPA_{L_1} to *HPAs*. It has no visibility into how L_1 manages the nested guest's memory – specifically, how GPA_{L_2} is mapped to GPA_{L_1}. This lack of cross-world visibility between L_0 and L_2 complicates the construction of a direct translation path from GPA_{L_2} to *HPA*. To bridge this gap, two techniques have emerged in practice: *SPT-on-EPT* and *EPT-on-EPT* [12]. The former introduces a software-maintained *SPT* to translate GVA_{L_2} to GPA_{L_1}, while the latter constructs a nested EPT hierarchy that composes mappings from both L_1 and L_0 to translate GPA_{L_2} directly to *HPA*.

PVM-on-EPT. We first describe the advanced SPT-on-EPT model used by PVM-on-EPT [21], which complements PVM's lightweight, switcher-based CPU virtualization (§2.1).

As shown in Figure 4(a), while L_2 maintains its own guest page tables, the effective first-level address translation is carried out by *SPT* maintained by L_1 [2]. During L_2 execution, L_1 hypervisor loads the *SPT* into *CR*3, and protects the memory pages containing the L_2 page table entries as *read-only*. It

[2]For clarity, the construction of $EPT_{0\to1}$ is omitted, as it is orthogonal to the nested translation path under discussion.

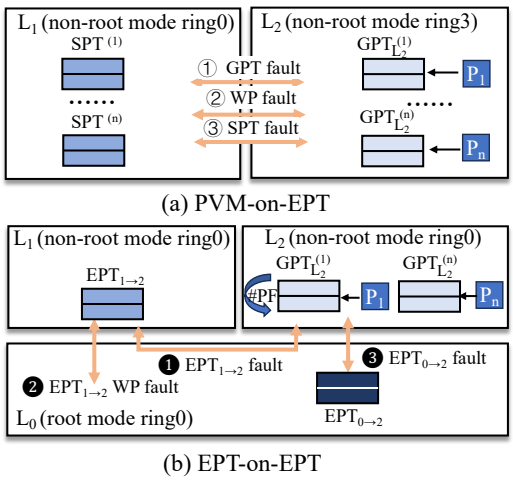

Figure 4: Two approaches for nested memory virtualization

ensures that any modifications to GPT_{L_2} are intercepted and mediated exclusively by L_1.

Therefore, when L_2 accesses a GVA_{L_2} without a valid mapping in *SPT*, a page fault is raised and delivered to L_1. L_1 inspects GPT_{L_2} to identify the cause of the fault. If the corresponding entry is missing in GPT_{L_2}, indicating a *GPT* fault (①), L_1 injects the fault back into L_2, allowing L_2 to update its own page table using the faulting address recorded in *CR*2. This process triggers another page fault because updating the read-only guest page table entries causes a *write-protect* (WP) fault (②). The system must then exit to L_1 to emulate the write to the corresponding L_2 page table page. Once L_2 page table is updated, a subsequent access to the same address triggers another *SPT* fault (③), which L_1 can now resolve by walking both GPT_{L_2} and GPT_{L_1} to construct the translation entry in *SPT*. L_1 then marks the relevant GPT_{L_2} entries as read-only to capture future updates. This process involves *three* world switches between L_1 and L_2 and may repeat until the full translation hierarchy is established.

As *SPT* operates at process granularity and each L_2 process has its own GPT_{L_2}, L_1 must allocate and manage a distinct *SPT* for each L_2 process (e.g., $SPT^{(n)}$ corresponds to the $GPT_{L_2}^{(n)}$ of process *n*). When L_2 runs multi-process workloads, constructing multiple *SPT* significantly increases the frequency of shadow page faults. Moreover, any modification to GPT_{L_2} by L_2 applications triggers a VM exit to L_1, which must update the corresponding entries in *SPT*. Although it can be handled through lightweight world switches between L_1 and L_2 (i.e., via the switcher), their cumulative frequency amplifies lock contention within L_1's memory management subsystem, leading to degraded scalability under multi-process workloads.

EPT-on-EPT. Existing KVM hypervisors employ an EPT-on-EPT approach in conjunction with the hardware-assisted CPU virtualization (§2.1), which introduces significant cross-world synchronization overhead.

As shown in Figure 4(b), GPT_{L_2} directly serves as the first-

level page table, enabling L_2 to handle its own page faults locally without trapping into lower layers. However, when L_2 accesses a GPA_{L_2} whose translation is missing in $EPT_{0\to2}$, an EPT fault is raised. Because L_0 cannot interpret the intermediate mapping between GPA_{L_2} and GPA_{L_1} (maintained by L_1), this EPT fault must first be injected into L_1 (❶). L_1 then constructs the missing translation in $EPT_{1\to2}$, which requires modifying one level of the table entry and triggers a VM exit (due to WP fault) to L_0 for write emulation (❷). After L_0 emulating the page modification, control returns to L_1, which resumes L_2 execution. The resumed L_2 then traps to L_0 once more for the actual VM resume operation. Since $EPT_{0\to2}$ remains incomplete, a final EPT fault occurs (❸). In response, L_0 repairs $EPT_{0\to2}$ by synchronizing it with $EPT_{1\to2}$ and marking the corresponding entries in $EPT_{1\to2}$ as read-only to capture furture updates. Once this fixup completes, L_0 resumes L_2, allowing subsequent accesses to the same GPA_{L_2} to proceed without trapping. Each missing GPA_{L_2} translation therefore requires *three* costly world switches across L_0, L_1, and L_2, and this procedure may repeat multiple times until all levels of GPT_{L_2} are resolved.

3 Motivation and Opportunities

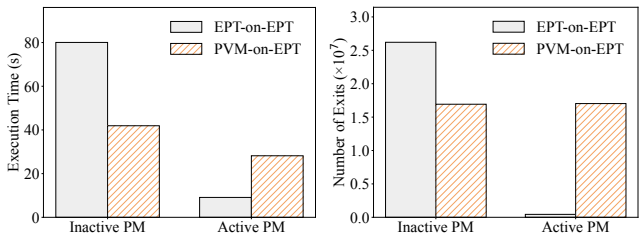
Nested virtualization is a key enabler for cloud platforms to run secure containers inside VM instances while preserving the elasticity and cost efficiency of modern cloud infrastructure. However, the performance costs of existing approaches, especially in nested memory virtualization, remain a critical bottleneck. These overheads continue to hinder the efficient deployment of secure containers, and the impact becomes especially visible for memory-intensive workloads.

3.1 Limitation: Missing L_0-L_1 Coordination

To demonstrate this, we evaluated the performance of accessing 32 GB of physical memory under the EPT-on-EPT and PVM-on-EPT by repeatedly invoking `mmap`, performing memory accesses, and then calling `munmap`. As shown in Figure 5, our experiments include tests on *inactive* physical memory that has never been touched and *active* physical memory whose low-level mappings have already been established.

When accessing *inactive* physical memory, EPT-on-EPT requires nearly twice the execution time of PVM-on-EPT (Figure 5 (a)) because it must construct the lower-level $EPT_{0\to2}$ entries, triggering a larger number of expensive exits to L_0 with most exits caused by EPT violations and a significant portion caused by VMRESUME emulation (Figure 5 (b)).

When accessing *active* physical memory, EPT-on-EPT becomes more efficient than PVM-on-EPT because the necessary $EPT_{0\to2}$ mappings are already present and only a small number of exits to L_0 occur. In contrast, PVM-on-EPT continues to incur a similar number of exits in each iteration because the `mmap` and `munmap` operations modify the L_2 page table, which repeatedly induces GPT_{L_2} and SPT synchronization.



(a) Time (b) Exits

Figure 5: Performance of physical memory (PM) access

When applications run inside secure containers within VMs, their memory access behavior combines both active and inactive physical memory. However, existing nested virtualization approaches perform well in isolated cases – either active or inactive memory accesses – but fail to handle the mixed access patterns that real applications typically exhibit.

These inefficiencies are rooted in the lack of cross-world coordination between L_0 and L_1 in existing nested designs. Hardware-assisted approaches (e.g., EPT-on-EPT) delegate most memory virtualization tasks to the L_0 hypervisor and depend on hardware CPU virtualization to perform costly world switches. In contrast, software-based approaches (e.g., PVM) enable efficient world switches between L_1 and L_2, but at the expense of frequent transitions between these two, imposing significant overhead on L_1 to manage multiple, software-based shadow page tables across multi-process workloads.

3.2 Opportunities: Advanced HW Features

These observations underscore the opportunity for a *cross-world, coordinated* nested memory virtualization architecture that unifies the advantages of efficient software-based world switching with the simplicity of hardware-assisted memory virtualization. Recent hardware advances make such coordination not only feasible but also efficient.

Multi-level Page Tables. Software-based world switching requires that the switching code and its data be mapped at identical virtual addresses (within a PUD range) in both GPT_{L_2} and GPT_{L_1}. Making GPT_{L_2} read-only would degenerate into full shadow paging and undermine JANUS's goal of allowing L_2 to manage its own address space. Instead, JANUS can exploit hierarchical page tables to enforce fine-grained, root-level mediation. It interposes only on top-level (PGD) updates, maintaining a protected shadow PGD as the authoritative root. While L_2 can modify its in-memory PGD, only updates issued via a hypercall to L_1 are validated and applied to the shadow PGD, which is the root page loaded into CR3 during L_2 execution. L_1 allows updates to non-critical regions, but strictly blocks any attempt by L_2 to modify the PGD entry referencing the PUD covering the switching range. This yields a partially shadowed page-table abstraction: the PGD entry for the switching-critical PUD is pinned and immutable, while other entries–and their lower-level page tables

(PUD/PMD/PTE)–remain fully writable. Thus, JANUS preserves L_2's flexibility while ensuring the invariant required for correct and secure world switching.

VMFUNC and EPTP Switching. JANUS enforces L_2 to execute with a dedicated EPT, which is maintained by the L_0 and isolated from L_1's EPT, to enable second-level address translation. Switching between L_1 and L_2 therefore requires changing the active EPT, which would incur significant overhead if handled via host intervention. Modern Intel CPUs provide `VMFUNC` (function 0), enabling EPTP switching entirely in non-root mode and atomic transitions without VM exits. However, because `VMFUNC` is unprivileged, L_2 might switch to any EPTP in the pre-configured EPTP list by the host, potentially including those not intended for its execution. To prevent such malicious switches from taking effect, JANUS binds each L_2 execution context to its designated EPT by restricting the visibility of its shadow root to that EPT only. Consequently, if L_2 switches to a different EPT via `VMFUNC`, the shadow root required for first-level address translation becomes inaccessible, triggering a fault that traps into L_1, which can immediately detect the violation and terminate L_2. This design preserves the performance benefits of `VMFUNC` while enforcing strict EPT isolation without restricting its usage.

Virtualization Exception. The host maintains EPT mappings for L_2, while relying on L_1 to provide the mapping from GPA_{L_2} to GPA_{L_1}. Traditionally, an EPT violation triggers a VM exit to the L_0, which injects an exception into the L_1; the L_1 then forwards the required mapping information back to the host. This back-and-forth interaction significantly increases VM exit frequency and limits the efficiency of $EPT_{0\to2}$ construction. Modern Intel CPUs introduce the *Virtualization Exception* (#VE) mechanism, which delivers EPT violations for designated address ranges directly to a guest-level handler. By resolving violations within the L_1, #VE eliminates L_0 involvement in exception injection and substantially improves cross-layer coordination efficiency.

3.3 Threat Model

Cross-world cooperative nested virtualization preserves the isolation guarantees of conventional single-level virtualization. We assume trusted hardware CPU protection mechanisms, including VMX-based root and non-root modes, as well as ring-based privilege separation between kernel and user execution. We further rely on hardware-enforced memory protection: first-level page tables constrain accesses to guest physical memory, while second-level EPTs restrict accesses to host physical memory within designated regions. Together, these mechanisms enforce strong isolation between the host and its guests, and extend naturally to nested guests.

Our focus is on software-level vulnerabilities in paravirtualized nested guest kernels, guest hypervisors, and the host hypervisor, which might be exposed through virtualization interfaces. We consider the following threat scenarios: (1) a malicious secure container may attempt to compromise nested CPU and memory virtualization by exploiting shared-memory regions or unauthorized address-space switching via the non-privileged `VMFUNC` instruction, potentially targeting the guest or co-located nested guests; and (2) a malicious guest may attempt to violate single-level virtualization boundaries by exploiting the memory virtualization coordination interface or vulnerabilities in the host hypervisor, thereby targeting the host or other guests.

These threats directly guide the design principles of JANUS. First, the system must protect the shared-memory region used for world switching from modification by the nested guest, even when it is mapped into the nested guest page table, in order to preserve the integrity of the switching mechanism and ensure correct guest-level execution. To this end, we design a shadow root mechanism (§4.2) that exposes a controlled view of the root page table (PGD) to the nested guest while maintaining consistency with the actual page-table state. Second, the system must intercept `VMFUNC` invocations that attempt to switch to unauthorized EPTs, thereby preventing illicit cross-domain memory access at the guest level. Accordingly, we develop an enhanced EPT mapping design that leverages GPA disaggregation to detect and block unauthorized EPTP switching via first-level page-table enforcement (§4.3). Finally, when extending memory-related hypercall interfaces to the host hypervisor, the system must enforce strict validation of memory mappings to ensure consistency with kernel memory management (§4.4).

4 JANUS: Design and Implementation

We present JANUS, a high-performance, nested virtualization framework that enables close cooperation between the L_0 and L_1 hypervisors to achieve efficient CPU and memory virtualization. Unlike prior nested virtualization approaches that consolidate CPU virtualization (world switching) and memory virtualization (three-level address translation) within a single hypervisor (PVM-on-EPT) or across both hypervisors (EPT-on-EPT), JANUS separates these mechanisms by assigning the responsibilities of world switching and page-table management to distinct hypervisors. Specifically, JANUS employs a switcher-like, software-based approach in L_1 to handle world switches due to L_2's system calls, page faults, interrupts, and exceptions, while delegating all memory virtualization to the L_0 hypervisor. The separation of CPU and memory virtualization provides two key benefits: (1) world switches become cheaper because all L_2 CPU state transitions can be handled locally within the L_1 hypervisor, closer to the L_2 guest and without involving L_0; and (2) the consolidation of nested three-dimensional page tables onto the two-dimensional paging hardware is delegated entirely to the most privileged hypervisor, L_0, thereby avoiding repetitive and costly world switches across L_2, L_1, and L_0.

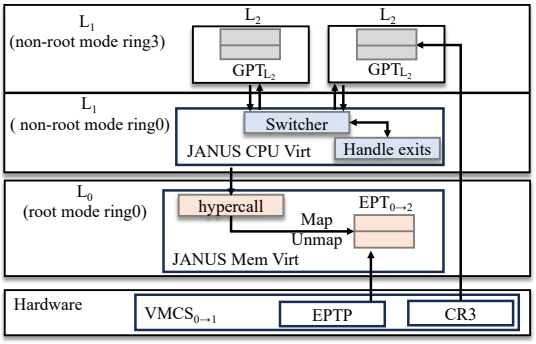


Figure 6: The JANUS architecture

4.1 Architecture Overview

Figure 6 illustrates the overall architecture of JANUS. JANUS leverages the two dimensional page tables in hardware to facilitate the three-level memory address translation in nested virtualization. It directly loads the L_2 guest's page table onto `CR3` for the first level address translation. Accordingly, JANUS loads $EPT_{0\to2}$ onto EPTP to directly translate GPA_{L_2} to HPA, and manages $EPT_{0\to2}$ exclusively in the L_0 hypervisor. While this design is architecturally similar to EPT-on-EPT, JANUS's key contribution is its ability to guarantee that (1) all L_2 visible events, such as page faults, system calls, and interrupts, are either handled natively by L_2 or efficiently processed within L_1, and (2) the management of $EPT_{0\to2}$ at L_0 bypasses any intermediate L_1 page tables and requires only a single world switch to L_0 per $EPT_{0\to2}$ update.

As shown in Figure 6, JANUS's key mechanisms include a software-based switcher that performs world switches for handling L_2 events, and a hypercall interface that enables cooperation between L_1 and L_0 for managing $EPT_{0\to2}$.

4.2 World Switch

Inspired by CPU para-virtualization techniques used in traditional hypervisors such as Xen [11], Lguest [6], and particularly PVM [21], the switcher in JANUS is implemented as a code and data segment within the per-CPU entry area, enabling efficient CPU state transitions in response to L_2 events. In general, switcher is a software-based mechanism that emulates VMCS functionality within non-root mode (i.e., the L_1 hypervisor) to save and restore CPU states across mode switches. Similar to the switcher design in PVM, JANUS places both the L_2 user and kernel spaces in hardware ring 3 of non-root mode, while the switcher itself resides in ring 0 of non-root mode. Thus, all L_2 privileged instructions, system calls, and interrupts trap into the switcher for world switching. To execute correctly across domains during switchover (which involves switching page tables and address spaces), the switcher must reside at the same virtual address in the L_2 user space, L_2 kernel space, and the L_1 hypervisor.

The delegation of memory virtualization, i.e., the management of $EPT_{0\to2}$, entirely to the L_0 hypervisor introduces unique challenges in JANUS's switcher design. Since L_2 directly loads its page table onto `CR3` for the first level address translation and there is no intermediate page table in L_1, the switcher must be indexed by both GPT_{L_2} and GPT_{L_1} to enable L_2-L_1 world switches. Consequently, the world switches involve the switching of GPT_{L_2} and GPT_{L_1} on `CR3`, and the switching of $EPT_{0\to2}$ and $EPT_{0\to1}$ on EPTP. Building on this design, JANUS's switcher offers two key advantages over prior approaches. (1) It resides on the L_1-maintained shadow root page table during L_2 execution, requiring only synchronization with the actual L_2 root page table, analogous to how the switcher resides within GPT_{L_2}. (2) It performs all required EPT switching without trapping to L_0, and efficiently handles switcher-induced EPT faults at runtime.

Table 1: World switches within non-root mode.

Execution Context	CR3	EPTP	Switcher mapping in EPT
L_1 Hypervisor	GPT_{L_1}	$EPT_{0\to1}$	Always present
① **call vm_entry**			
VM Entry	② $\to GPT_{L_2}$	$EPT_{0\to1}$	Always present
	GPT_{L_2}	③ $\to EPT_{0\to2}$	**On demand**
④ **IRET to** L_2			
L_2 Context (h_ring3)	GPT_{L_2}	$EPT_{0\to2}$	not used
⑤ **interrupt/exception/syscall/hypercall**			
VM Exit	GPT_{L_2}	⑥ $\to EPT_{0\to1}$	Always present
	⑦ $\to GPT_{L_1}$	$EPT_{0\to1}$	Always present
⑧ **ret to** L_1 **Hypervisor**			

Algorithm 1 VM Entry–Exit Cycle: $L_1 \to L_2 \to L_1$

Require: Initial state: $CR3 = GPT_{L_1}$, $EPTP = EPT_{0\to1}$.
Ensure: After cycle: L_2 executed and L_1 state restored.

VM Entry ($L_1 \to L_2$):
  Construct L_2 context onto L_2 entry stack
  Save L_1 context on L_1 kernel stack
  Switch to L_1 entry stack
  Switch $CR3$ to GPT_{L_2} (switch to L_2 entry stack)
  Invoke `VMFUNC(0, index)` to switch to $EPT_{0\to2}$
  Execute `IRET` (switch ring, pop stack and restore L_2)
L_2 **Execution**:
  State: $CR3 = GPT_{L_2}$, $EPTP = EPT_{0\to2}$
  Execute L_2 user process or kernel
VM Exit ($L_2 \to L_1$):
  Save L_2 context on L_2 entry stack
  Invoke `VMFUNC(0, 0)` to switch back to $EPT_{0\to1}$
  Restore $CR3$ to GPT_{L_1} (switch to L_1 entry stack)
  Restore L_1 context.

Table 1 summarizes page table switches for various mode transitions and execution contexts, and Algorithm 1 illustrates the execution flow of the complete VM entry–exit cycle. We begin with the L_1 execution context before an L_2 guest is launched. Upon the creation of an L_2 guest and before entering this guest, L_1 hypervisor installs a corresponding switcher in both GPT_{L_1} and $EPT_{0\to1}$. To facilitate L_2 mode switching, the L_1 hypervisor pins the switcher address mapping in L_1. To switch from the L_1 to L_2 context (①), i.e., performing a VM entry, the switcher first loads L_2's page table GPT_{L_2} onto

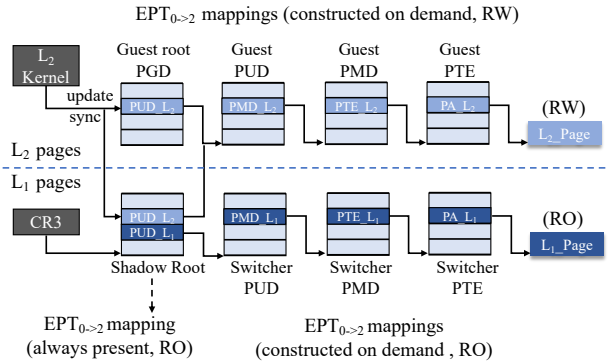

Figure 7: The relationship between shadow root and GPT_{L_2}

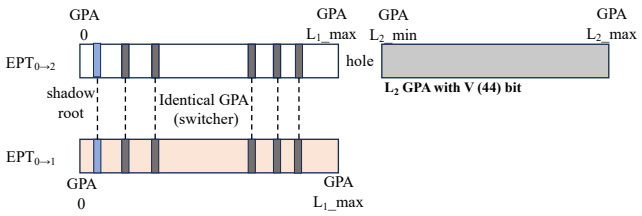

Figure 8: The layout of $EPT_{0\to1}$ and $EPT_{0\to2}$

`CR3` by simply using instruction `mov cr3, phys_addr` (②, Algorithm 1, line 5). However, the switching from $EPT_{0\to1}$ to $EPT_{0\to2}$ (③) is challenging. To ensure all page table switching does not trap into L_0, JANUS uses **VMFUNC-based EPTP switching** to change EPT entirely within the non-root mode, eliminating costly VM exits to L_0. With VMFUNC function 0, the hardware can switch among a set of preconfigured EPT roots supplied by L_0. L_1 uses EPT index 0 for $EPT_{0\to1}$ and maintains a mapping from each L_2 context to its corresponding $EPT_{0\to2}$ entry. During an $L_1 \to L_2$ transition, the switcher executes `VMFUNC` with the target EPT index (Algorithm 1, line 6), enabling a fast, trap-free EPTP switch.

Maintaining per L_2 switchers and directly placing the switcher inside GPT_{L_2} is unsafe because a compromised or malicious L_2 kernel could modify its page tables to remap or overwrite the switcher, potentially subverting the world-switching mechanism. To ensure integrity, JANUS introduces a *shadow-root* mechanism that constructs a shadow page global directory (PGD) mirroring the real GPT_{L_2}. As shown in Figure 7, the corresponding shadow PGD entries are pre-mapped as read-only in $EPT_{0\to2}$ to prevent unauthorized modification. The L_1 hypervisor installs the switcher by configuring the relevant PGD entries to reference the switcher's PUD and its subordinate tables (PUD, PMD, PTE). When an L_2 attempts to modify PGD entries, it also issues a hypercall to L_1 which validates the update and synchronizes it with the shadow root before applying the change. Otherwise, updates to PGD entries in GPT_{L_2} do not take effect, as only modifications propagated to the L_1-authorized shadow root are visible to the hardware MMU. Importantly, such PGD-level updates are infrequent in L_2, while lower-level page table modifications (PUD, PMD, PTE) proceed by L_2 kernel without L_1 involvement, incurring no overhead in the common case. The shadow root mechanism also enforces the security of EPTP switching, as the lower-level EPT mappings associated with each shadow root exist only within the EPT corresponding to its own L_2. Any unauthorized VMFUNC attempt by a malicious L_2 triggers an EPT violation that is trapped by L_1, due to the absence of the required first-level page table mappings, thereby preventing cross-L_2 memory access.

Note that $EPT_{0\to2}$ initially contains only the shadow-root mappings, and the switcher mappings are created on demand. When an access to the switcher triggers an EPT fault, L_0 intercepts, switches to $EPT_{0\to1}$, and completes the exit to L_1, which already has the correct switcher mappings. L_0 then installs the required switcher entries into $EPT_{0\to2}$ with proper permissions. This incurs only a one-time overhead because the switcher region is small and must be initialized only once per $EPT_{0\to2}$.

To finally enter L_2, the switcher performs an `IRET` (Algorithm 1, line 7) using a pre-built cross-page `IRET` frame: the *ss* field is mapped read-only to protect the user-mode *rip*, while the rest of the frame sits on a writable adjacent page. Execution then proceeds in hardware ring 3 under non-root mode, and although $EPT_{0\to2}$ includes the switcher, L_2 cannot access it. System calls and interrupts in L_2 trap to hardware ring 0 (non-root mode), where the switcher performs a VMFUNC-based switch to $EPT_{0\to1}$, loads GPT_{L_1}, and returns to the L_1 hypervisor via `ret` (⑤-⑧, Algorithm 1, line 12-15). This design enables secure, low-latency transitions while preserving strong isolation between L_1 and L_2.

4.3 Memory Virtualization

JANUS achieves nested memory virtualization using the L_2 guest's own page table as the first-level translation, paired with a second-level translation layer managed by the host (L_0) hypervisor. Thus, a GVA_{L_2} is first translated to GPA_{L_2} via GPT_{L_2}, and then to a *host physical address* (HPA) through $EPT_{0\to2}$. Unlike PVM-on-EPT, which marks GPT_{L_2} read-only to intercept and emulate every page-table update, JANUS keeps GPT_{L_2} *writable* so that L_2 can update its page tables without trapping into L_1. Unlike KVM's EPT-on-EPT design, JANUS removes the intermediate $EPT_{1\to2}$ maintained by L_1, avoiding both the synchronization between $EPT_{1\to2}$ and $EPT_{0\to2}$ and the additional exits required for write emulation. These two choices – writable GPT_{L_2} and a single host-managed $EPT_{0\to2}$ – reduce cross-layer switches and shrink the amount of page-table state maintained by L_1.

We now describe how JANUS safely supports writable guest page tables and efficient fault resolution without compromising isolation or incurring cross-layer overhead.

GPA disaggregation and mapping validation. Because GPT_{L_2} is writable, JANUS must ensure that updates made by L_2 cannot map over the switcher. To enforce this separation, JANUS arranges the L_2 GPA layout exposed through $EPT_{0\to2}$ into two regions: (1) the *read-only* shadow-root and switcher

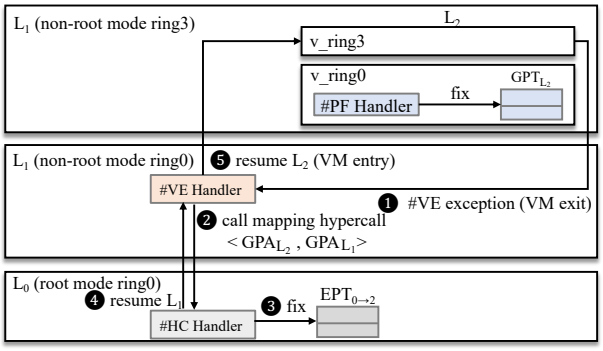

Figure 9: The memory virtualization of JANUS

pages, and (2) the regular *writable* GPA range assigned to L_2.

As shown in Figure 8, $EPT_{0\to2}$ maps the shadow-root and switcher pages at the same GPA positions as in $EPT_{0\to1}$. These entries are marked *read-only* to protect the switcher, except for the writable portion of the `IRET` frame required for world switches. The GPA region assigned to L_2 remains unmapped initially; entries are installed on demand by L_0 as translation faults occur. To ensure that L_1 interprets only legitimate GPT_{L_2} updates, each GPT_{L_2} entry mapping an L_2-assigned page carries a *software-defined V-bit* – set by the paravirtualized L_2 kernel. The V-bit marks the entry as created by L_2, allowing L_1 to distinguish such updates from other arbitrary memory contents (e.g., the shadow-root and switcher pages). When validating a mapping request during a translation fault, L_1 checks the V-bit and rejects any request that lacks it.[3] These checks prevent a compromised L_2 from mapping over privileged memory while allowing ordinary page-table updates to proceed. In this way, JANUS maintains isolation without marking GPT_{L_2} read-only or intercepting its internal updates.

GPT fault handling. With GPT_{L_2} kept writable, JANUS allows L_2 to handle its own first-level translation faults without involving L_1.

Specifically, when a page fault is triggered due to a missing GPT_{L_2} entry, the switcher's #PF handler intercepts the exception and performs *direct page-fault injection* into the L_2 kernel without exiting to the L_1 hypervisor – i.e., the switcher (1) saves the current execution context, including the faulting address stored in `CR2`, into its state-save area; (2) switches to the L_2 kernel context by updating execution stack and adress space (via `SWAPGS` and `MOV CR3`); and (3) returns control to the L_2 guest kernel using `IRET`. Subsequently, the paravirtualized L_2 kernel retrieves the `CR2` value and fault vector to handle the exception natively. Once L_2 resolves the fault and updates its GPT_{L_2}, execution resumes directly in L_2 user mode at ring 3 without any L_1 hypervisor intervention. The only exception arises when the fault modifies the root page directory (PGD). In such cases, a hypercall is issued to synchronize the shadow root maintained by L_1 (§4.2).

[3] L_2 cannot set the V-bit on GPT_{L_2} entries corresponding to the shadow-root or switcher pages, as they are read-only protected from L_2.

EPT fault handling. Faults in $EPT_{0\to2}$ are handled by the L_1 hypervisor via the *Virtualization Exception* (#VE), an Intel VT-x feature that enables selective in-guest handling of virtualization events without exiting to the host L_0 hypervisor.

When #VE is enabled for a vCPU (via the VE enable bit in the VMCS control field), EPT violations that would normally trigger a VM exit can instead raise a #VE (vector 20) within the guest. The #VE Information Area, defined by the VMCS, records details such as the faulting GPA, access type (read-/write/execute), violation cause (e.g., missing translation or permission fault), and the faulting instruction pointer, allowing L_1 to diagnose and handle the fault with L_0 assistance [4].

More specifically, when a GPA_{L_2} lacks a valid mapping in $EPT_{0\to2}$ (Figure 9), a #VE is raised and delivered to L_1 (❶). The L_1 handler (1) inspects the faulting GPA_{L_2}; (2) performs a GPT_{L_1} walk to resolve the corresponding GPA_{L_1}; and (3) issues a `KVM_HC_JANUS_OPS` hypercall with `JANUS_MAP` operation (as listed in Table 2) to L_0 containing the mapping information including GPA_{L_1} and GPA_{L_2} (❷). The L_0 hypervisor then locates the *host physical address* (HPA) associated with the GPA_{L_1} and updates $EPT_{0\to2}$ based on GPA_{L_2} accordingly (❸). By eliminating intermediate shadow page tables in L_1, this process requires only a single lightweight exit to L_1 followed by one exit to L_0, substantially reducing cross-world synchronization overhead compared to conventional nested memory virtualization mechanisms.

Table 2: JANUS hypercall operations and their usage

Operation	Description
JANUS_CREATE	Create the $EPT_{0\to2}$ structure corresponding to the specified JANUS index.
JANUS_DESTROY	Destroy the corresponding $EPT_{0\to2}$ and release all associated structures within L_0.
JANUS_MAP	Construct $EPT_{0\to2}$ mappings based on GPA_{L_2}, GPA_{L_1}, permission, and length.
JANUS_UNMAP	Remove (*zap*) the existing $EPT_{0\to2}$ mappings.
JANUS_CHECK	Check if existing mapping is young and clear it if required.

JANUS introduces only a single hypercall for managing $EPT_{0\to2}$ operations (Table 2), whose semantics are simple and well-defined compared with the complex nested virtualization logic in conventional KVM. Frequent invocation of the new hypercall behaves similarly to standard KVM hypercalls, causing additional vCPU exits without compromising host stability. However, the `JANUS_CREATE` operation requires special handling because it triggers structural initialization in L_0 and must be restricted to control the number of $EPT_{0\to2}$ instances allocated. For data protection, L_0 performs strict validation to ensure that no mapping references *HPAs* beyond the range owned by its corresponding L_1. These checks include boundary and length verification, and the removal of stale mappings after reconfiguration.

[4] Note that, in our design, the Suppress #VE bit (bit 63) is set for *switcher EPT entries* to force a normal EPT violation VM exit for on-demand switcher construction, while it remains cleared for regular L_2 EPT entries to enable in-guest #VE handling.

4.4 JANUS-Assisted Memory Management

Having offloaded nested memory virtualization to the host (L_0) and eliminated the intermediate guest page tables maintained by L_1, JANUS must ensure that this two-level translation model continues to interoperate correctly with existing memory management in both the host hypervisor (L_0) and the guest hypervisor (L_1). This section examines two important memory management scenarios that arise frequently in production clouds – i.e., memory reclamation and secure container live migration – and describes how JANUS enables these operations to proceed efficiently under its design.

4.4.1 Memory Reclamation

Both the L_0 host and the L_1 guest maintain their own memory management subsystems. Under memory pressure, each may reclaim memory previously allocated to guests or nested guests. In current Linux systems, the host kernel at L_0 or L_1 uses the `mmu_notifier` interface (e.g., `invalidate_range`, `change_pte`, and `clear_young`) to inform the L_0 or L_1 hypervisor of modifications to the host page tables that back guest or nested guest physical memory. These notifications ensure that the hypervisor's memory-virtualization structures (e.g., EPT mappings) remain coherent with the kernel's memory view. With the introduction of $EPT_{0\to2}$ for L_2, JANUS extends this mechanism to ensure that host kernel side invalidations propagate correctly across all layers.

At L_0, any `unmap` or reclamation operation may affect the memory view of both L_1 and L_2. Because the host kernel at L_0 performs reclamation using the GPA_{L_1} ranges that back the guest memory, the L_0 hypervisor must be able to locate all second-level mappings derived from a given GPA_{L_1}. To support this, each entry in $EPT_{0\to2}$ is associated with a reverse-mapping (`rmap`) structure keyed by GPA_{L_1}, allowing L_0 to identify and invalidate all relevant $EPT_{0\to2}$ entries when the host kernel reclaims memory. This ensures that memory invalidations initiated by L_0 propagate consistently across the multi-level translation hierarchy.

At L_1, in conventional nested virtualization (SPT-on-EPT), L_1 updates the shadow table to reflect changes to the page tables backing L_2 and all metadata associated with its shadow PTEs (e.g., access permissions and dirty bits). Under JANUS, however, all second-level translations are maintained by L_0 in $EPT_{0\to2}$, so memory invalidations initiated at L_1 must now be delegated directly to L_0. Specifically, when `invalidate_range` is invoked at L_1, the L_1 hypervisor issues a `JANUS_UNMAP` hypercall to L_0, which removes the corresponding entries from $EPT_{0\to2}$ for the affected GPA_{L_1} range. Although L_1 no longer updates a shadow page table for L_2, it still manages its own GPAs and thus must update its internal per-page attributes to keep its local memory state consistent with the mappings removed by L_0. More concretely, pages that become read-only are reflected via `set_pfn_access`, while writable pages record dirtiness using `set_pfn_dirty`.

This way, JANUS enables coherent memory reclamation across layers by allowing L_0 to invalidate nested mappings directly and by having L_1 forward its invalidations while still maintaining its own page metadata.

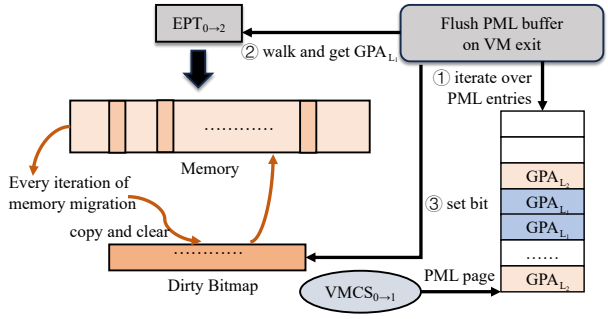

Figure 10: The live migration progress of L_1 with JANUS.

4.4.2 Live Migration

Live migration is a critical capability in cloud environments, enabling VMs to be relocated transparently without disrupting ongoing services. In nested virtualization settings, it is the L_1 VM that is migrated by the cloud provider; all state belonging to an L_2 guest is encapsulated within L_1's memory and is therefore transferred as part of the L_1 migration. Among the stages of live migration, memory migration is particularly important, as it moves the full in-memory state of L_1 (and transitively L_2) to the destination host to ensure seamless resumption of execution. A key requirement for this process is accurate dirty-page tracking, which identifies pages modified during migration so that only changed memory must be resent.

Under conventional hardware-assisted nested virtualization (EPT-on-EPT), VMX's *Page Modification Logging* (PML)[5] cannot be used to track modifications made by L_2. PML logs only the guest physical addresses of trapped writes, but provides no indication of which EPT translation context generated them; writes serviced through $EPT_{0\to1}$ (from L_1) and those serviced through $EPT_{0\to2}$ (from L_2) are indistinguishable in the PML buffer. Consequently, even with PML enabled for L_1 during migration, the host hypervisor must resort to software-based dirty-page tracking for $EPT_{0\to2}$, typically by clearing the write bit of those entries and trapping subsequent updates. This write-protection approach severely degrades L_2 performance during migration because every modified page incurs a fault and exits to L_0.

JANUS overcomes this by leveraging its GPA disaggregation (§4.3), where L_2's GPAs are assigned to a dedicated, non-overlapping region. Since PML logs the guest physical address of each trapped write, this separation allows L_0 to identify PML entries originating from L_2 simply by checking whether the logged GPA falls within the GPA_{L_2} range. As shown in Figure 10, (1) during iterative pre-copy migration,

[5]PML is an Intel VT-x mechanism that records guest-physical pages modified by a VM by logging their GPAs into a hardware-managed buffer, allowing the hypervisor to track dirty pages for operations such as live migration without trapping each write.

(e) Dedup (f) Specjbb (g) In-memory Analysis (h) Graph Analysis

Figure 11: The performance of eight memory-intensive applications

when a PML entry corresponds to an L_2 GPA (①), the migration procedure walks $EPT_{0\to2}$ (its `rmap`, §4.4.1) to translate the GPA_{L_2} to its backing GPA_{L_1} (②). (2) The resulting GPA_{L_1} is then marked dirty in L_1's dirty bitmap (③), ensuring that all L_2 memory modifications are correctly reflected in the set of pages to be transferred. (3) After each iteration, the dirty bits are cleared on the source host, and (4) once no additional dirty pages remain, the L_1 VM is suspended and resumed on the destination host, completing the migration.

5 Evaluation

Real-world adoption. We implement JANUS with 1662 lines of modifications in the host KVM hypervisor, 3702 lines in the PVM guest hypervisor, and 264 lines in the PVM nested guest kernel. JANUS has been deployed in production on a leading cloud provider's PaaS platform to support the Flink distributed stream and batch processing system, enabling secure container execution without compromising elasticity. PVM [21] – a state-of-the-art software-based nested virtualization system – increases total query time across 17 Flink queries by roughly 30% for C++ and 20% for Java engines compared to traditional RunC containers [43]. In contrast, JANUS-based secure containers add less than 5% overhead relative to RunC. These results demonstrate that JANUS achieves hardware-grade isolation with near-native performance, making it well suited for latency-sensitive, multi-tenant cloud environments.

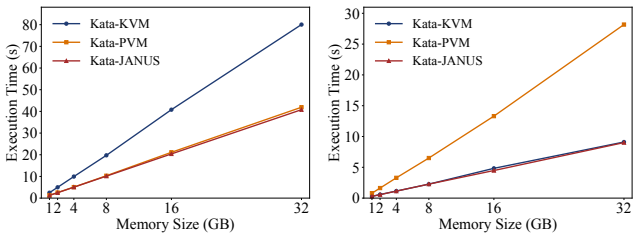
Testbed and configurations. To further assess JANUS under controlled conditions, we conducted experiments within L_1 VMs running atop the L_0 host. The host machine was equipped with an Intel(R) Xeon(R) Platinum 8475B processor (3200 MHz) featuring 192 physical CPUs and 384 GB RAM, running the Linux 5.10.134 kernel, the dominant version in our production environment, consistently across all layers (L_0, L_1, and L_2). Both L_0 and L_1 KVM hypervisors are configured with `tpd_mmu=y`, a Google-proposed enhancement that improves parallelism in memory virtualization by mitigating contention on the global MMU lock. The L_0 hypervisor enabled VMCS Shadowing, allowing the L_1 KVM hypervisor to directly manage its own VMCS structures for L_2 guests without causing additional exits. To align with common cloud configurations, Transparent Huge Pages (THP) were enabled in L_1 (`transparent_hugepage=always`, and `shmem_enabled=advise`) to accelerate memory efficiency.

Baselines for comparison. We evaluated three nested container configurations for comparison: (1) Kata-KVM: Kata Containers using hardware-assisted nested virtualization via the L_1 KVM hypervisor (standard nested KVM); (2) Kata-PVM: Kata Containers using software-based nested virtualization via the L_1 PVM hypervisor (the PVM [21] approach); and (3) Kata-JANUS: our JANUS-based nested virtualization.

5.1 Memory-Intensive Applications

In this section, we first evaluated eight representative memory-intensive applications under multiple resource configurations. The benchmarks consisted of four multi-process applications, including ebizzy [4], UnixBench execl and shell [8], and Kbuild [5]; and four multi-threaded applications, including SPECjbb [39] and Dedup from the PARSEC3.0 [52] and In-Memory Analytics and Graph Analytics from the CloudSuite [3]. We then used the stress-ng [7] memory test to capture memory accesses to both inactive guest physical memory that was never touched and to active guest physical memory whose mappings were already established. Together, these applications exhibit a wide range of memory behaviors, including random memory initialization, frequent modification, and high-intensity data access.

The performance results for memory-intensive applications are shown in Figure 11. Across both multi-process and multi-



(a) Inactive physical memory (b) Active physical memory

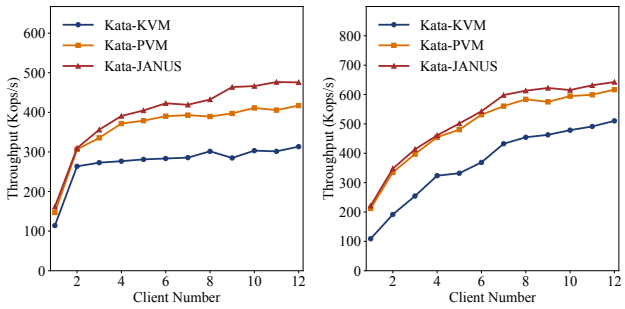
Figure 12: Performance of physical memory (PM) access.

threaded workloads, Kata-JANUS achieves the best overall performance and superior scalability by eliminating intermediate page-table management within the guest hypervisor. Specifically, for multi-process applications, Kata-PVM consistently delivers the lowest performance because it must maintain a distinct shadow page table for each process, which incurs substantial overhead from intensive SPT management and synchronization. In contrast, Kata-JANUS improves multi-process performance by 339.7% on average over Kata-PVM and further outperforms Kata-KVM by 51.8% when using 8 vCPUs. For multi-threaded applications, Kata-PVM outperforms Kata-KVM because it avoids the expensive EPT reconstructions that dominate Kata-KVM's execution time. Dedup is the only exception, as its frequent GPT_{L_2} updates trigger numerous exits for synchronizing with $SPT_{1\to2}$. Kata-JANUS still achieves an average performance improvement of 37% over Kata-PVM and 13.3% over Kata-KVM when using 8 vCPUs, due to its faster mapping-construction path.

The results in Figure 12 show that Kata-JANUS consistently achieves the best performance for both inactive and active memory access patterns. Specifically, when the system accesses inactive guest physical memory, Kata-KVM experiences a substantial performance drop because the construction of the low-level EPT mapping requires multiple expensive exits to L_0. When the system accesses active guest physical memory, Kata-PVM becomes the slowest design because it repeatedly synchronizes the L_2 guest page table with the corresponding shadow page table in L_1. In contrast, Kata-JANUS performs slightly better than Kata-PVM during the initial construction of memory mappings, and this behavior confirms the benefit of its direct page-fault injection for repairing the L_2 guest page table together with its lightweight procedure for constructing the low-level EPT mapping.

5.2 In-memory Key-Value Stores

We also evaluated the performance of two widely deployed in-memory key-value stores, Redis and Memcached, to assess system efficiency under realistic and latency-sensitive workloads. These systems are representative of memory-centric cloud services that issue frequent fine-grained read and write operations and are therefore highly sensitive to the overhead introduced by nested memory virtualization. In our tests, the Redis and Memcached servers executed inside the L_2, while



(a) Redis (b) Memcached

Figure 13: Throughput of in-memory key-value stores

clients ran in L_1 and continuously generated requests.

The performance results are shown in Figure 13. Across all workloads, Kata-JANUS provides the highest throughput and best scalability. For example, Kata-JANUS increases Redis throughput by an average of 9.7% and 45.1% relative to Kata-PVM and Kata-KVM, respectively, and boosts Memcached throughput by an average of 4.4% and 48.2%. Again, JANUS's performance advantage arises from its lightweight, host-managed memory virtualization design, which minimizes cross-world exits and eliminates the costly synchronization overhead.

We also evaluated these applications in both host and guest, while scaling the number of co-located malicious guests from 0 to 8 to stress the JANUS-introduced hypercalls. The results show that the performance impact is negligible.

5.3 Micro-benchmarks

We finally used various microbenchmarks to quantify the fundamental costs introduced by nested virtualization, focusing on world-switch latency, two-level address mapping, and memory modification tracking.

Table 3: Comparison of world-switch costs

Configuration	Switching Path	Cycles
Kata-KVM	$L_2 \to L_0 \to L_1 \to L_0 \to L_2$	16,002
Kata-PVM	$L_2 \to L_1 \to L_2$	2,681
Kata-JANUS	$L_2 \to L_1 \to L_2$	2,700

Cost of world switch. A world switch occurs when the processor exits to the hypervisor to handle events of the guest and then re-enters the guest after completion. These events include the execution of sensitive instructions such as `CPUID` or `HLT`, accesses to privileged registers, external interrupts, page faults, I/O operations, and guest-issued hypercalls that require hypervisor intervention to preserve virtualization integrity.

During Kata container execution, the world switch occurs between L_2 and L_1, as L_2 runs on top of L_1. With hardware-assisted nested virtualization (i.e., Kata-KVM), the switching process involves two exits to L_0, while switcher-based nested virtualization (i.e., Kata-PVM) completes the switch with a single exit to L_1. JANUS inherits this switcher-based world switch design and introduces an additional `VMFUNC`-based mechanism to switch EPT mappings between L_1 and L_2.

We conducted a microbenchmark that invoked one million hypercalls, each triggering a pure world switch. We measured the average cost of a complete switch cycle. The results are summarized in Table 3. The world switch of Kata-KVM takes approximately 16,002 cycles, as the L_0 KVM must perform costly synchronization between $VMCS_{0\to2}$ and $VMCS_{1\to2}$ during nested virtualization transitions. PVM achieves 2,681 cycles per switch owing to its lightweight switcher-based CPU virtualization. JANUS achieves a similar latency of 2,700 cycles, demonstrating that the additional `VMFUNC` operation introduces negligible overhead.

Cost of mapping construction. Constructing a two-level hardware memory mapping involves handling both GPT faults and SPT/EPT faults. For Kata-KVM and Kata-JANUS, GPT_{L_2} faults can be resolved locally without VM exits, whereas Kata-PVM must exit to the L_1 hypervisor to reinject the #PF fault into L_2. After the GPT_{L_2} is repaired, Kata-PVM performs the $SPT_{1\to2}$ fixup within L_1, while Kata-KVM and Kata-JANUS require L_0 assistance to update $EPT_{0\to2}$. As discussed earlier, Kata-JANUS incurs only one additional exit to L_0, whereas Kata-KVM requires multiple exits.

Table 4: Mapping construction overheads (cycles)

Configuration	GPT fault (Fix GPT)	EPT/SPT fault	Total
Kata-KVM	1,960 (576)	55,980	57,840
Kata-PVM	7,048 (2,736)	12,218	19,266
Kata-JANUS	3,186 (1,546)	24,914	28,100
Kata-JANUS (#VE)	3,026 (1,316)	23,934	26,960

We implemented a microbenchmark that repeatedly triggered the mapping construction path. As shown in Table 4, Kata-PVM incurs higher overhead for handling GPT faults, while Kata-KVM suffers from substantial costs associated with EPT fault handling. In contrast, Kata-JANUS benefits from direct #PF injection, enabling more efficient GPT fault processing, and outperforms Kata-KVM in EPT fault handling by issuing fewer exits to L_0 and using lightweight hypercall-based EPT updates. Notably, when constructing an initial mapping, Kata-JANUS is slightly slower than Kata-PVM due to its use of $EPT_{0\to2}$, which requires one additional expensive exit to L_0. However, once the low-level $EPT_{0\to2}$ mapping is established, the overhead of both Kata-KVM and Kata-JANUS becomes dominated solely by GPT faults, whereas Kata-PVM must continue synchronizing SPT updates with the GPT mapping, resulting in additional overhead.

Performance impact of dirty-page tracking. Maintaining stable performance during L_1 migration is essential for cloud providers. We evaluated memory modification overheads before and after enabling dirty-page tracking.

As summarized in Table 5, since the low-level $EPT_{0\to2}$ mappings are already established, memory writes do not trigger additional mapping construction, and both Kata-KVM and Kata-JANUS initially exhibit performance comparable to native L_1 execution. However, once dirty-page tracking is enabled, Kata-KVM experiences substantial degradation because all $EPT_{0\to2}$ entries must be write-protected to track dirty pages, causing every memory write to trigger an exit to L_0. As a result, Kata-KVM incurs a 175.5% increase in memory modification overhead on average. In contrast, JANUS leverages hardware PML directly on $EPT_{0\to2}$ without requiring write protection, thereby avoiding excessive VM exits and maintaining near-identical performance.

Table 5: Memory performance before and after enabling dirty-page tracking

	Execution Time (s)			
	1GB	2GB	4GB	8GB
L_1 VM	0.27/0.35	0.55/0.70	1.16/1.48	2.29/2.93
Kata-KVM	0.294/0.80	0.59/1.70	1.20/3.23	2.38/6.49
Kata-JANUS	0.28/0.37	0.57/0.75	1.16/1.67	2.36/2.97

6 Discussion and Future Work

JANUS currently relies on CR3-based page table switching to isolate the kernel and user spaces of L_2, requiring transitions through the switcher to update CR3 during context switches. In future work, we plan to leverage EPT-based isolation between the L_2 kernel and user spaces, enabling direct and lightweight context switches entirely within L_2 without involving the switcher. In addition, we are exploring the use of *Hypervisor-managed Linear Address Translation* (HLAT) [48] to protect the switcher while eliminating the need to maintain a shadow root for the GPT_{L_2}.

7 Related Work

Securing containers. The security of containerized workloads has drawn extensive attention due to the shared-kernel architecture of conventional containers, which allows a single compromised container to potentially escalate privileges and compromise the host system [19, 20, 24, 31]. Existing work on shared-kernel security enhancement emphasizes strengthening memory isolation [45] and privilege protection [22, 46], reducing the exposed attack surface by intercepting or restricting system calls [34, 47], and enforcing runtime security monitoring [41] to detect or mitigate malicious behavior within containers. Hardware-assisted designs such as RContainer [55], BlackBox [41], and LightZone [51] leverage trusted execution environments to ensure strong isolation of container workloads. Microkernel-based systems including MettEagle [33], LITESHIELD [32], and split containers [37] limit the impact of compromised containers on critical system components, while recent WebAssembly-based containers [23, 29, 50] enhance security by exploiting the inherent isolation provided by the Wasm runtime. In contrast to kernel-sharing approaches, some systems duplicate kernel functionality for each container, with gVisor [49] implementing a user-space kernel that intercepts and validates system calls to decouple containerized applications from the host kernel, and X-Container [36] and μKontainer [40] relying on separate Library OS instances to provide stronger isolation. Secure container frameworks such as Kata Containers [25] and Firecracker [9] further en-

hance isolation by running each container inside a lightweight virtual machine, combining container agility with hardware-enforced security guarantees, and secure containers have now emerged as a practical foundation for cloud-native security with production deployment in modern hyperscale platforms such as Alibaba Cloud [25].

Enabling nested virtualization. Virtualization has long been a cornerstone of cloud computing, evolving from early full virtualization to paravirtualization [11], then hardware-assisted virtualization [18], and more recently to delegated user-level virtualization [14]. Nested virtualization remains a challenging problem, as it must support running guest hypervisors within virtualized guests, which is essential for deploying secure containers in cloud-native infrastructures. Early systems such as Turtles [12] and NEVE [26] demonstrated the feasibility of nested execution by emulating hardware virtualization features at the host level. Later processor extensions, including VMCS shadowing, reduced the number of VM exits by allowing guest hypervisors to directly access certain control structures. More recent work adopts architectural co-design strategies to minimize cross-world semantic gaps. For example, SVT [42] leverages *simultaneous multithreading* (SMT) to maintain guest hypervisor and nested guest on separate logical threads, while DVH [27] enables direct virtual hardware provisioning to streamline interrupt delivery and device emulation. Despite these advances, memory virtualization remains the primary bottleneck, as cross-world synchronization continues to dominate overhead in nested environments.

Optimizing nested memory virtualization. Nested memory virtualization requires composing three translation page tables into two hardware-supported stages, which often incurs substantial overhead due to multi-level synchronization. Prior efforts have sought to mitigate costly world switches through optimized page-fault handling. PVM [21] enables lightweight world switches and handles L_2 page faults entirely within L_1, avoiding L_0 involvement, but frequent updates to GPT_{L_2} increase the overall number of page faults. CKI [38] embeds GVA_{L_2}-GPA_{L_1} mappings directly within GPT_{L_2} using contiguous segment allocation, trading flexibility for improved page-fault handling efficiency. Other designs [35, 53] reduce translation overhead through direct address exposure or huge-page coalescing, while Hyperturtle [56] leverages eBPF-based hyper-upcalls to synchronize EPT hierarchies across layers, lowering update latency yet retaining cross-world dependencies. In contrast, JANUS redefines nested memory virtualization by decoupling CPU and memory control across layers and exposing nested guest page tables directly to the host-managed EPT hierarchy, achieving near-native performance with minimal modifications to the host.

8 Conclusion

This paper presents JANUS, a high-performance nested virtualization architecture that reimagines memory virtualization for secure containers. JANUS decouples CPU and memory virtualization across layers, eliminates intermediate shadow mappings, and exposes the nested guest page table directly to the host-managed EPT hierarchy. Leveraging optimized fault-handling mechanisms, it provides efficient, trap-free memory virtualization with minimal host intervention. As a self-contained and host-transparent design, JANUS simplifies the nested virtualization stack while achieving better performance for secure containers, bridging the longstanding gap between strong workload isolation and cloud-native efficiency. JANUS has been adopted by multiple Alibaba Cloud PaaS platforms to host secure containers, providing a more performant and cost-effective solution for cloud deployments.

Abstract

There is increasing interest in privacy-preserving data analytics applications. These applications rely on Secure Computation (SC), a family of cryptographic techniques for computing on encrypted data. Unfortunately, SC amplifies the memory overhead of data-intensive data analytics applications, presenting a serious obstacle to their widespread deployment.

Osprey is a memory management framework that enables SC to efficiently page to an SSD. It works at runtime and is transparent to SC applications, similar to classical OS virtual memory. This resolves a serious limitation in prior SC-aware memory management, which requires up-front planning and rewriting applications in a new programming framework.

Osprey achieves this using speculative execution. While speculative execution is powerful, it normally requires complex and error-prone in-kernel support, and therefore is not widely deployed for OS processes. Our central observation in Osprey is that, by carefully leveraging SC's obliviousness, we can make speculative execution for SC workloads practical and efficient. Osprey requires changing < 200 lines of code in each SC library that we tested, and no lines of code in SC applications written against those libraries.

1 Introduction

Data analytics is pervasive across applications and industries. But security and privacy concerns are a significant obstacle. For example, an organization may be hesitant to outsource its sensitive data to the cloud for data analytics. As another example, hospitals may want to combine their patient datasets to do research on rare diseases, or financial institutions may wish to combine their customers' data for fraud detection [14]—but privacy concerns prevent them from directly sharing their data with each other. These concerns have led to research on secure/private data analytics systems [2, 43, 47, 52, 57, 65, 66].

A compelling approach to secure data analytics systems is Secure Computation (SC). SC is a collection of techniques for computing on encrypted data, including Secure Multi-Party Computation (SMPC) and Homomorphic Encryption (HE). Google and Meta use SC in their advertising products [23, 46, 58], an industry consortium has formed around SMPC [40], researchers have used SC to facilitate secure data sharing for clinical research [2, 47], and Web3 wallets use SC to secure billions of dollars' worth of digital assets [16, 50].

Still, SC is not widely used for data-intensive analytics [2, 23, 57]. One reason is that SC is very resource-intensive (e.g., in CPU, memory, and network usage). In particular, SC can introduce a significant *expansion factor* on all encrypted data. For example, when using garbled circuits (a type of SMPC), each bit of plaintext takes up 16 B in encrypted form—a 128× expansion factor. As a result, SC-based data analytics systems run out of memory on even moderately-sized datasets [44, 57, 67, 69]. For example, the authors of Conclave report that SMPC "in practice only scales to a few thousand input records" (e.g., 30,000 records per party for a join) [57]. Once memory is exhausted, these workloads become infeasibly slow because the OS starts paging to secondary storage [44].

State of the Art. A promising direction is to make paging more efficient for SC workloads. There exist two approaches for this, memory programming and speculative execution. Both have significant downsides, which we now explain.

The first approach, memory programming, is to calculate the SC program's memory access pattern in advance, to pre-plan memory management [28]. This is possible because SC protocols are *oblivious*—that is, their memory access patterns are independent of the input data. Unfortunately, it requires changing applications to use a particular DSL/programming framework—a serious limitation because the SC ecosystem has a huge diversity of DSLs/frameworks [10, 12, 13, 20, 25, 29, 31, 42, 51, 56, 60], and it is not feasible to port all of them and their applications to a single DSL framework and runtime. Furthermore, this planner-based approach cannot respond to memory pressure at runtime, and produces a memory management plan that can be very large (e.g., gigabytes for a program that runs in just a few seconds).

The second approach, speculative execution, is to run the program speculatively [7, 8, 17, 30, 32, 41], *concurrently* with

the actual execution, to inform memory management [17]. If done by running a full duplicate execution, speculation incurs the program's memory overhead *again*, requiring more paging and worsening the problem. To address this, existing approaches use heuristics to skip I/Os and drop pages from memory when speculating. Unfortunately, this means that speculation may make mistakes—that is, "misspeculate." Process state must then be rolled back, which is complex and error-prone (e.g., implemented by "re-forking" processes [17]). Due to this complexity, no mainstream operating system, to our knowledge, uses speculative execution. It is only used in cases where the cost of a full duplicate execution is acceptable—for example, for straggler tasks in Hadoop and Spark [54, 63].

Main Insight. Our work uses an observation regarding *obliviousness*, a core property of SC, to overcome the challenges of speculative execution. There are actually *two* important aspects of SC's obliviousness. The first aspect, leveraged by prior work, is that access patterns remain unchanged regardless of program inputs, a property referred to as "input-oblivious" (IO). We identify a second aspect that prior work has largely missed: overwriting ciphertext data with arbitrary bytes during execution does not alter the program's memory access pattern. We refer to this as *"content-oblivious"* (CO).

The key insight behind our approach is that **CO enables us to eliminate misspeculation entirely, making speculative execution practical**. Traditional speculation requires dropping pages to control memory overhead, which inevitably leads to misspeculation. In SC, however, we can safely drop any data that is CO. Since ciphertexts, which dominate memory usage, are CO, discarding them dramatically reduces memory overhead without risking misspeculation.

Normally, speculative execution requires executing the program twice—speculatively and then concretely—doubling the CPU load. Yet, we circumvent this by leveraging CO again. We omit operations on ciphertexts during speculation and instead only record their would-be memory accesses. Because the dominant CPU cost arises from cryptographic operations on ciphertexts, this greatly reduces CPU usage of speculation.

By dropping CO data from memory and skipping computation on CO data, our approach addresses both the memory overhead and compute overhead of speculative execution. The result is a highly efficient speculative engine that provides timely guidance to the actual execution at a very low cost.

Design. Leveraging this insight, we design Osprey,[1] the first memory-management framework that runs SC workloads with *exceptionally low overhead* while being *transparent* to SC workloads. By "transparent" we mean *application-level* transparency: SC applications written against an SC library require zero source changes to use Osprey. SC library maintainers, however, must perform a small one-time port ($<$ 200 LoC in each library we tested, discussed in §3.2 and §9.7) to annotate memory allocations of CO data and computations over CO data. Osprey depends on these annotations for performance, not correctness, and it can bring substantial benefits even if the developer's annotations are not complete. Osprey uses speculative execution to predict an SC program's future memory accesses, and then uses those predictions to manage memory in the concrete execution, issuing `madvise` syscalls to prefetch and reclaim pages. We next describe four key challenges in realizing Osprey.

First, how and when should Osprey drop CO data during speculation? Prior speculation systems use complex heuristics to determine when to drop pages [17, §6.1]. We observe that Osprey can instead take a simple approach: it maps all virtual pages containing only CO data to a single physical page from the beginning, to avoid having to drop pages later. To do this, and to skip computations on CO data, we rely on changes/annotations in source code. However, these annotations can be confined to the *SC library* that defines the objects/classes for ciphertexts and provides functions to operate on them; this requires changing only a few lines of library code. The SC programs that *use* an SC library remain unmodified, making Osprey a transparent approach for legacy programs.

The second challenge is that each page may contain a mix of CO and non-CO data, preventing Osprey from being able to drop those pages when speculating. For example, pointers are *not* CO, so using `malloc` to allocate CO data mixes non-CO data (from `malloc`'s data structures) with CO data. To prevent mixing CO and non-CO data, Osprey uses a two-step solution. The first step is to use a dedicated section of its address space for CO data. The second step is to use a new kind of memory allocator that can allocate space in the CO region, while keeping the memory allocator's own pointer-rich data structures outside of the CO region. Non-CO data is duplicated between the speculative and concrete executions, so we design this memory allocator to have low memory overhead regardless of the allocation pattern.

Third, Osprey relies on the OS virtual memory system for flexibility (e.g., reacting to memory pressure, etc.), but this raises challenges for performance. Prior approaches achieve good performance via significant kernel changes—for example, by making policy decisions in the kernel [4] or modifying the page migration datapath [1]. However, we observe that most of the overhead of OS virtual memory comes from one operation: deciding which pages to reclaim from a process, for `cgroup` accounting. We remove this overhead by extending the `madvise` syscall with an option to reclaim specific pages. We also extend `userfaultfd` to support private anonymous segments. These simple, general-purpose extensions to Linux enable Osprey to run in user space with good performance.

Fourth, multithreaded applications are a special challenge, because the memory access patterns may differ between speculation and true execution. Furthermore, Osprey relies on page faults to trigger prefetching; multithreading complicates this because a different thread than intended may fault in a page. We address this problem with a novel use of Memory

[1] Osprey stands for "**O**blivious **S**peculation for **Pr**ogramming M**e**mor**y**."

Protection Keys (MPK) [21, 55]. We use MPKs to trigger page faults independently in each thread, so that each thread gets the same page faults regardless of the schedule.

We implemented Osprey in C++ and applied it to two SC protocol libraries: CKKS homomorphic encryption in SEAL [51] and garbled circuits in EMP-Toolkit [28]. We evaluated Osprey with 8 workloads. Osprey outperforms the operating system's virtual memory for all of the workloads, by up to 12× in the best case. For 7 workloads, Osprey performs comparably to or better than MAGE [28], the state-of-the-art SC-aware memory management system—but unlike MAGE, Osprey does not require developers to rewrite SC applications in a new DSL and is not limited to planning memory management in advance. For 6 workloads, Osprey performs within 60% of having enough memory to fit the entire computation. Osprey required changing less than 200 lines of code in each SC protocol library, and required no source code instrumentation in SC applications written against these libraries.

Our implementation of Osprey is available on GitHub at https://github.com/mpc-systems/osprey-project.

2 Background

2.1 Secure Computation

Secure Computation (SC) refers to techniques for computing on encrypted data. Below, we discuss two SC protocols that we use in our evaluation: *CKKS* and *garbled circuits*.

2.1.1 CKKS Homomorphic Encryption

CKKS [9] is a scheme for *Homomorphic Encryption (HE)*. A party can directly compute on HE ciphertexts to obtain an encrypted result, without ever decrypting the ciphertexts or having access to the decryption key. The input and output of the computation are both in ciphertext form (i.e., encrypted).

In the CKKS scheme, a ciphertext represents a vector of numbers. A party can compute element-wise addition and multiplication directly on the ciphertexts. The maximum depth in multiplications is limited by a *level* parameter chosen during key generation. Specifically, each ciphertext has a level, and each time a multiplication is performed, the result's level is one less than the operands' level (both operands must be the same level). Once the level reaches 0, no more multiplications can be performed. A procedure called *bootstrapping* can sidestep this limitation, but it is computationally expensive.

2.1.2 Garbled Circuits

Garbled circuits [61] are a protocol for Secure Multi-Party Computation (SMPC). SMPC enables multiple parties to compute a program over their private data and learn the result, without revealing each party's data to the others. To compute the function, the parties must communicate over the network.

Garbled circuits enable SMPC between *two* parties, called the *garbler* and the *evaluator*. The program to compute is represented as a circuit of AND and XOR gates. The garbler computes an encryption of the circuit, called the *garbled circuit*, and sends it to the evaluator. The evaluator obtains encrypted inputs of both parties, using a protocol called *oblivious transfer* for the garbler's input. The evaluator then executes each gate of the circuit—given the encryption of a gate, and the encrypted values of its input wires, the evaluator can compute the encrypted value of its output wire. In this way, they compute the encrypted values of all wires of the circuit. Then, they decrypt the output with the help of the garbler.

2.2 Memory Overhead

The memory overhead is a key factor that degrades the performance of SC protocols. Below, we discuss the memory demand in CKKS and garbled circuits.

For CKKS homomorphic encryption, the size of the ciphertext is determined by its level and the dimension of the vector. The higher the level, the larger the ciphertext, and the larger the dimension, the larger the ciphertext. For a vector with 8192 elements, the size of the ciphertext is around tens of kilobytes when the level is between 0 and 2.

For garbled circuits, the size of the garbled circuit is determined by the number of wires and gates in the circuit. While gates consume memory, they can be generated by the garbler and consumed by the evaluator in a streaming fashion, without ever all being materialized at once [22]. Additionally, only the wires that correspond to in-scope variables of the program being executed must be kept in memory; the values of out-of-scope or not-yet-computed wires may be discarded. Thus, the memory overhead of garbled circuits, for both garbler and evaluator, is dominated only by the program's variables that are live at any instant [27]. This can be large due to garbled circuits' large expansion factor; each bit of plaintext (i.e., a single wire) corresponds to a 128-bit ciphertext.

As we discuss in §10, prior work explores reducing the memory overhead of SC using approaches such as improving the cryptographic protocol, enhancing the SC framework, or finding ways to perform parts of the computation in plaintext. These techniques do not guarantee that memory will fit within a given limit. Memory programming and speculative execution (explained in §1) optimize performance given limited memory, and are complementary to the above approaches.

3 System Overview

Osprey is a memory management framework for SC workloads, with two goals. The first goal is to make virtual memory **efficient**, so that SC applications that do not fit in main memory can very efficiently page to an SSD. The second goal is to be **transparent to applications**, so that SC applications written against an SC library require no code changes

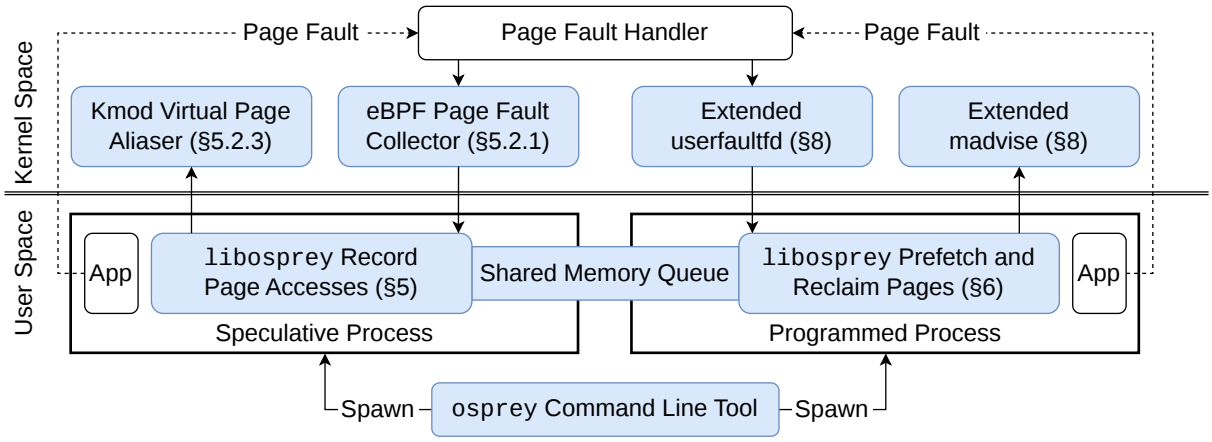

Figure 1: Osprey's system architecture. Osprey's components are marked blue.

to use Osprey. The SC library, however, must be annotated (i.e., lightly modified) to mark allocations of CO memory (e.g., ciphertexts) and computation on CO data (§3.2). These annotations enable Osprey's performance gains, but are not required for correctness; Osprey brings substantial performance benefits even with incomplete annotations (results in §9.7).

As shown in Fig. 1, Osprey executes an SC program as two concurrent user space processes. The first process executes a *speculative pass*, which transparently records the program's memory accesses; the second process executes a *programmed pass*, which uses the recorded memory accesses to manage memory. Both processes link against the same lightly ported SC library and use Osprey's *CO allocator* (§4) to place ciphertext data in a dedicated *CO region* of the virtual address space. Most of Osprey, including its core prefetching and speculation algorithms, lives in user space, within these two processes. To support these algorithms efficiently, Osprey also includes some extensions to the kernel. Osprey's kernel-side extensions comprise three components: (1) an eBPF program that forwards page-fault addresses to user space, (2) a very simple (124 LoC) kernel module that allows virtual pages to be efficiently aliased to the same physical page, and (3) general-purpose extensions to `userfaultfd` and `madvise`, which we anticipate could be mainlined.

3.1 Making Speculation Simple and Efficient

Naïvely running a speculative pass concurrently with the programmed pass would effectively double the program's memory usage and CPU usage. Osprey's main insight is to make the speculative pass very efficient, in both memory usage and CPU usage, by exploiting a property of SC called *content obliviousness (CO)*. CO is the property that overwriting ciphertext data with arbitrary bytes at runtime does not change the memory access pattern. We refer to memory that can be so altered without affecting the access pattern as *content-oblivious (CO) memory*. For example, ciphertext data is CO.

```
class Bit {
    __m128i bit; // ciphertext data (16 B)
};
class Integer {
    std::vector<Bit> bits;
};
```

Figure 2: Structure for an encrypted integer in EMP-Toolkit.

In the speculative pass, Osprey uses CO in two ways. First, Osprey maps all virtual pages containing ciphertext data to the same physical page. This eliminates most of the speculative pass's memory usage, because ciphertext data normally dominates memory usage (its expansion factor is the reason why SC programs are so memory-intensive). Second, Osprey skips computations on ciphertext data, instead recording their would-be memory accesses. This eliminates most of the speculative pass's CPU usage, because cryptographic routines for computing on the ciphertexts normally dominate CPU time. Crucially, CO means that these changes will not affect the access pattern recorded by the speculative pass.

3.2 Annotating SC Libraries

An important challenge in realizing Osprey is that not all of the memory in an SC program is CO. In particular, *any memory containing a pointer is not CO!* For example, stack memory is not CO, since the return addresses pushed to the stack constitute pointers and cannot be safely overwritten. As another example, SC libraries often provide "ciphertext" types to an application that contain metadata about the ciphertext, and a pointer to the actual ciphertext data allocated elsewhere. In Fig. 2, for example, the memory storing the `Bit` class is CO, because it directly contains ciphertext data. However, the memory backing an instance of the `Integer` class, which

```
// (a) Annotate CO Memory
class Integer {
  std::vector<Bit, COAllocator> bits;
};

// (b) Annotate Operations
Integer add(Integer a, Integer b) {
  Integer res;
  OSPREY_TOUCH(a, b, res);
  ...
  return res;
}
```

Figure 3: An example porting EMP-Toolkit to Osprey.

represents an encrypted integer, is not CO, because its memory contains (within the `std::vector` instance) the length of the integer in bits and a pointer to the actual ciphertext data, and changing these fields would affect the memory access pattern.

Osprey relies on annotations in the SC library to identify CO memory. Concretely, Osprey provides a memory allocator for CO memory that allocates all CO memory in a dedicated region of the virtual address space called the *CO region*. The SC library should use Osprey's CO memory allocator for ciphertext data. This is designed not to require modifications to the SC application, only to the type declarations in the SC library. In Fig. 3(a), for example, the only required change is to pass Osprey's `COAllocator` as the allocator template argument to the `std::vector` that holds an `Integer`'s bits. After this one-line change, the `Bit` elements stored in any `Integer`—no matter how the application constructs or uses it—reside in the CO region. The `Bit` class itself is unchanged.

Osprey reduces CPU overhead of speculation by skipping computations on CO memory. To enable this, we designed a one-line annotation API, `OSPREY_TOUCH` (Fig. 3(b)). In the programmed pass, `OSPREY_TOUCH` does nothing, but in the speculative pass it does the following: it (1) touches the memory region provided as an argument, and then (2) returns from the calling function. The idea is that by placing a call to `OSPREY_TOUCH` at the start of a function that implements a cryptographic operation, one skips the computation when speculating and simply records which memory the operation would have touched. It is not mandatory to use `OSPREY_TOUCH`, but more complete `OSPREY_TOUCH` annotations generally lead to greater CPU savings during speculation. We optimize this process further in §5.2.2.

Any non-CO memory, and computations on non-CO memory, are duplicated between the speculative and programmed passes. For SC programs, where ciphertexts dominate memory usage (due to their expansion factor) and cryptographic operations dominate CPU usage, this duplication is a tiny cost compared to running the SC program.

3.3 Transparent Interface

Osprey is implemented as two components: `osprey`, a command-line tool, and `libosprey`, a runtime library. Osprey-enabled SC libraries must be linked with `libosprey`, which makes Osprey's annotation APIs available to the SC library developer and adds a runtime component (e.g., threads) to execute Osprey's logic in the speculative and programmed passes. The `osprey` command-line tool is a frontend, allowing applications to be invoked as `osprey ./a.out`. It spawns the speculative and programmed passes as child processes, and it sets up a shared-memory buffer to transfer predicted memory accesses from the speculative pass to the programmed pass.

Osprey requires the source code of the SC library—but not the SC application that uses it—to be annotated, by way of calls into `libosprey`. Osprey is designed to make these annotations as minor and lightweight as possible (i.e., requiring very few changes to the SC library source code).

3.4 Comparison with Prior Approaches

Prior work on memory programming, like Osprey, predicts future memory accesses and exploits the obliviousness of SC. In this sense, Osprey combines ideas from both speculative execution and memory programming—it may be considered "speculative memory programming." However, by leveraging CO, Osprey overcomes the shortcomings of both approaches.

The state-of-the-art speculative execution system for memory management [17] can misspeculate, hurting performance and requiring complex in-kernel support (e.g., checkpointing or re-forking). In contrast, Osprey leverages CO in a way that ensures that the speculative pass will never misspeculate, improving performance and avoiding complexity.

The state-of-the-art memory programming system, MAGE [28], exploits only the weaker notion of *input obliviousness (IO)*—the property that changing an SC program's inputs does not change the program's memory access pattern. This leads to three shortcomings: (1) MAGE requires SC applications to be rewritten in a DSL, (2) MAGE requires SC libraries to be rewritten to work with MAGE's backend, and (3) MAGE's planner materializes a memory management plan in a file that is concretely very large, and proportional in length to the program's execution time. By exploiting CO and not merely IO, Osprey addresses all three shortcomings: (1) it avoids changes to SC applications, (2) it requires only minor annotations to SC libraries, and (3) the speculative pass runs "on the fly," concurrently with the programmed pass, so no "plan" must be materialized.

4 Content-Oblivious Memory Allocator

In Osprey, we design a new memory allocator that is suitable for allocating memory in the CO region. We refer to it as the "CO allocator." The CO allocator keeps *all* of its data

structures in regular memory. The reason for this is that a memory allocator's structures (pointers, bitmaps, etc.) are not CO and therefore cannot be kept in the CO region.

Existing memory allocators are unsuitable for allocating CO memory because they place their own pointer-rich data structures in or next to the blocks that they allocate. Hoard [3], `tcmalloc`, and `mimalloc` use linked lists for each allocation size, storing a pointer—which is not CO—on each free block. `jemalloc` [15], which uses a bitmap instead of a list, is a step in the right direction, as the bitmap is not mixed with the data. But `jemalloc` still relies on the metadata and data for each run[2] being nearby in the address space, to easily find the metadata for a data block (e.g., when `free`'ing it).

For Osprey's memory allocator, we use a slab allocator design, to minimize the space overhead of our allocator. Unlike existing slab allocators, we store slab data in the CO region, but slab metadata in regular memory. Whereas prior allocators depend on the data and metadata being nearby (e.g., adjacent) in the address space, our design requires a way to "link" the two. To get from the metadata for a slab to its data, we can simply include a pointer in the metadata. However, getting from a slab's data to its metadata—necessary to `free` an object—is tricky, as we cannot place a pointer in CO memory.

A simple way to map from slab data to slab metadata is to create a hash table in regular memory for this purpose. An early version of Osprey did this, but we found that it measurably impacted performance. Therefore, Osprey uses an array-based mapping instead. We treat the CO region as an array of slabs, and keep a parallel array in regular memory that stores, for each slab, a pointer (8 B) to its corresponding slab metadata (or `nullptr` if unallocated). We set the slab size to 2 MiB and the CO region to 1 TiB; for these parameters, our array-based mapping is only 4 MiB, which is negligible compared to the actual data of an SC application.

5 Speculative Pass

5.1 Collecting Memory Accesses

To collect memory accesses, a straightforward solution is binary instrumentation [33]: inserting instructions around each memory access instruction to record the address. This strawman is known to be very inefficient and produces memory access traces that are impractically large [4, 28].

For Osprey's purpose, memory management, it is sufficient to collect a more coarse-grained access trace, at page granularity. To achieve this goal, we rely on page faults to detect accesses to new pages so their addresses can be recorded [4,6]. The lazy allocation strategy used by kernels like Linux ensures that a page fault is triggered on the first access to each page, giving Osprey a chance to record its address. This can be achieved without modifying the target program.

[2] A "run" is the slab-like structure in `jemalloc`.

So far, this approach records only the first access to each page. To address this, we limit the number of pages that can be mapped simultaneously, by unmapping pages that were mapped in on prior page faults. This causes subsequent accesses to those pages to trigger page faults, allowing us to detect and record subsequent accesses to those pages. Allowing few pages to be mapped at a time allows for a more precise trace, at the cost of making the tracer bigger and longer to collect. Allowing many mapped pages makes the trace shorter and faster to collect, but makes it less precise.

Multiple solutions have been proposed for choosing which pages to unmap in this scheme, including FIFO [6]. Osprey defaults to the *microset* strategy from 3PO [4], which unmaps *all* mapped pages once the number of mapped pages reaches a threshold; we call that threshold the *window size*. We use this strategy because it allows the access trace to be interpreted as a sequence of working sets of the program.

5.2 Making Collection Efficient

3PO uses a similar page-fault-based approach to trace collection, but implements it entirely in the kernel for efficiency and performs it during a preparation/planning phase where performance is not critical. We now contribute techniques to perform trace collection without significant changes to the kernel source, and to make trace collection efficient enough to be run alongside the program's main execution.

5.2.1 Avoiding Kernel Source Changes

An intuitive solution is to use *userfaultfd* [62], a Linux feature that allows an application to register a custom page fault handler in user space. However, this approach adds overhead to each page fault, requiring additional user-kernel mode switches and thread scheduling operations.

Instead, our approach is to inject minimal logic into the kernel using eBPF, hooking into a pre-handler in the page fault handler. When a page fault occurs, Osprey's eBPF module writes the address and relevant error information into a ring buffer shared between kernel space and user space. In user space, a separate thread asynchronously reads page fault addresses and metadata from the ring buffer, and performs the remaining parts of the collection logic as described in §5.1. This hybrid approach balances performance with flexibility, avoiding kernel source changes while achieving faster performance than `userfaultfd`.

5.2.2 Accelerating Collection with `OSPREY_TOUCH`

We use `OSPREY_TOUCH` (§3.2) to not only skip the cryptographic computations, but also accelerate trace collection. Annotating the data touched by cryptographic operations with `OSPREY_TOUCH` completely bypasses the faulting mechanism and explicitly provides the tracing algorithm with the addresses that would have been accessed.

Note that Osprey collects memory accesses using eBPF and `OSPREY_TOUCH` at the same time. To maintain their order, it timestamps each access when it is recorded and then uses these timestamps to correctly order them during aggregation.

5.2.3 Aliasing Memory Efficiently

As described in §3.1, Osprey maps all content-oblivious memory to a single physical page in the speculative pass. The most straightforward approach is to create a 4 KiB in-memory file and repeatedly use the `mmap` system call to map each virtual page to this file. However, each such mapping creates a separate Virtual Memory Area (VMA) in the Linux kernel. An excessive number of VMAs leads to two major issues: 1. Increased overhead for the kernel to search VMAs, which are organized as a red-black tree. 2. Unnecessary memory overhead from maintaining metadata for each VMA.

Our solution is to implement a simple (124 LoC) kernel module providing a virtual device, `/dev/aliased`. In the speculative pass, Osprey creates the CO region by using `open` and `mmap` on `/dev/aliased`. In our kernel module, we implement a custom `mmap` handler for this device, so that the memory region produced by `mmap` (i.e., the CO region) has all virtual pages mapped to a single 4 KiB physical page, while using only a single VMA for the whole region.

5.3 Isolating Side Effects

For speculation, isolation of side effects is just as critical as performance optimization. In particular, interactions with external systems—such as disk and network I/O—must be isolated during speculative execution.

For disk isolation, we utilize `overlayfs` to achieve transparent separation. By creating a read-only mapping of the existing working directory, the program under speculative execution observes a file system view identical to that of normal execution. Any modifications to existing files or creation of new files are transparently redirected to newly created files in the upper layer of the overlay. With the help of `overlayfs`, we achieve seamless and effective disk isolation.

For SMPC protocols (e.g., garbled circuits; see §2.1.2), it is also necessary to isolate the network interactions of the speculative pass. We observe that SMPC typically only involves network communication in the following scenarios: (1) during initialization, to establish network connections; (2) during teardown, to disconnect from the network; and (3) during arithmetic or boolean operations on ciphertexts, which involve data exchange over the network.

For the first two cases, we achieve isolation with minimal changes by inserting `OSPREY_TOUCH` without providing address ranges to bypass the network connection setup and teardown phases. For the third case, since `OSPREY_TOUCH` is already present in the computation logic—as described in §5.2.2—and inherently includes the ability to skip operations, it naturally avoids triggering this type of network interaction. Through our APIs, we provide a lightweight and minimally invasive mechanism for achieving complete network isolation during speculative execution.

6 Programmed Pass

6.1 Page-Fault-Based Synchronization

In the programmed pass, the *memory programmer* is responsible for processing the memory access sequence streamed from the speculative pass, in order to prefetch and evict pages. To do so, the memory programmer must keep track of the program's execution position within the memory access sequence. This is crucial so that Osprey can prefetch each page in the future memory access sequence at the right time.

Inspired by 3PO [4], we use a mechanism based on page faults to synchronize memory access processing and program execution. In short, we periodically select a **key page** every fixed-size batch of memory accesses along the predicted memory access sequence. We ensure that, once a key page is selected, the next access to that page triggers a page fault. 3PO ensured this property by always selecting, as the key page, a page that is not currently mapped in the page table. In Osprey, our approach is instead to first select a key page, and then alter its page table entry so that a page fault occurs the next time it is accessed; we explain this mechanism in §7.3. When a page fault is triggered, the memory programmer can accurately determine the current execution position within the memory access sequence (i.e., the execution position is at the chosen key page). Based on this position, it prefetches the next batch of pages along the memory access sequence and designates the next key page. This repeats on each key page, giving the memory programmer a chance to periodically execute at known positions along the memory access sequence, until the entire memory access sequence is processed.

Whereas 3PO places its prefetcher entirely in the kernel, we use `userfaultfd` to implement the memory programming logic purely in user space. When a page fault occurs, it is captured by `userfaultfd`, giving the memory programmer in user space a chance to run. We contribute an eviction codepath and the requisite user/kernel APIs so that the memory programmer can efficiently prefetch and evict pages.

6.2 Asynchronous Swapping Mechanism

The batching optimization described above reduces user-kernel mode switches, but does not mask disk I/O. To deliver satisfactory performance, the missing piece is **asynchrony**.

To this end, we carefully design the logic for handling a batch of memory accesses as two decoupled steps: (1) **Issuing I/O requests** to asynchronously load the pages corresponding to the memory access sequence from disk into memory. (2)

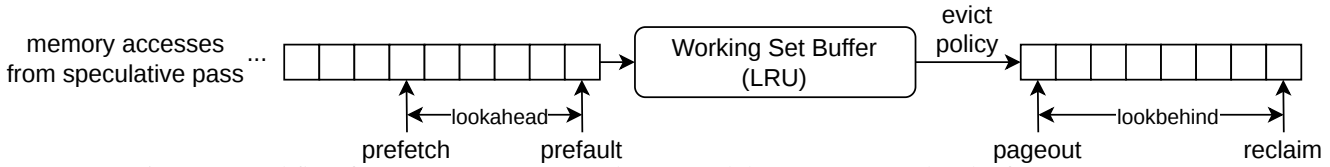

Figure 4: Workflow for Osprey's programmed pass. Each box represents a batch of memory accesses.

Waiting for completion of the I/O requests, ensuring the pages are fully loaded into memory and ready for access.

The time gap (in batches) between Step 1 and Step 2 is controlled by a tunable parameter called **lookahead**. By appropriately setting the lookahead value, we can ensure that memory pages are prefetched and ready by the time they are needed by the program—thus achieving a nearly wait-free memory swap-in mechanism.

While the above supports prefetching pages into memory, we still need a swap-out strategy to complement it. Initially, we tried relying on `cgroup`s to limit memory usage, relying on OS mechanisms to swap out pages. Unfortunately, this resulted in poor performance due to the swap-out mechanism in the kernel: on every kernel-to-user transition, the system checks the `cgroup`'s configured memory limits, and when the limit is exceeded, it synchronously selects and then swaps out pages. This takes significant time and ultimately becomes a performance bottleneck.

To address this, and to complement our asynchronous swap-in mechanism, we implement a *fully asynchronous swap-out mechanism* as well. This process consists of two steps: (1) Issuing disk I/O requests to begin swapping out a batch of memory pages. (2) Polling for completion to ensure the pages are safely backed up to disk, after which they are unmapped from the virtual address space. The time gap (in batches) between Step 1 and Step 2 is controlled by a tunable parameter called **lookbehind**.

6.3 Swap-Out Policy Design

Osprey's speculation approach provides only a limited window of future accesses, precluding MAGE's approach of using Belady's algorithm. Different swap-out policies have only limited impact on overall performance. We therefore implement a simple, intuitive, and lightweight strategy that is well-suited to our system design. Our policy addresses two key questions:

- **When** should the system begin swapping out?
- **Which** pages should be selected to be swapped out?

6.3.1 When to Swap Out

Inspired by Linux `cgroup`s, we define three memory thresholds to control swap-out behavior:

- `mem-limit-low` ("low watermark"): Indicates low memory pressure. No swap-out operations are triggered.
- `mem-limit-high` ("high watermark"): Memory usage has reached a high watermark. The system begins asynchronous swap-out operations to reduce usage to the low watermark.
- `mem-limit-max` ("maximum watermark"): Memory usage has reached the maximum allowable limit. The system halts speculative execution (stop-the-world) and immediately evicts all *content-oblivious* memory pages.

6.3.2 Which Pages to Swap Out

Our page selection strategy is guided by two eligibility conditions: First, the page must have resided in memory for at least a certain amount of time. This duration is controlled by the parameter `execnow`. Second, the page must be known to not be accessed again in the near future, based on the window of future accesses. Among the candidate pages satisfying the above conditions, we apply the following eviction priorities:

- **Priority 1:** Prefer evicting pages that are likely to be non-dirty, based on read/write information provided by the speculative pass. Evicting non-dirty pages does not require disk writes, so their eviction incurs less overhead.
- **Priority 2:** Among remaining pages, select those that have stayed in memory the longest since being swapped in—this follows an LRU-like strategy.

This policy enables efficient and controlled swap-out while minimizing interference with program execution.

7 Multithreaded Applications

Because SC applications must have CO access patterns, it is generally possible to write them in such a way that each thread operates on a fixed, predetermined partition of the input data, in order to avoid most multithreading issues. Prior work [28] leveraged this fact, and this property holds in our evaluation.

Still, the partitions assigned to the threads may partially overlap. For example, when parallelizing a matrix-vector multiplication, the matrix may be split among the threads, but the vector is shared (i.e., the vector is in every thread's partition). Therefore, we design support for multithreaded SC applications that can work even if threads share data.

7.1 CO Allocator with Multithreading

We provide each thread with its own CO region for its allocations and its own CO allocator. This ensures that, although different executions may interleave the threads' allocations differently, they will still have the same memory layout. We separately collect the memory access trace for each thread in

the speculative pass, and run a separate instance of the memory programmer per thread in the programmed pass. This "one trace per thread" design helps eliminate scheduling-induced nondeterminism and synchronization overhead.

7.2 Speculative Pass with Multithreading

Thread scheduling nondeterminism impacts the page-fault-based memory access collection and the memory programming strategy. We illustrate this with two concrete scenarios:

Scenario 1: Fault Skipping. Suppose two threads access a shared data segment sequentially. The first thread accesses the data and triggers a `page fault`. When the second thread accesses the same data later, no fault will be triggered. This results in incomplete memory access logs during the speculative phase. A high degree of such omissions significantly degrades the performance of the memory programmer.

Scenario 2: Out-of-Order Access. Assume thread 1 and thread 2 access memory regions A and B respectively. During speculative execution, the collected memory access sequence is $[A,B]$. However, due to nondeterministic scheduling during actual execution, thread 2 may run ahead and access region B before thread 1 accesses region A, resulting in the real access sequence $[B,A]$. The memory programmer, still operating under the assumption of the $[A,B]$ sequence, designates key page 1 in region A and key page 2 in region B. When key page 1 triggers a page fault, it swaps in region B next, expecting key page 2 to be the next fault trigger. However, since region B has already been accessed, no fault occurs. This breaks the synchronization between the memory programmer and the actual program execution.

A simple solution, as employed by prior work [4], is to bind all threads to a single CPU core when collecting the access trace, effectively serializing the multithreaded execution. While this approach guarantees determinism, it imposes a severe performance penalty—particularly unacceptable for Osprey, where the speculative pass occurs at runtime.

Instead, two of Osprey's key design choices enable Osprey to sidestep these challenges and run the threads in the speculative pass on separate cores. First, because the `OSPREY_TOUCH` APIs enable collecting the memory access trace without triggering page faults, it decouples the memory access trace from thread scheduling. Thus, if the SC library is fully annotated with `OSPREY_TOUCH` APIs, a fully deterministic memory access sequence can be collected for each thread. Second, because we use a separate trace for each thread, the threads' memory access patterns are processed separately regardless of their interleaving.

7.3 Programmed Pass with Multithreading

As explained in §6.1, in the programmed pass, Osprey uses page faults on key pages for synchronization purposes. Therefore, it is essential that, once a key page is selected, the next access to that page triggers a page fault. The multithreaded setting makes this significantly more challenging to achieve. Below, we first describe how we achieve this in the single-threaded setting, and then discuss the additional challenges due to multithreading and our approach to overcoming them.

7.3.1 Single-Threaded Setting

After selecting a key page, a natural approach is to use `madvise` to ask the kernel to unmap the page. Unfortunately, this approach does not work reliably—the kernel may not immediately take the advice. To address this, our approach for the single-threaded setting is instead to use `mprotect` to set page permissions to `PROT_NONE`. This strategy is attractive because it is lightweight, deterministic, and synchronous.

7.3.2 Multithreaded Setting

In the multithreaded setting, additional nondeterminism arises from interleaving of threads. Osprey's prefetcher must remain synchronized with each thread. But page faults, which Osprey uses for synchronization, occur at a per-process level—a page fault on a given page fires at most once (until the page is evicted again), regardless of which thread caused it.

As a concrete example, consider matrix-vector multiplication, in which the matrix is partitioned row-wise across threads but the vector is shared by all threads. Suppose the memory programmer for thread A picks a page backing the shared vector as A's next key page, and evicts that page so A's upcoming access will fault. If another thread B accesses the page first—a likely event, since every thread also scans the vector—the access faults and `userfaultfd` delivers it to the handler. But this fault belongs to B, not A: the handler sees an unexpected access and simply maps the page in. When thread A later reaches the page, the access no longer faults (the page is already resident), so A's expected key-page fault never arrives, and the memory programmer for A loses synchronization for the remainder of the run.

The root cause of this issue is that all of the threads share the same page table, so that a page fault that occurs in one thread prevents page faults on that page from occurring in other threads. In principle, this could be solved by changing the kernel to have a separate page table for each thread, but this would be a complex and serious change.

Instead, we observe that we can get the intended effect entirely in user space by using Intel Memory Protection Keys (MPKs) in a novel way. Our use of MPKs solves all three issues, producing a robust solution for Osprey to support multithreaded applications. The idea is to trigger page faults using the MPK bits in the page table entry. Each thread is assigned an MPK ID, and a page can be marked as the "key page" for a thread in such a way that *only* that thread would get a page fault on that page. If another thread were to page fault on a thread's key page and map it into the address space,

the MPK field would still guarantee that the intended thread will get a page fault when accessing it.

This MPK-based approach (i.e., using `pkey_mprotect` instead of `mprotect`) brings efficiency advantages, and our Osprey implementation uses it even in the single-threaded case.

8 Kernel Modifications

To support efficient and reliable memory programming, we implemented several new APIs and kernel-level extensions based on Linux 5.15.0. These extensions fill critical functionality gaps in the existing Linux kernel interface and significantly broaden the applicability of our system.

- **New `madvise` Flag: `MADV_RECLAIM`**
  We introduced a new `madvise` operation, `MADV_RECLAIM`, which synchronously writes the specified pages to the swap space and removes their mapping from memory.
- **Extending `userfaultfd`: `PRIVATE_ANON` Memory**
  The Linux kernel's `userfaultfd` interface has traditionally only supported monitoring both minor and major page faults for `SHARED_ANON` memory regions. However, writebacks on `SHARED` memory pages are conservative and always trigger I/O regardless of dirtiness, due to ambiguity introduced by multiple PTEs. We extended `userfaultfd` to support `PRIVATE_ANON` memory as well, enabling precise and efficient tracking of faults without unnecessary disk I/O.
- **Extending `userfaultfd`: Handling Access Violations**
  Accessing pages marked as `PROT_NONE` using `mprotect` results in access violation faults (`SEGV_ACCERR`). The original Linux `userfaultfd` interface does not forward such faults to user space for handling, breaking the ability to programmatically respond to controlled faults used in our key page strategy. We extended `userfaultfd` to intercept and forward access errors caused by protection violations, enabling full support for page-fault-driven progress tracking.

These kernel modifications support our design goals while being general enough to be potentially mainlined.

9 Evaluation

9.1 SC Protocols

We evaluate Osprey using two types of SC: homomorphic encryption (HE) and SMPC. For HE, we use CKKS [9] as implemented in the Microsoft SEAL library [51]. For SMPC, we focus on Yao's Garbled Circuits [61] with the HalfGates optimization [64], provided by EMP-Toolkit [60].

9.2 Workloads

For evaluation, we use workloads representing data-intensive "kernels" that could be part of larger SC applications, like data analytics or ML/linear algebra applications. Using the same workloads as MAGE allows for a convenient comparison of MAGE and Osprey. To use them with Osprey, we re-implemented them to directly use the SC libraries instead of using MAGE's DSL; in cases where the SC libraries supported slightly different primitive operations, we sometimes modified the implementations of the MAGE workloads to keep the computational work similar between the two.

For CKKS (SEAL), we use the following workloads:

- **Sum**: *Sum a list of numbers and store it as a new ciphertext.*
- **Statistics**: *Calculate the mean and the variance of a list of numbers and store it in two new ciphertexts.*
- **Matrix-vector multiply**: *Multiply a matrix with a vector and store the result in a new vector.*
- **Tiled matrix multiply**: *Matrix multiply with manual tiling optimizations.*

CKKS ciphertexts can encrypt vectors of numbers and operate on them in a SIMD fashion. In Osprey, we treat each ciphertext as a single element, so that our workloads could be applied to many instances of each problem (one per slot in the vector) without additional overhead. While techniques exist to use the vectorized nature of these protocols to accelerate a single problem instance, they are out of scope for our study.

For garbled circuits (EMP-Toolkit), we use the workloads:

- **Merge sorted**: *Merge two sorted lists into a larger list.*
- **Full sort**: *Sort a list in place.*
- **Loop join**: *Join two tables into a larger table.*
- **Matrix-vector multiply**: *Multiply a matrix with a vector and store the result in a new vector.*

We do not include the **binfclayer** workload from MAGE [28]. The reason is that **binfclayer** calls the SC library at a very fine granularity (e.g., processing one bit at a time), calling `OSPREY_TOUCH` very frequently. Though the final access trace is small, the speculative pass takes a long time, even longer than the programmed pass. The programmed pass still achieves good performance for this workload (e.g., if the speculative pass is run separately in advance).

9.3 Empirical Methodology

We compare Osprey's performance to three baselines:

1. *Unbounded.* We run the original program with enough memory to fit the whole program, without any `cgroup`. This gives a lower bound on the program's runtime.
2. *OS Swapping.* We run the program with a `cgroup` that limits the available memory, resulting in OS swapping. This is an upper bound on time that Osprey should beat.
3. *MAGE.* We use MAGE, which plans paging in advance, to execute a version of the program written in MAGE's DSL.

Since MAGE performs its planning in advance, whereas Osprey performs paging on the fly, we expect MAGE to, in general, outperform Osprey. Note that our measurements for Unbounded and OS Swapping are not comparable to those presented in MAGE's evaluation [28, §8] because we use a program written directly against the SC library for these base-

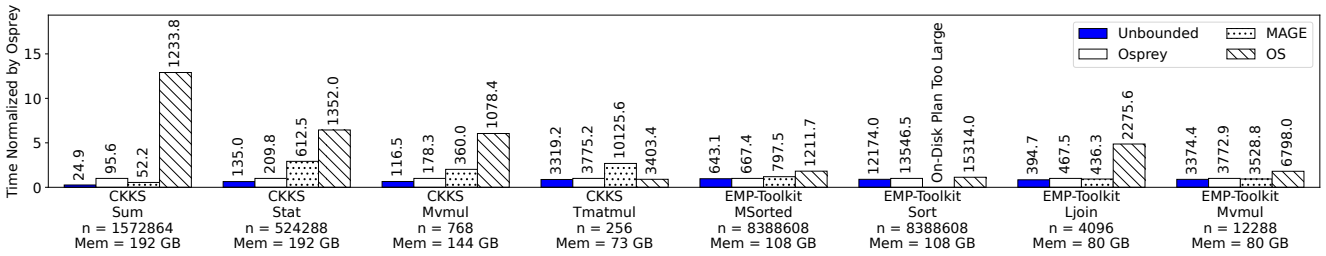

Figure 5: Performance of Unbounded, OS Swapping, MAGE, and Osprey, normalized by the time for Osprey. Each x-axis label gives the protocol, workload name, problem size n, and the workload's approximate unbounded memory consumption (e.g., *CKKS, Sum, n = 1572864, Mem = 192 GB*); under the bounded configurations, all workloads are capped at 32 GB (Table 1).

Parameter	Value
low watermark	24 GB
high watermark	28 GB
maximum watermark	32 GB
lookahead	4 batches
lookbehind	2 batches
workingset	2 batches
batch size	131072 per thread
window size	32768 per thread

Table 1: Configuration for Osprey in our evaluation.

lines. In contrast, MAGE's evaluation, for these baselines, uses MAGE's own interpreter to run the SC protocols, to normalize for differences in performance between MAGE's protocol backend and SC libraries [28, §8.3]. As a result, MAGE's "Unbounded" and "OS" baselines incur additional costs that our baselines do not, like serialization/deserialization costs for SEAL ciphertexts (explained in §9.4).

We ran experiments on rack servers with INTEL(R) XEON(R) GOLD 5520+ @ 2.20 GHz in an 8×32 GB @ 4800 MT/s memory configuration. We configured swap space on a 4 TB Micron 7450 PRO SSD, with theoretical read and write speeds of 6800 MB/s and 5300 MB/s, respectively. For SMPC workloads, we run the two parties on two servers connected via a direct bidirectional 200 Gbit/s link, using the Linux network stack; our actual network bandwidth usage was much less, likely $\approx$ 10 Gbit/s or less. While SMPC is often run with a wide-area network, previous experiments [28, §8.7 and §8.8] using MAGE suggest that, with appropriate TCP tuning, a wide-area network is not a significant performance bottleneck for HalfGates compared to a local network like we used in our experiments.

Across all experiments, Osprey uses the same set of configurations, shown in Table 1. All runtimes reported in this section are end-to-end and include Osprey's warm-up: spawning the speculative and programmed passes as child processes, attaching the eBPF page-fault pre-handler, initializing the custom kernel module that backs the CO region, allocating the shared-memory access-trace ring buffer, and filling the first batch of the trace before the programmed pass begins prefetching. Warm-up is a fixed, one-time cost: it does not grow with workload size and therefore is amortized over longer runs.

We do not run Osprey in a `cgroup`, since we observed that the OS would swap out pages even though Osprey stays within the limit. Instead, we rely on Osprey's own internal mechanisms (low watermark, high watermark, etc.) to bound its memory usage; to check that the memory usage is as intended, we poll the RSS inside Osprey, and also check memory usage externally using `htop`. For the other configurations—Unbounded, OS, and MAGE—we limited memory to 32 GB.

9.4 Performance Comparison

We compare performance across our workloads in Fig. 5.

Osprey consistently improves performance compared to OS and is often competitive with Unbounded. For many workloads it provides nearly the same performance as Unbounded while using a fraction of the memory. For workloads that are less compute-intensive, like the Sum and Stat workloads with SEAL, Osprey outperforms OS by up to 12×.

For CKKS/SEAL workloads, MAGE performs worse than Osprey in most workloads. This is because MAGE's CKKS backend requires each SEAL ciphertext to be serialized and deserialized on each operation, adding computational overhead [28, §7.4 and §8.3]. For the tiled matrix multiplication workload, for example, this serialization/deserialization in MAGE's backend accounts for $\approx$ 40% of the overall runtime. In contrast, Osprey and OS can work with programs that are directly written against the SEAL library, and therefore do not have these overheads. The only workload where MAGE outperforms Osprey is the Sum workload. The reason for this is that this workload is so memory-intensive that the overhead from `madvise` dominates the total runtime. MAGE avoids this cost because its memory management happens entirely in user space via async I/O operations, bypassing the kernel's virtual memory system.

For EMP-Toolkit workloads, MAGE uses its own re-

implemented version of EMP-Toolkit to remove overheads caused by memory-irrelevant inefficiencies, such as frequent virtual function calls through a vTable and a small network buffer that underutilizes available throughput. We applied the same optimizations used by MAGE to the baseline EMP-Toolkit so that their unbounded performance becomes comparable (within 5% across the evaluated workloads). Under memory constraints, the performance difference between Osprey and MAGE remains below 10%. This at-most 10% gap provides an upper bound on the overhead introduced by Osprey's use of a suboptimal eviction policy. In particular, unlike MAGE, which plans offline with full knowledge of the entire memory access trace and can apply Belady's algorithm, Osprey must make decisions online and only sees a limited window of future accesses.

The performance of the matrix multiplication workload is dependent on the tiling optimization. Without tiling, Osprey performs worse than OS. The reason is that Osprey's speculative pass produces much more output for a naïvely written matrix multiplication, as the microset strategy for compressing the output is far less effective; this causes the programmed pass to spend extra time prefetching pages already in memory. Even so, the performance degradation is small, within 2× of the tiled case (and still better than MAGE).

9.5 End-to-End Applications

The workloads above are data-intensive kernels; we now turn to end-to-end SC applications drawn from prior work [2, 28, 44, 59]: password reuse detection ("pwd") and comorbidity analysis ("com"). The password reuse detection workload uses EMP-Toolkit's HalfGates implementation to check, in two-party SMPC, whether any of the n users in one party's dataset appears with a matching password hash in the other party's dataset. Each dataset contains user IDs and password hashes. We use $n = 8388608$ (2^{23}), for which the workload's unbounded memory footprint is approximately 163 GB. The comorbidity analysis workload checks whether patients in a cohort with a specified diagnosis also jointly have other diagnoses. It takes as input a cohort table containing the patients with the given diagnosis and a diagnosis table containing diagnosis records for all patients. The task is to join the cohort patients with the diagnosis table, count the occurrences of each diagnosis among the cohort, and return the top-10 most common diagnoses. We use $n = 32768 \times 1000$: the cohort table contains 32768 rows, and the diagnosis table is 1000× larger. The workload's unbounded memory footprint is approximately 91.9 GB. All bounded configurations are capped at 32 GB (Table 1). Fig. 6 reports end-to-end runtime.

For password reuse detection, Osprey achieves near-unbounded performance under the memory cap. For comorbidity analysis, Osprey substantially outperforms OS because the workload has a highly structured, phase-by-phase memory access pattern. The first phase linearly scans patient IDs; the second phase performs a bitonic sort on the valid bit; and from the third phase onward, the computation primarily focuses on the leading n rows of the large table. Without application-level hints, the OS replacement policy preserves data that is not accessed again in the future. Osprey identifies the phase structure and preserves the useful working set, thereby achieving performance close to the unbounded configuration.

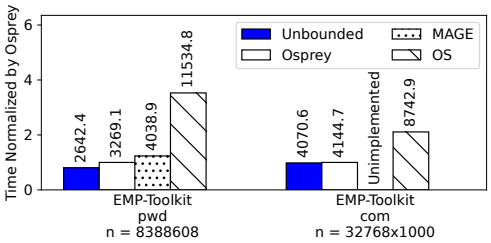

Figure 6: SC applications' end-to-end runtime.

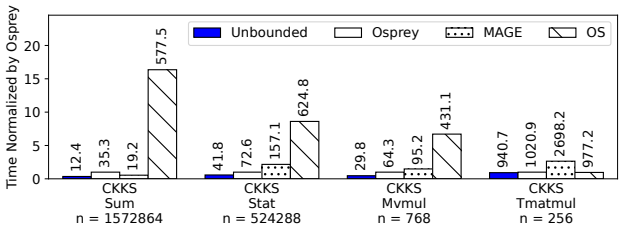

Figure 7: Multithreaded performance with four threads.

9.6 Impact of Parallelism

To evaluate Osprey's support for multithreaded programs, we focus only on SEAL. The reason is that, whereas SEAL allows applications to use HE from multiple threads, the EMP-Toolkit framework only supports single-threaded applications.

Fig. 7 shows the results using four threads. Fig. 8 shows the results as we vary the number of threads for the matrix-vector multiply and tiled matrix multiply workloads.

The performance gap between OS Swapping and Osprey grows under multithreading, reaching up to 16×, because OS Swapping is bottlenecked by I/O latency. Osprey avoids this bottleneck through prefetching.

For matrix-vector multiply, Osprey scales linearly with the number of threads and consistently outperforms both MAGE and OS Swapping. For matrix-matrix multiply, Osprey is slightly slower than OS Swapping when using 1, 2, or 4 threads because the workload is highly compute-intensive. However, when the thread count increases to 8, Osprey becomes faster than OS Swapping. As compute resources grow, the bottleneck shifts from computation to memory, a scenario that Osprey handles more efficiently.

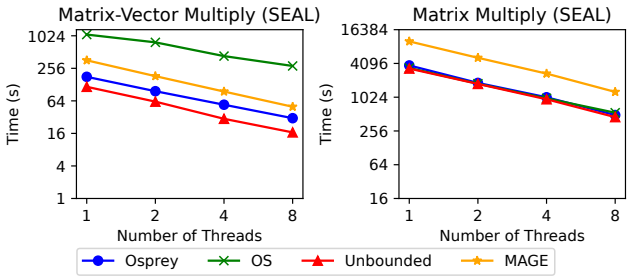

Figure 8: Multithreaded performance.

SC Library	Minimal	Recommended	Total Library LoC
SEAL	96	143	69211
EMP-Toolkit	7	106	9207

Table 2: Lines of code changed for Osprey.

9.7 Source Code Modifications to SC Library

With Osprey, we aim to require no source code changes to SC applications, and minimal changes to SC libraries. We count the lines of code we changed using `git diff --stat` and show the results in Table 2. The "Minimal" column shows the number of lines changed to use Osprey's CO memory allocator and isolate side effects in the speculative pass. The "Recommended" column includes both the "Minimal" changes and `OSPREY_TOUCH` annotations in the cryptographic routines to get the best performance. Overall, Osprey requires changing only a few lines of code in each SC library, compared to the total size of these libraries ("Total Library LoC").

In contrast, MAGE requires developers to rewrite the application in a special DSL. MAGE also requires integrating new SC libraries via implementing new protocol drivers, which can add significant overheads (e.g., serialization costs described in §9.4) or require significant rewriting effort.

9.8 Benefits of Data Annotations

Fig. 9 shows the performance difference between the two levels of Osprey integration in SC libraries explained in §9.7: "Minimal" (using CO memory allocator and isolating side effects in the speculative pass) and "Recommended" (using the `OSPREY_TOUCH` API, in addition to the "Minimal" changes). We evaluate both CKKS and EMP-Toolkit using the single-threaded matrix-vector multiplication workload.

From the "Calculation Time" graph, we see that "Minimal" and "Recommended" integration lead to almost identical runtime performance. This result shows that it is very easy to adopt Osprey in an SC library when the main goal is simply to preserve performance.

"CPU Usage per Thread" represents the average CPU consumption of each thread in an SC workload. Since Osprey

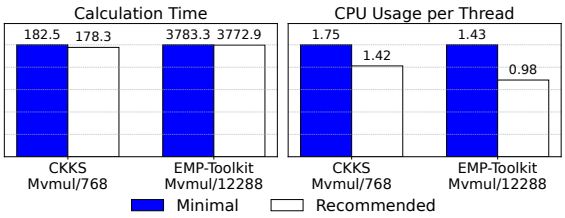

Figure 9: Comparison between "Minimal" and "Recommended" changes for single-threaded workloads.

creates two background threads for every application thread, i.e., one speculative thread and one programming thread, the average CPU usage per application thread can exceed 1. From the "CPU Usage per Thread" graph, we observe that "Recommended" integration significantly reduces CPU usage, by up to 45%. This means that for users who care not only about performance but also about reducing resource consumption, adding data annotations can be very helpful. Importantly, data annotations are not an all-or-nothing feature but are gradual: the more complete the annotations are, the more resource savings the system achieves.

A notable case is EMP-Toolkit: under "Recommended" integration, its CPU usage per thread drops below 1. This result shows that EMP-Toolkit can achieve over 90% of the unbounded performance while using only about 30% of the memory and the same amount of CPU (at most 1 CPU per application thread).

10 Related Work

Much research has focused on developing faster or better cryptographic protocols for SC by improving the underlying theory [9, 11, 18, 48]. Prior research has also developed efficient implementations of SC [22, 26, 53] and programming frameworks to make SC accessible to non-experts [12, 20]. Osprey aims to improve the performance of SC without introducing a new DSL/programming framework, and without requiring the SC protocols to be re-implemented or new SC protocols to be designed. Thus, Osprey is complementary to these existing lines of research.

An existing line of work focuses on making SMPC scale to large data analytics workloads by identifying portions of an analytics query that can be safely executed at a single party or a subset of parties [2, 44, 47, 57]. Another line of work performs similar analysis for workloads like cooperative machine learning—in effect, developing custom SC protocols for particular tasks of interest [24, 36, 37]. Osprey is complementary to these efforts as well—one can first apply techniques from these lines of work to minimize the size of the SC computation, and then apply Osprey to execute the resulting computation efficiently.

In one line of work, the compiler analyzes the program

and inserts prefetch and release directives in the generated code [5, 38, 39]. This approach is mostly limited to matrix computations consisting of array accesses in a loop, and does not generalize easily to cases where the computation is recursively structured or where the access patterns are in an SC library removed from the looping array accesses. Later work used software speculation to remove such assumptions about the structure of the computation [17]. However, software speculation adds additional overhead and complexity in the kernel due to the need to recover from misspeculation.

Some recent systems focus on *oblivious* workloads. One such prior work is MAGE [28], to which we have already compared Osprey extensively. Another such work is 3PO [4], which has to run the speculative pass separately to get memory accesses beforehand. Osprey's main improvement over 3PO is that it leverages content obliviousness to make the speculative pass efficient enough to be run together with the main execution. Osprey makes two additional improvements compared to 3PO: (1) whereas 3PO requires all of the program's heap accesses to be oblivious, Osprey allows program annotations to mark content-oblivious memory, and (2) whereas Osprey is implemented mostly in user space with minimally extended user/kernel interfaces, 3PO is implemented almost entirely in the kernel with significant changes to the page fault handler. Another difference is that Osprey focuses on paging to secondary storage, while 3PO focuses on prefetching from far memory. In §5 and §6, we explained how we build on 3PO's techniques and the new techniques that we contribute.

There is also a growing body of research on far memory [1, 19,34,45,49,68]. Some of these approaches rely on significant application modifications, which Osprey avoids. Others aim to work transparently, using paging. None of these systems leverage the obliviousness or content obliviousness of SC applications for memory management, as Osprey does.

11 Discussion

11.1 Misspeculation Tolerance

Our earlier claim that "CO enables us to eliminate misspeculation entirely" (§1) deserves a more precise statement. In a certain case, Osprey's speculative pass may "miss" some accesses, and Osprey tolerates this. Osprey eliminates misspeculation in the sense that the speculative pass never predicts "incorrect" accesses that the program does not actually make.

If the SC library does not have complete `OSPREY_TOUCH` annotations, then the speculative pass may miss some accesses. In this setting, the speculative pass's trace is (at least partially) collected from page faults via the eBPF handler (§5). If thread A is the first to access a page, then the eBPF handler records the access; if thread B later accesses the same page before it is swapped out, then B's access does not fault and therefore does not appear in the trace. As a result, the programmed pass may not prefetch the page in time, but the program runs correctly, with (perhaps) a small loss in performance.

Osprey does not tolerate phantom accesses, where the speculative pass predicts an access that does not actually occur in the programmed pass. Such accesses cannot arise in our setting: the speculative pass's trace is derived only from real page faults and from `OSPREY_TOUCH` calls on cryptographic operations the application will actually execute.

11.2 Speculation Cost

It is a deployment choice whether, for a multithreaded workload, to run the speculative passes for the threads on a single core or on multiple cores. The trade-off is that consolidating speculative threads onto fewer cores may cause speculation to become CPU-bottlenecked and generate predictions more slowly, which could slow down the programmed pass. As a concrete example, with full `OSPREY_TOUCH` annotations (Fig. 9), the speculative pass uses approximately 42% of the programmed pass's CPU per thread for SEAL/CKKS's matrix-vector multiplication, but under 10% for EMP-Toolkit's matrix-vector multiplication. This means that co-locating many speculative threads on a single core may be viable for EMP-Toolkit's matrix-vector multiplication.

11.3 Swap Backends

Because Osprey pages aggressively to an SSD, a natural concern is that the resulting write traffic may shorten the SSD's lifetime. This is a real cost, but two points put it in perspective. First, this is a trade-off that the industry accommodates: major cloud providers offer general-purpose VM instance families with local NVMe SSDs (e.g., AWS `m5d`, Azure `Ddsv6`), and swap space is one of the recommended uses of this local storage [35]. Second, Osprey's techniques could be generalized to swap backends beyond SSD: its paging design is agnostic to the backing store, so its techniques could be applied using backends without write-endurance limits, such as far memory or CXL-attached memory.

12 Conclusion

We presented Osprey, a system for addressing the high memory overhead of SC by very efficiently paging to secondary storage. By leveraging speculative execution, it achieves transparency—it does not require applications to be rewritten. We observe that SC has a property called *content obliviousness*, which is a different aspect of obliviousness than what prior work has explored. We leverage this property to make speculative execution simpler and more efficient.

Osprey's observations and techniques can also potentially be applied to certain non-SC workloads like neural network training/inference and oblivious database engines. This could be an interesting direction for future work.

Acknowledgments

We would like to thank David E. Culler for formative conversations in the early stages of this research project. We would also like to thank the anonymous reviewers and shepherd for their constructive feedback, and members of the systems group at UCLA for their feedback on a draft of this paper. Abstract

In cloud environments, sensitive information in virtual machines (VMs) is exposed to insider threats. To protect VMs from malicious cloud insiders, modern clouds provide confidential VMs based on technologies such as AMD SEV, which transparently encrypts the memory of VMs and the state of CPU registers while ensuring their integrity. However, existing SEV support is not sufficient for nested virtualization, where a guest hypervisor (L1 hypervisor) runs inside a host VM (L1 VM) managed by the host hypervisor (L0 hypervisor) and creates guest VMs (L2 VMs). This paper proposes *nested SEV* to provide more secure and generic SEV support for nested virtualization. Nested SEV allows SEV-enabled L2 VMs to run inside an SEV-enabled L1 VM. It supports two trust models: (1) both the L0 and L1 hypervisors are untrusted, and (2) the L0 hypervisor is untrusted but the L1 hypervisor is trusted. For these trust models, nested SEV provides two mechanisms. *SEV virtualization* protects L2 VMs against both the L0 and L1 hypervisors. In contrast, *SEV passthrough* protects them against the L0 hypervisor but allows the L1 hypervisor to access the memory of L2 VMs by sharing the SEV context. These mechanisms rely on *emulation-less multiplexing* and *SEV context decoupling*. We implemented nested SEV in three different types of hypervisors and showed that the average performance degradation ranged from 0.9% to 30% across three SEV variants.

1 Introduction

As users deal with sensitive information in virtual machines (VMs) provided by clouds, the threat from cloud insiders is growing. To protect sensitive information in users' VMs, modern clouds such as Amazon Web Services, Google Cloud, and Microsoft Azure offer confidential VMs [8, 19, 33] based on technologies such as AMD SEV [3]. SEV transparently encrypts the memory of VMs and allows its contents to be decrypted only inside the VMs. SEV-ES [1] extends SEV by protecting the state of CPU registers, while SEV-SNP [2] further enhances protection by ensuring memory integrity. Using these technologies, even cloud insiders cannot eavesdrop on or tamper with sensitive information in users' VMs.

On the other hand, nested virtualization [10, 28] has been used for various purposes, including virtual clouds [14, 21, 30, 36, 47]. It enables a guest hypervisor (hereafter, the L1 hypervisor) to run inside a host VM (L1 VM) managed by the host hypervisor (L0 hypervisor) and to create guest VMs (L2 VMs). However, existing SEV support for nested virtualization is limited. For example, Microsoft's patch [40] enables SEV-SNP for L2 VMs but cannot protect the underlying L1 VM with SEV. As a result, the L0 hypervisor can compromise the L1 hypervisor running inside the L1 VM. Hecate [16] and OpenHCL [37] enable SEV-SNP for both L1 and L2 VMs, but they support only a single L2 VM.

This paper proposes *nested SEV* to provide more secure and generic SEV support for nested virtualization. Nested SEV allows multiple SEV-enabled L2 VMs to run inside an SEV-enabled L1 VM. It supports two trust models: (1) both the L0 and L1 hypervisors are untrusted, and (2) the L0 hypervisor is untrusted but the L1 hypervisor is trusted. For these trust models, nested SEV provides two mechanisms: *SEV virtualization* and *SEV passthrough*. *SEV virtualization* applies virtual SEV to an L2 VM and protects its memory and register state using a different SEV context from that of the L1 VM, e.g., an encryption key. As a result, it protects L2 VMs against both the L0 and L1 hypervisors. In contrast, *SEV passthrough* partially virtualizes SEV and uses the same SEV context as the L1 VM. It protects L2 VMs against the L0 hypervisor but allows the L1 hypervisor to access the internal state of L2 VMs.

These mechanisms rely on two key techniques. The first technique, *emulation-less multiplexing*, securely manages sensitive SEV contexts for L2 VMs. Rather than emulating the AMD Secure Processor (AMD-SP) in an untrusted L0 hypervisor, it multiplexes SEV contexts for both L1 and L2 VMs on the physical AMD-SP. The second technique, *SEV context decoupling*, enables an L1 VM and its L2 VMs to share a single SEV context. It decouples the SEV context from the VM and allows each L2 VM to use the same SEV context as its L1

VM. We have implemented nested SEV using KVM [26] as the L0 hypervisor and KVM, BitVisor [41], and Xen (paravirtualization) [9] as L1 hypervisors. Nested SEV supports three SEV variants and allows users to balance security and performance. We analyzed the security of nested SEV and showed that the average performance degradation ranged from 0.9% to 30% across two mechanisms, three SEV variants, and three L1 hypervisors.

In summary, this paper makes the following contributions.

- We propose nested SEV, which enables the secure execution of an L1 hypervisor and multiple L2 VMs inside an SEV-enabled L1 VM under both trusted and untrusted L1 hypervisors.
- We design and implement SEV virtualization and SEV passthrough using two novel techniques and support three SEV variants, allowing users to balance security and performance.
- We evaluate nested SEV using three different types of L1 hypervisors and quantify its overhead under various workloads.

Nested SEV is open-sourced and publicly available at https://github.com/ksl-kyutech/nested-sev.

2 Background

2.1 AMD SEV

Secure Encrypted Virtualization (SEV). SEV [3] is a security feature that enables transparent memory encryption for VMs on AMD EPYC processors. The memory controller encrypts data in a VM when it is written to physical memory and decrypts it when it is read. The AMD Secure Processor (AMD-SP) generates a distinct encryption key for each VM and manages it as part of an SEV context. Therefore, the memory of a VM cannot be eavesdropped on by the hypervisor, devices, or other VMs. In an SEV-enabled VM, a memory page is encrypted when the guest operating system (OS) sets the C-bit of the corresponding page table entry (PTE). For memory regions shared with the hypervisor, e.g., DMA bounce buffers, the guest OS clears the C-bit to mark the corresponding page as unencrypted. In this paper, we refer to this baseline version as SEV_0 to distinguish it from the generic term SEV, which collectively refers to SEV, SEV-ES, and SEV-SNP.

SEV Encrypted State (ES). SEV-ES [1] is an extension of SEV_0, introduced in second-generation EPYC processors. It additionally encrypts the state of CPU registers on VM exits. Traditionally, the Secure Virtual Machine (SVM) extension in the AMD Virtualization (AMD-V) architecture stores the register state in a memory region called the VM Control Block (VMCB) when a VM exit occurs. In contrast, SEV-ES encrypts this state using the VM-specific key and stores it in a memory region called the VM save area (VMSA). This mechanism can prevent information leakage from CPU registers. As a downside, the hypervisor cannot handle VM exits in a traditional manner because it needs access to the register state to emulate instructions.

In SEV-ES, a VMM communication exception (#VC) is raised in a VM when an event that would normally trigger a VM exit occurs. At this time, the #VC handler of the guest OS is invoked. It stores only the necessary register state for handling the event in a memory region shared with the hypervisor, called the Guest-Hypervisor Communication Block (GHCB) [6]. Then, it executes the `VMGEXIT` instruction to trigger a VM exit. The hypervisor reads the values stored in the GHCB, handles the event, and writes the results back to the GHCB. Note that several events, such as external interrupts, do not raise #VC exceptions but directly cause VM exits.

SEV Secure Nested Paging (SNP). SEV-SNP [3] is an extension introduced in third-generation EPYC processors. It prevents software-based integrity attacks such as data corruption, replay attacks, memory aliasing, and memory remapping. To enable this, it uses the Reverse Map Table (RMP), which has an entry for each host physical page and maintains ownership information for that page. A guest-owned page is a page assigned to a VM, while a hypervisor-owned page is a page that is shared with or not assigned to a VM. Since the hypervisor cannot write data to guest-owned pages, it cannot corrupt the memory of a VM or replace it with stale data.

The RMP is used to verify the page owner more rigorously. When a guest physical address (GPA) is translated into a host physical address (HPA), an RMP check fails if the address space identifier (ASID) of the current VM does not match that stored in the corresponding RMP entry. If the GPA does not match that in the RMP entry, the RMP check also fails. This prevents aliasing attacks, where the hypervisor maps a host physical page to multiple VMs. However, the hypervisor can alter the mapping by executing the `RMPUPDATE` instruction. To prevent such remapping attacks, the guest OS in a VM validates its memory pages by executing the `PVALIDATE` instruction. A page is changed to the invalid state when the hypervisor executes `RMPUPDATE`. Since a VM cannot access invalid pages, remapping attacks can be detected.

SEV-SNP also introduces VM Privilege Levels (VMPLs), which enable a VM to divide its GPA space into four levels. VMPL0 is the highest privilege level and is protected from lower VMPLs.

2.2 Nested Virtualization

Nested virtualization [10, 28] enables a guest hypervisor to run inside a host VM and create guest VMs on top of it. A system using nested virtualization consists of three levels. The host hypervisor runs at level 0 (L0) and is called the L0 hypervisor. A host VM managed by the L0 hypervisor runs at level 1 (L1) and is called an L1 VM. The guest hypervisor running inside an L1 VM is called the L1 hypervisor. A guest

(a) Untrusted L1 hypervisor (b) Trusted L1 hypervisor

Figure 2: Two trust models in nested SEV.

VM created by the L1 hypervisor runs at level 2 (L2) and is called an L2 VM.

One application of nested virtualization is virtual clouds [14, 21, 30, 36, 47] constructed on existing clouds. Virtual cloud providers can run their custom cloud infrastructure using L1 VMs without preparing their own physical hosts. Cloud users can benefit from virtual clouds if such virtual clouds provide more attractive services than existing clouds, such as better instance types and lower prices. Since users increasingly rely on SEV to protect their VMs in untrusted public clouds, it is natural to expect SEV protection for L2 VMs in virtual clouds. Likewise, virtual cloud providers would benefit from being able to protect the L1 VMs hosting their cloud infrastructure against the underlying public clouds.

However, SEV support for nested virtualization is still limited. Microsoft's patch [40] enables SEV-SNP only for L2 VMs, as shown in Figure 1(a). Since it cannot apply SEV to the L1 VM running L2 VMs, the L1 hypervisor in the L1 VM is not protected against the L0 hypervisor. This means that the L1 hypervisor must trust the L0 hypervisor. This trust assumption is a fundamental limitation for virtual clouds running on untrusted public clouds. Even though L2 VMs are protected by SEV-SNP, they cannot be expected to operate correctly if the underlying L1 hypervisor has been compromised.

Hecate [16] and OpenHCL [37] can apply SEV-SNP not only to L2 VMs but also to L1 VMs, as shown in Figure 1(b). However, they can run only one L2 VM per L1 VM because they are implemented using VMPLs, which lack support for MMU virtualization. This limitation severely restricts the applicability of virtual clouds, which need to run many L2 VMs. In terms of security, Hecate and OpenHCL cannot protect the L2 VM from the L1 hypervisor. They divide the GPA space of the L1 VM using VMPLs and assign the portion that is not used by the L1 hypervisor running in VMPL0 to the L2 VM. Consequently, the L2 VM shares the SEV context with the L1 VM, and its memory is encrypted using the same key as the L1 VM. Although this allows the L2 VM to directly share encrypted memory with the L1 hypervisor, the L1 hypervisor can freely access the internal state of the L2 VM, which runs at a lower privilege level. Therefore, the L2 VM must trust the L1 hypervisor. Since VMPLs are used to implement nested virtualization, neither L1 nor L2 VMs can use them for other purposes, such as vTPM [35]. Table 1 summarizes the characteristics of these existing approaches.

2.3 Threat Model

The threat model of this paper is similar to that of SEV. We assume that the processors and the AMD-SP are trusted. Since the L0 hypervisor is untrusted, it can mount attacks against both L1 and L2 VMs. Unlike the original threat model of SEV, we consider both untrusted and trusted L1 hypervisors. When the L1 hypervisor is untrusted, it can also mount attacks against L2 VMs.

As attack vectors, we consider attacks against the confidentiality and integrity of the memory and register states of L1 and L2 VMs. However, we do not consider control-flow manipulation attacks that change the handling of VM exits or modify the VMCB in the hypervisors. Therefore, we exclude attacks in which the L0 hypervisor bypasses the L1 hypervisor by not redirecting VM exits to it. Also, we do not consider side-channel attacks against L1 and L2 VMs. For example, the L0 hypervisor can observe control flows, e.g., interactions between the L1 hypervisor and L2 VMs, as well as memory access patterns, to infer the internal states of L2 VMs. These attacks are inherent limitations of SEV because the hypervisor must control SEV-enabled VMs. Furthermore, these limitations are not specific to SEV but are common to most trusted execution environments (TEEs). In addition, we do not consider collusion attacks between the L0 hypervisor and L2 VMs because L2 VMs do not trust the L0 hypervisor. Denial-of-service (DoS) attacks against L1 and L2 VMs are also out of scope.

3 Nested SEV

This paper proposes *nested SEV* to provide more secure and generic SEV support for nested virtualization. Nested SEV allows multiple SEV-enabled L2 VMs to run inside an SEV-enabled L1 VM. It enables the L1 hypervisor to run in an SEV-enabled L1 VM and applies SEV to L2 VMs running on top of the L1 hypervisor. Nested SEV supports two trust models, as illustrated in Figure 2. In both models, the L0 hypervisor is untrusted. When the L1 hypervisor is also untrusted, L2 VMs need to be protected not only against the L0 hypervisor but also against the L1 hypervisor. When the L1 hypervisor is trusted, L2 VMs do not need to be protected against the

Table 1: Comparison of previous systems and our two mechanisms for nested SEV

	L1's trust	L2's trust	# of L2 VMs	VMPLs availability	SEV context	L1-L2 shared memory	available L2 GPA
Microsoft's patch [40]	L0	none	many	L2	L2 only	unencrypted	all
Hecate [16]	none	L1	one	–	L1-L2 shared	encrypted	all but VMPL0's
SEV virtualization	none	none	many	L1 / L2	L1 / L2	unencrypted	all
SEV passthrough	none	L1	many	L1	L1-L2 shared	encrypted	part (§5.3)

L1 hypervisor, but they still have to be protected against the L0 hypervisor. To achieve these two trust models, nested SEV provides two mechanisms: *SEV virtualization* and *SEV passthrough*. Table 1 compares these mechanisms with the previous systems.

SEV virtualization protects L2 VMs against an untrusted L1 hypervisor by using different SEV contexts, such as encryption keys and ASIDs, for L1 and L2 VMs. It provides virtual SEV to an L1 VM and enables the L1 hypervisor to apply virtual SEV to L2 VMs. To support virtual SEV, it virtualizes the AMD-SP and the RMP using a technique called *emulation-less multiplexing*. For security, the L0 hypervisor does not emulate these hardware components. Specifically, SEV contexts for L2 VMs remain in the physical AMD-SP rather than being managed by a virtual AMD-SP. Similarly, RMP entries for L2 VMs are maintained by the physical processors and AMD-SP rather than by virtual CPUs and AMD-SP. This is achieved by multiplexing SEV contexts for both L1 and L2 VMs on the physical AMD-SP and accommodating memory mappings for both L1 and L2 VMs in the RMP, which is protected by hardware. SEV virtualization shares some similarities with Microsoft's patch, but it additionally applies SEV to the L1 VM, thereby protecting the L1 hypervisor against the L0 hypervisor.

SEV virtualization can be used, for example, to construct virtual *public* clouds on top of untrusted public clouds. Public cloud providers run the L0 hypervisors, while virtual cloud providers build their own virtual public clouds using confidential VMs, i.e., SEV-enabled L1 VMs, as virtual hosts. Each virtual public cloud then provides users with SEV-enabled L2 VMs as confidential VMs. Similarly, such virtual public clouds can provide confidential containers [11], which are based on confidential VMs. Even without nested SEV, virtual cloud providers can run their custom cloud infrastructure on public bare-metal clouds. However, they cannot protect their cloud infrastructure, including hypervisors, because the underlying public clouds have direct access to the hardware. Although physical memory can be encrypted using AMD Secure Memory Encryption (SME) [4], SME does not provide memory integrity or attestation support.

On the other hand, *SEV passthrough* allows a trusted L1 hypervisor to access the memory and register states of L2 VMs by sharing the same SEV context between an L1 VM and its L2 VMs. To enable such a non-standard use of SEV contexts without VMPLs, it uses a technique called *SEV context decoupling*. In traditional SEV and SEV virtualization, each VM has a unique SEV context in the AMD-SP and the processors. In SEV passthrough, in contrast, the SEV context is decoupled from the VM. As a result, an L1 VM and its L2 VMs can share a single SEV context. This is achieved by partially virtualizing SEV and running SEV-enabled L2 VMs without involving the AMD-SP. Since the AMD-SP does not recognize L2 VMs, SEV passthrough also supports L2 VMs that do not rely on SVM, such as paravirtualized VMs in Xen [9] and software-based L2 VMs in PVM [21]. It is similar to Hecate and OpenHCL in that it trusts the L1 hypervisor, but it enables the L1 hypervisor to run multiple L2 VMs. Hecate and OpenHCL can also use the same SEV context between an L1 VM and its L2 VM using VMPLs provided only by SEV-SNP, but SEV passthrough does not rely on VMPLs. Therefore, it allows L1 VMs to use VMPLs for their own purposes.

SEV passthrough can be used, for example, to construct virtual *private* clouds. As with virtual public clouds, virtual cloud providers can construct their own virtual private clouds using confidential VMs, i.e., SEV-enabled L1 VMs, provided by public clouds. Since both administrators and users belong to the same organization, virtual private clouds can provide users with non-confidential VMs, i.e., SEV-disabled L2 VMs. Note that L2 VMs are still protected against the L0 hypervisor by SEV-enabled L1 VMs. Even without nested SEV, existing clouds already provide virtual private clouds, such as Amazon Virtual Private Cloud (VPC) [7]. Using such services, virtual cloud providers can build their own private networks, but they cannot run custom hypervisors or protect their infrastructure. Another application of SEV passthrough is to monitor the internal states of L2 VMs using VM introspection [15]. Since the L1 hypervisor can access the memory and register states of L2 VMs, it can obtain system information inside L2 VMs.

Nested SEV allows users to apply any of the three SEV variants to both L1 and L2 VMs because security often comes at the expense of performance. The strongest security is not always the best solution. Specifically, SEV-SNP provides the strongest security but incurs the highest performance overhead due to the check of memory integrity. In contrast, SEV_0 offers the highest performance by simply encrypting the memory of VMs, although it provides weaker security. SEV-ES lies between these two extremes. As a result, users can use the SEV variant that best matches their security and performance requirements.

4 SEV Virtualization

To run the L1 hypervisor in an SEV-enabled L1 VM, the L1 hypervisor needs to be modified to support SEV, as the L1 OS does. In addition, both the L1 and L0 hypervisors require additional SEV support to run L2 VMs in the L1 VM. Emulation-less multiplexing is used for RMP virtualization (§4.5) and AMD-SP virtualization (§4.6). Unless otherwise specified, this section focuses on SEV-SNP.

4.1 Unencrypted Memory Sharing for L2 VMs

In single-level virtualization with SEV, it is sufficient for the guest OS in a VM to mark memory as unencrypted to share it with the hypervisor, e.g., DMA bounce buffers. In nested virtualization, not only the L2 OS but also the L1 hypervisor needs to clear the C-bits of the corresponding PTEs in their page tables. This is because the L1 hypervisor cannot access memory encrypted with the key of the L2 VM. However, it is not easy for the L1 hypervisor to identify such pages because the L2 VM dynamically marks memory as unencrypted.

Therefore, the L1 hypervisor clears the C-bits of the PTEs corresponding to all the pages assigned to the L2 VM. If the L2 VM also clears the C-bit of its PTE, both the L2 VM and the L1 hypervisor can access the page without memory encryption. Note that the L1 hypervisor still cannot access the encrypted memory of the L2 VM unless the L2 OS explicitly clears the C-bits. As a result of this sharing mechanism, the L0 hypervisor can also access the memory shared between an L2 VM and the L1 hypervisor by clearing the C-bits. However, data in the shared memory is expected to be encrypted by the L2 VM because the L1 hypervisor is untrusted.

4.2 VMCB Virtualization

When the L1 hypervisor runs an L2 VM, it executes the `VMRUN` instruction. Since this instruction cannot be executed in an L1 VM, it causes a VM exit to the L0 hypervisor. Then, the L0 hypervisor executes the instruction on behalf of the L1 hypervisor. This instruction uses a VMCB, which is used to control the execution of an L2 VM and is stored in the memory of the L1 VM. This VMCB is called $VMCB_{12}$ to distinguish it from the VMCB used for the L1 VM. Since $VMCB_{12}$ is virtualized for the L1 hypervisor, the L0 hypervisor translates it into $VMCB_{02}$, also known as a *shadow VMCB*.

Since the memory of the L1 VM is encrypted, the L0 hypervisor cannot access $VMCB_{12}$ to generate the shadow VMCB. Therefore, the L1 hypervisor keeps $VMCB_{12}$ unencrypted, as illustrated in Figure 3. This does not lower the security of L2 VMs because the VMCB is inherently under the control of an untrusted hypervisor. As a result, attacks on the VMCB are outside the threat model of SEV.

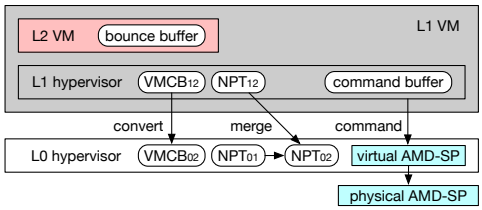

Figure 3: Unencrypted memory regions.

4.3 NPT Virtualization

In nested virtualization, the L1 hypervisor creates Nested Page Tables (NPT) for each L2 VM to translate an L2 GPA into an L1 GPA. This NPT is called NPT_{12}. Similarly, the L0 hypervisor creates NPT_{01} for each L1 VM to translate an L1 GPA into an L0 HPA. Since processors can use only one NPT during the translation of a guest virtual address (GVA) into an HPA, the L0 hypervisor merges these two NPTs and generates NPT_{02}. This NPT, also known as a *shadow NPT*, can be used to directly translate an L2 GPA into an L0 HPA.

To generate the shadow NPT, the L0 hypervisor needs to read NPT_{12} from the memory of the L1 VM, but it cannot access that NPT because that memory is encrypted. Therefore, the L1 hypervisor keeps NPT_{12} unencrypted. Consequently, the L0 hypervisor can modify the NPT_{12}, but this does not introduce additional security risks because the NPT is inherently managed by an untrusted hypervisor.

In general, the shadow NPT can be implemented using a synchronous or asynchronous method. However, the synchronous method cannot be used for SEV-enabled L1 VMs. Traditionally, the L0 hypervisor write-protects NPT_{12} in the L1 VM and configures the VMCB for the L1 VM so that a VM exit occurs when the L1 hypervisor attempts to update NPT_{12}. When a VM exit occurs, the L0 hypervisor emulates the instruction used to update NPT_{12} and modifies both NPT_{12} and its shadow NPT, i.e., NPT_{02}. To emulate the instruction, a #VC exception must be triggered by setting a reserved bit in NPT_{01} so that a reserved-bit error occurs on access. However, this significantly degrades the performance of NPT access because the #VC exception occurs even for read access.

Therefore, SEV virtualization uses the asynchronous method. This method also write-protects NPT_{12}, as in the synchronous method, but it does not emulate the instruction on a VM exit. Instead, the L0 hypervisor removes write protection from the PTE to allow it to be updated and makes the L1 hypervisor resume execution at that instruction. As a result, NPT_{12} is updated, while its shadow NPT is not. Although NPT_{12} and the shadow NPT are temporarily out of sync, they are synchronized later upon a TLB flush, which is always performed by the L1 hypervisor after NPT updates. At that time, the L0 hypervisor updates the shadow NPT to synchronize it with NPT_{12} and write-protects the PTE of NPT_{12} again.

4.4 MMIO Virtualization

To virtualize memory-mapped I/O (MMIO) in an L2 VM, the L1 hypervisor writes invalid values to the PTEs corresponding to MMIO regions in NPT_{12}. As a result, a VM exit is caused to the L0 hypervisor when the L2 VM accesses the regions. To redirect it to the L1 hypervisor, the L0 hypervisor invokes the L1 VM by executing the `VMRUN` instruction. To emulate the instruction for accessing the MMIO region, the L1 hypervisor needs to decode the instruction stored in the memory of the L2 VM.

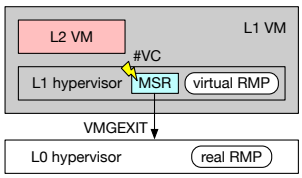
Unlike the VMCB and the NPT, however, the L2 VM cannot mark the code area as unencrypted because SEV requires the code area to remain encrypted. Therefore, the L1 hypervisor sets a reserved bit in the corresponding PTEs of NPT_{12} so that a #VC exception is raised when the L2 VM accesses the MMIO region. To virtualize the reserved bit, the L0 hypervisor synchronizes the reserved bit in the shadow NPT with that in NPT_{12}. In the L2 VM, the #VC handler decodes the instruction and stores its bytes in the GHCB. In addition, it stores the L2 GPA of the accessed MMIO region in the GHCB. Then, it executes the `VMGEXIT` instruction to cause a VM exit to the L1 hypervisor via the L0 hypervisor.

When SEV_0 is applied to an L2 VM, the L1 hypervisor cannot obtain the instruction used to access the MMIO region through a #VC exception. Therefore, the L1 hypervisor uses the Decode Assists feature in SVM, which stores the bytes of the instruction that causes a VM exit in the VMCB. Since the instruction bytes are stored in the shadow VMCB in nested virtualization, the L0 hypervisor synchronizes the corresponding fields in $VMCB_{12}$ with those in the shadow VMCB to virtualize Decode Assists.

Using PCI passthrough, an L2 VM can directly access the virtual devices provided by the L0 hypervisor rather than those provided by the L1 hypervisor [29]. To enable MMIO accesses to the L0 virtual devices, the L1 hypervisor maps the MMIO regions of the L0 virtual devices into the GPA space of the L2 VM. When the L2 VM accesses one of these MMIO regions, a VM exit occurs. To emulate the MMIO access, the L0 hypervisor needs the corresponding L1 GPA, but the GHCB or the shadow VMCB contains only the accessed L2 GPA. Therefore, the L0 hypervisor translates the L2 GPA into an L1 GPA using NPT_{12}, which is kept unencrypted by the L1 hypervisor.

4.5 RMP Virtualization

The `RMPUPDATE` instruction for updating an RMP entry can be executed only by the L0 hypervisor. To virtualize this instruction, it is recommended to use the `VIRT_RMPUPDATE` model-specific register (MSR) [5]. When the L1 hypervisor writes data to this MSR, a #VC exception is raised, as illustrated in Figure 4(a). After the #VC handler executes the `VMGEXIT` instruction, the L0 hypervisor translates the specified virtual ASID, which is assigned to the L2 VM by the L1 hypervisor, into the real ASID. It also translates the specified L1 GPA into an L0 HPA using NPT_{01}. Then, it executes `RMPUPDATE` with the real ASID, the L0 HPA, and the specified L2 GPA. As such, the L0 hypervisor does not emulate the RMP. Instead, it leverages the existing RMP by translating L1 virtual mappings into their corresponding L0 mappings.



(a) RMP for L2 VMs

HPA	Assigned	ASID	GPA
:			
0x1000	0	0	0
:			
0x3000	1	L1's	L1's
:			
0x5000	1	L2's real	L2's
:			

(b) Real RMP

Figure 4: Virtualizing the RMP.

Since the L1 hypervisor needs to read the RMP directly from memory, it creates its own virtual RMP. The virtual RMP is similar to the real RMP but maintains the virtual mapping from an L1 GPA to its owner. For a guest-owned page, the L1 hypervisor sets the Assigned field and stores the virtual ASID and GPA of an L2 VM in the RMP entry. For a hypervisor-owned page, it clears the Assigned field. The L1 hypervisor updates the virtual RMP when writing data to the `VIRT_RMPUPDATE` MSR and synchronizes it with the real RMP, which is managed by the L0 hypervisor. Since the virtual RMP is just a cache, tampering with it does not affect the security of L2 VMs.

To virtualize the RMP, it is not sufficient to manage only the traditional two types of owners. Since a guest-owned page can be assigned to either an L1 or L2 VM, it is necessary to manage three types of owners. An L2-owned page is a guest-owned page accessible only by an L2 VM. An L1-owned page is a guest-owned page that the L1 hypervisor does not assign to any L2 VMs in the L1 VM. An L0-owned page is a hypervisor-owned page that is either shared between the L0 and L1 hypervisors, shared between the L1 hypervisor and an L2 VM, or not assigned to any L1 VMs. Note that a shared page between the L1 hypervisor and an L2 VM is not an L1-owned page because it must be accessible to both the L1 and L2 VMs.

To accommodate these three types of owners in the real RMP, the L0 hypervisor constructs the real RMP as shown in Figure 4(b). It sets the Assigned field of the RMP entry for an L2-owned page and stores the real ASID and GPA of an L2 VM in the entry. For an L1-owned page, it also sets the Assigned field and stores the ASID and GPA of an L1 VM. For an L0-owned page, it clears the Assigned field. When the L1 hypervisor changes a page from L0-owned or L1-owned to L2-owned, it writes the virtual ASID of an L2 VM to the `VIRT_RMPUPDATE` MSR. When changing a page to L1-owned, it writes -1, which represents the ASID of the L1 VM itself, to

the MSR. In this case, the L0 hypervisor executes RMPUPDATE with the ASID of the L1 VM.

4.6 AMD-SP Virtualization

To boot an SEV-enabled VM, the hypervisor issues various commands for guest management to the AMD-SP. For example, it issues the SNP_GCTX_CREATE command to generate a memory encryption key and store it in the guest context page. Since the guest context page is protected by memory encryption and the RMP, the hypervisor cannot eavesdrop on or tamper with it. Then, it issues the SNP_ACTIVATE command to install the key into the memory controller and bind the specified ASID to the VM. Next, the hypervisor issues the SNP_LAUNCH_UPDATE command to encrypt the specified memory regions in the VM, such as firmware, and the VMSAs using the key. In addition, the AMD-SP marks the pages as guest-owned and validated by updating the RMP.

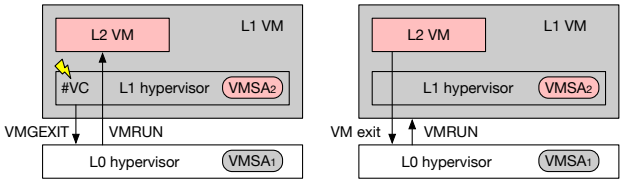
To boot an SEV-enabled L2 VM, the L0 hypervisor provides a *virtual AMD-SP* to an L1 VM. The L1 hypervisor issues a set of commands to the virtual AMD-SP. However, it would not be secure for the virtual AMD-SP itself to manage sensitive SEV contexts, e.g., encryption keys. Therefore, the L0 hypervisor does not emulate the AMD-SP. SEV contexts are securely managed only inside the physical AMD-SP, as in single-level virtualization. The guest context page is also protected against both the L0 and L1 hypervisors. When the virtual AMD-SP receives a command, it simply forwards that command to the physical AMD-SP. To allow both the virtual and physical AMD-SPs to access the command buffer, the L1 hypervisor keeps it unencrypted. If necessary, the virtual AMD-SP translates several parameters in the command buffer, e.g., the virtual ASID and the L1 GPA.

The AMD-SP provides a different set of commands for SEV_0 and SEV-ES. The command set is similar to that of SEV-SNP, but it does not use the guest context page. Sensitive SEV contexts are stored only in the AMD-SP, instead of the guest context pages. Since the virtual AMD-SP does not store any sensitive data for SEV_0 and SEV-ES, it does not introduce additional security risks.

4.7 Direct Context Switching with VMSAs

In single-level virtualization, when the hypervisor executes the VMRUN instruction to run an SEV-enabled VM, the processor saves the minimal state, such as the instruction pointer, to the host save area. Then, it loads the entire register state from the encrypted VMSA for the VM. In contrast, when a VM exit occurs, the processor encrypts the entire register state and saves it to the VMSA. Then, it loads the minimal state from the host save area.

In nested virtualization, when the L1 hypervisor executes VMRUN to run an SEV-enabled L2 VM, a #VC exception occurs, and the #VC handler invokes the L0 hypervisor using the



(a) VMRUN (b) VM exit

Figure 5: Context switching between the L1 hypervisor and an L2 VM.

VMGEXIT instruction, as illustrated in Figure 5(a). To emulate VMRUN, the L0 hypervisor needs to save the state of the L1 VM to the host save area in the L1 VM. When a VM exit occurs in the L2 VM, the L0 hypervisor needs to load the state of the L1 VM from the host save area. However, it cannot access the register state or the host save area of the L1 VM because the memory and register state of the L1 VM are encrypted.

Therefore, the L0 hypervisor simply executes VMRUN to load the VMSA for the L2 VM. It does not explicitly save the state of the L1 VM because the state is implicitly saved to the VMSA by the processor on the VM exit caused by VMGEXIT. Similarly, when a VM exit occurs in an L2 VM, the L0 hypervisor is invoked and simply executes VMRUN to load the VMSA for the L1 VM, as in Figure 5(b). It does not explicitly load the state of the L1 VM from the host save area.

For optimization, the L1 hypervisor directly configures the GHCB and executes VMGEXIT, instead of executing VMRUN. It is wasteful to cause a #VC exception by executing that instruction. This optimization can eliminate the overhead of the #VC exception.

5 SEV Passthrough

In addition to SEV support for the L1 hypervisor, SEV passthrough requires mechanisms for RMP virtualization and direct context switches, as well as SEV support for VMCB virtualization and NPT virtualization. However, it does not require the remaining mechanisms used by SEV virtualization, namely unencrypted memory sharing, SEV support for MMIO virtualization, ASID virtualization, and AMD-SP virtualization.

5.1 SEV Context Decoupling

Unlike SEV virtualization, SEV passthrough does not virtualize the AMD-SP to enable L2 VMs to share the same SEV context with their L1 VM. The L1 hypervisor does not issue commands to the virtual AMD-SP to boot L2 VMs. Also, it does not assign virtual ASIDs to L2 VMs. Instead, it assigns the ASID of the L1 VM to all the L2 VMs running in the L1 VM, so that the L2 VMs can use the same encryption key as the L1 VM. This assignment is possible because SEV

passthrough boots L2 VMs without involving the AMD-SP. Otherwise, the AMD-SP would bind a unique ASID to each L2 VM. In addition, not only the L2 OS but also the L1 hypervisor can validate the memory of the L2 VM. This does not introduce a security concern because the L1 hypervisor is trusted.

5.2 Encrypted Memory Sharing for L2 VMs

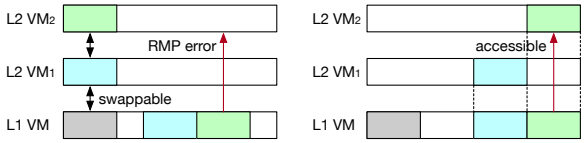
SEV passthrough enables an L2 VM to share encrypted memory with the L1 hypervisor. In SEV virtualization, shared memory needs to be kept unencrypted because the encryption keys differ between L1 and L2 VMs. Since the same ASID is assigned to both L1 and L2 VMs in SEV passthrough, the L1 hypervisor can directly access the encrypted memory of the L2 VM by using the encryption key associated with that ASID. Therefore, both the L2 OS and the L1 hypervisor can leave the corresponding C-bits set in their page tables. Consequently, the L0 hypervisor cannot eavesdrop on the shared memory between the L1 hypervisor and the L2 VM because the memory remains encrypted.

Furthermore, this can improve the I/O performance of the L2 VM. The L2 VM can perform DMA using encrypted buffers without copying data to and from unencrypted bounce buffers. In addition, the L1 hypervisor can decode instructions for MMIO virtualization by directly accessing the encrypted memory of the L2 VM. It can access the encrypted VMSAs of the L2 VM, which are stored in the memory of the L1 VM. Since a #VC exception is not necessary, the L1 hypervisor does not set the reserved bit in the PTEs of NPT_{12} corresponding to MMIO regions. This prevents a #VC exception from being raised. Instead, the L1 hypervisor writes invalid values to the PTEs. When the L2 VM accesses the MMIO region, a VM exit occurs directly to the L0 hypervisor. Then, the invoked L1 hypervisor emulates the instruction for accessing the region using the register values saved in the VMSA.

5.3 Exclusive GPA Assignment

In SEV-SNP, encrypted memory sharing between L1 and L2 VMs conflicts with RMP checks. When the L1 hypervisor accesses the memory of an L2 VM, the processor performs an RMP check. Although the ASID of the L1 VM matches that of the L2 VM, the L2 GPA registered in the entry of the real RMP generally differs from the corresponding L1 GPA. Therefore, the RMP check fails, as illustrated in Figure 6(a). As a result, the L1 hypervisor cannot access the memory of the L2 VM. Conversely, if different memory pages are assigned the same L1 or L2 GPA, the L0 hypervisor can swap those pages between L1 and L2 VMs or between L2 VMs. In this case, the RMP check still passes, leading to incomplete integrity protection.

To address these issues, the L1 hypervisor exclusively assigns memory pages to the GPA spaces of L2 VMs so that



(a) Normal assignment (b) Exclusive assignment

Figure 6: Memory assignment in the GPA spaces of an L1 VM and its L2 VMs.

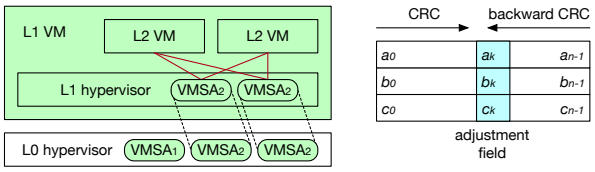
the L2 GPA of each page is identical to its L1 GPA, as illustrated in Figure 6(b). Since the L1 GPA matches the L2 GPA registered in the RMP entry, the RMP check passes when the L1 hypervisor accesses the memory of the L2 VM. In this assignment, GPAs are unique across all L2 VMs. Therefore, the RMP check fails even if the L0 hypervisor swaps memory pages because the GPAs assigned to these pages do not match those in the RMP entries. To simplify this memory assignment, the L1 hypervisor uses contiguous physical memory regions that are as large as possible for each L2 VM. Specifically, the L0 hypervisor allocates 1-GB huge pages for an L1 VM and assigns them to the GPA range above 4 GB in the L1 VM.

To boot an L2 VM with arbitrary GPAs, SEV passthrough uses custom firmware for the L2 VM. Since the x86 architecture starts the execution of firmware at a fixed physical address, an L2 VM whose memory is allocated only in the GPA space above 4 GB cannot run existing firmware such as OVMF. The custom firmware is based on qboot [38], which is designed for booting the Linux kernel and supports execution at arbitrary GPAs. It starts execution from a specified address and loads the ACPI table. To support GPAs above 4 GB, the ACPI table uses the 64-bit extension.

To initialize application processors (APs) with arbitrary GPAs, SEV passthrough uses the Wakeup Mailbox added in ACPI 6.4 [45]. Traditionally, APs are initialized in real mode using the INIT-SIPI mechanism, which requires low memory below 1 MB. This mechanism cannot be used when the kernel is placed in higher GPA regions. With the Wakeup Mailbox, APs start execution in long mode when the kernel writes the Wakeup command and the wakeup address to a dedicated memory region. In addition, the L1 hypervisor adds information on the Wakeup Mailbox to the ACPI table and provides the corresponding MMIO region.

5.4 Paravirtualized L2 VMs

SEV passthrough can support paravirtualized L2 VMs, which are created without using SVM. Since such L2 VMs are not recognized as VMs by processors, they share the same SEV context as the L1 VM. Therefore, SEV seamlessly encrypts their memory as part of the memory of the L1 VM. Note that the L2 OS can still control memory encryption by setting the C-bits in its page tables. For paravirtualized L2 VMs,



(a) VMSA pooling (b) VMSA adjustment

Figure 7: VMSA pooling and backward CRC computation.

the L1 hypervisor does not use NPT and directly assigns L1 GPAs, e.g., via pseudo-physical addresses in Xen [9], which naturally achieves exclusive GPA assignment.

When the L2 OS validates the memory of the L2 VM, it cannot execute the `PVALIDATE` instruction because this instruction is privileged. Its execution causes a general-protection exception (#GP), and the #GP handler in the L1 hypervisor executes that instruction on behalf of the L2 VM. Similarly, the L2 VM cannot use the `VMGEXIT` instruction to change the page owner because the L0 hypervisor cannot distinguish whether a VM exit originates from the L1 or L2 VM. Therefore, the L2 VM issues a new hypervisor call for changing the page owner to the L1 hypervisor.

5.5 VMSA Pooling for SEV-ES

Since SEV passthrough does not provide a virtual AMD-SP to an L1 VM, the L1 hypervisor cannot directly issue the `LAUNCH_UPDATE_VMSA` command to encrypt newly allocated VMSAs when booting ES-enabled L2 VMs. Therefore, the L0 hypervisor pre-allocates VMSAs for L2 VMs and issues the command to the physical AMD-SP when booting an L1 VM. The number of prepared VMSAs equals that of the virtual CPUs assigned to the L1 VM, but it can be smaller than the total number of virtual CPUs assigned to all L2 VMs. To support an arbitrary number of virtual CPUs, the L1 hypervisor does not statically assign the pre-allocated VMSAs to the virtual CPUs of L2 VMs. Instead, it pools VMSAs and dynamically assigns them to active virtual CPUs, as illustrated in Figure 7(a).

Since SEV passthrough shares the same SEV context between the L1 VM and its L2 VMs, the L1 hypervisor can directly initialize the register states in encrypted VMSAs when booting an L2 VM. When switching virtual CPUs, it can save the register state stored in the VMSA for the previously running virtual CPU to its memory and then load the saved register state of the next virtual CPU into the same VMSA. However, SEV-ES computes a checksum of a VMSA on each VM exit from an L2 VM to prevent rollback attacks. The checksum is securely stored in the Trusted Memory Region (TMR), which is inaccessible to software. If the L1 hypervisor modifies a VMSA, its checksum becomes inconsistent with the value stored in the TMR. This causes the failure of the `VMRUN` instruction executed by the L1 hypervisor.

To address this issue, the L1 hypervisor preserves the checksum by adjusting fields in a VMSA. The L1 hypervisor computes the checksum of a VMSA before modifying it. After modification, the L1 hypervisor computes the adjustment required to restore the original checksum. The checksum algorithm in SEV-ES is undocumented, but we found that EPYC processors compute three CRC-32C values for each VMSA. To adjust these values, the L1 hypervisor uses three 32-bit fields that are only used when a VM exit occurs. These fields are unused when the L1 hypervisor executes `VMRUN`. Note that the L0 hypervisor cannot modify VMSAs or adjust their checksums using the same technique because it cannot access encrypted VMSAs.

Specifically, the L1 hypervisor computes the adjustment value using the backward CRC algorithm [42], as in Figure 7(b). For the k-bit data before the field a_k used for the adjustment, it efficiently computes the CRC of $a_0 \cdots a_{k-1}$ using the `CRC32` instruction with the standard polynomial $P(x)$. For the $(n-k)$-bit data after that field, it must compute the CRC of $a_{n-1} \cdots a_k$ using a non-standard polynomial $x^{32} \cdot P(-x)$. To efficiently compute this value, the L1 hypervisor uses Barrett reduction with the `PCLMULQDQ` instruction [24], which computes the CRC using multiplication over 128-bit SSE registers. It further accelerates this computation using the `VPCLMULQDQ` instruction with 256-bit AVX registers.

VMSA pooling and the backward CRC computation are necessary only for SEV-ES. In SEV-SNP, the L1 hypervisor can initialize VMSAs when booting an L2 VM. It can dynamically allocate a new VMSA by updating the VMSA field in the RMP entry using the `RMPADJUST` instruction. Since VMSAs are protected from the L0 hypervisor by the RMP, their checksums are no longer stored in the TMR.

6 Security Analysis

In SEV virtualization, the L0 hypervisor can also access the memory shared between L2 VMs and the L1 hypervisor because such shared memory is kept unencrypted. However, L2 VMs can protect I/O data stored in shared memory against not only the L1 hypervisor but also the L0 hypervisor by using full disk encryption and end-to-end encryption. Even for data that is difficult to encrypt, the L0 hypervisor can mount only the same attacks as the L1 hypervisor. Note that it cannot access this shared memory in SEV passthrough because shared memory is encrypted.

Even in single-level virtualization, the hypervisor can alter the VMCB and the NPT used for VMs. In nested SEV, not only the L1 hypervisor but also the L0 hypervisor can alter unencrypted VMCB_{12} and NPT_{12} used for L2 VMs. More directly, the L0 hypervisor can alter the shadow VMCB and the shadow NPT. However, it can mount only the same class of attacks against L2 VMs as in single-level virtualization. Tampering with the NPT can be detected by RMP checks

in SEV-SNP. In addition, such attacks do not directly affect the security of the L1 hypervisor because the VMCB and the NPT control only the behavior of L2 VMs. As another attack, the L1 hypervisor can keep the NPT_{12} out of sync with the shadow NPT by not flushing the TLB. This attack is equivalent to the case where the L0 hypervisor does not update the shadow NPT as expected. Therefore, both the L0 and L1 hypervisors can mount only the same class of attacks against L2 VMs as in single-level virtualization.

The L0 hypervisor can compromise the virtual AMD-SP, but no sensitive data is stored in it. SEV contexts for L2 VMs are stored only in the physical AMD-SP, which is protected against the L0 hypervisor. Since the L1 hypervisor needs to pass an unencrypted command buffer to the virtual AMD-SP, the L0 hypervisor can tamper with this buffer. This type of attack can be detected by command-specific countermeasures, e.g., remote attestation. Similarly, the L0 hypervisor can alter the initial code, data, and register state of an L2 VM. This is because the L1 hypervisor needs to prepare them in the memory regions that are not yet protected and issue the `SNP_LAUNCH_UPDATE` command to the virtual AMD-SP. However, the owner of the L2 VM can verify that these memory regions have not been tampered with by the L0 and L1 hypervisors using remote attestation.

Hardware-based attestation of L2 VMs is not supported in SEV passthrough because L2 VMs are not directly managed by the AMD-SP. However, the correct boot of the L2 VM is ensured under the assumption that the L1 hypervisor is trusted. The memory of the L1 hypervisor and the L2 VM is protected against the L0 hypervisor. If necessary, software-based attestation using vTPM can be used.

The L0 hypervisor could bypass the L1 hypervisor if it handles all VM exits from L2 VMs because VM exits are first delivered to the L0 hypervisor. While this attack is relatively difficult in SEV passthrough, it is easier in SEV virtualization. This is because SEV virtualization does not encrypt not only the VMCB and the NPT for L2 VMs but also the GHCB and the shared memory between L2 VMs and the L1 hypervisor. Our threat model excludes such control-flow manipulation attacks as in that of SEV. A possible mitigation is that the L2 VM encrypts the GHCB and the shared memory by itself using the key shared only with the L1 hypervisor. Since the L1 hypervisor should not collude with an untrusted L0 hypervisor, the L0 hypervisor cannot obtain the necessary information to handle VM exits.

Since L2 VMs are not fully hidden from the L0 hypervisor, they could suffer from some of the side-channel attacks that the hypervisor can mount against SEV-enabled VMs in single-level virtualization. For example, the L0 hypervisor could infer the internal states of L2 VMs by observing VM exits. Using SEV passthrough and paravirtualized L2 VMs, nested SEV can hide most interactions between the L1 hypervisor and L2 VMs because L2 VMs are not mediated by the L0 hypervisor. If fully virtualized L2 VMs are used, hardware support is needed to protect such interactions. For example, TD partitioning in Intel TDX [25] enables nested virtualization similar to Hecate. Unlike Hecate, the L0 hypervisor cannot observe VM exits caused by L2 VMs because control is transferred via the trusted TDX module to the L1 hypervisor. Note that side-channel attacks are outside the scope of SEV.

The L0 hypervisor can also observe the VM exits of L1 VMs. Unlike traditional VMs and L2 VMs, the L1 VM runs a hypervisor and causes different types of VM exits, for example, by executing the `VMRUN` instruction. Such VM exits may introduce a new attack surface for L1 VMs. This is an inherent limitation of SEV because the L0 hypervisor must control the L1 VM that runs the L1 hypervisor.

In SEV passthrough, the L0 hypervisor can abuse the NPT for an L1 VM as the shadow NPT for its L2 VM. Since the L2 GPA is identical to the L1 GPA due to exclusive GPA assignment, and the ASID is the same, this shadow NPT can be used without RMP violations. As a result, the L2 VM can potentially access the entire memory of the L1 VM, including the memory used by other L2 VMs. However, this attack requires the collusion between the L0 hypervisor and the L2 VM. Since the L2 VM does not trust the L0 hypervisor, such an attack falls outside the scope of our threat model. A possible solution is to verify the GPA range used by an L2 VM. When the L2 OS sets the page table base register, the L1 hypervisor can inspect the page tables and write-protect them to monitor subsequent updates.

7 Experiments

We conducted several experiments to examine the performance of L2 VMs in nested SEV. In these experiments, we used two mechanisms in nested SEV and three SEV variants. We ran modified Linux/KVM 6.11.0 with QEMU 9.1.0 as the L0 hypervisor. In an L1 VM, we ran either modified Linux/KVM 6.11.0 with QEMU 9.1.0, BitVisor, or Xen 4.16 as the L1 hypervisor. KVM and BitVisor support full virtualization, while Xen supports paravirtualization without SVM. BitVisor adopts a passthrough-based architecture and supports only a single VM. In an L2 VM, we ran either modified OVMF from edk2-stable201903 or custom firmware as UEFI BIOS, and Linux 6.11.0 as the guest OS. For Xen, we used paravirtualized Domain 0 and Domain U. In the experiment examining the impact of VMPLs, we used the COCONUT Secure VM Service Module (SVSM) [43] in both the L1 and L2 VMs. For comparison, we also examined the performance of SEV-disabled L2 VMs and that of L1 VMs in single-level virtualization using KVM.

We used a server with a fourth-generation AMD EPYC 9334 processor, 128 GB of DDR5-4800 RDIMM memory, a 1.6 TB SAS SSD, and a 10 GbE NIC. We assigned resources to the L1 and L2 VMs as summarized in Table 2. The VMs used virtio-net as the network interface, except for Xen's Do-

Table 2: Resource allocation for VMs

	KVM		BitVisor		Xen		single
	L1	L2	L1	L2	L1	L2	virt
virtual CPU	12	6	6	6	12	6	6
memory (GB)	16	8	8	8	16	8	8

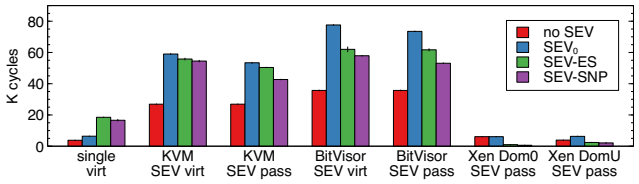


Figure 8: Overhead of VM exits.

main U, which used the xen-netfront driver. As a remote host, we used a server equipped with two Intel Xeon Silver 4110 processors, 256 GB of memory, and a 10 GbE NIC and ran Linux 5.4.189.

7.1 Overhead of VM Exits

To examine the overhead of a VM exit, we measured the number of CPU clock cycles required to execute the `VMMCALL` instruction. Figure 8 shows the results. Even in single-level virtualization, SEV_0 degraded the performance of a VM exit by 41%. SEV-ES was 2.9x slower than SEV_0 due to the #VC exception and the encryption of the register state. SEV-SNP was 12% faster than SEV-ES because CRC computation for VMSAs was not performed.

In nested virtualization, the performance of a VM exit significantly degraded. A VM exit in an L2 VM first invoked the L0 hypervisor, which executed the `VMRUN` instruction for the L1 VM. The L1 hypervisor then handled `VMMCALL` and executed `VMRUN` for the L2 VM. This instruction caused another VM exit to the L0 hypervisor, which executed `VMRUN` again to resume the L2 VM. As a result, SEV_0 virtualization was twice as slow as nested virtualization without SEV. Surprisingly, SEV-ES virtualization was faster than SEV_0 virtualization. This is because the L0 hypervisor could simply switch VMSAs between the L1 and L2 VMs during context switches. SEV-SNP virtualization was also faster than SEV-ES virtualization because the backward CRC computation was not required. Consequently, the overhead of a VM exit decreased in the order of SEV_0, SEV-ES, and SEV-SNP virtualization.

SEV passthrough was 0.5–28% faster than SEV virtualization because SEV is partially virtualized. In Xen, the #VC handler in the L1 hypervisor was invoked in SEV-ES and SEV-SNP passthrough because the L2 VMs were paravirtualized. Therefore, the #VC handler did not need to execute `VMGEXIT` to handle `VMMCALL`.

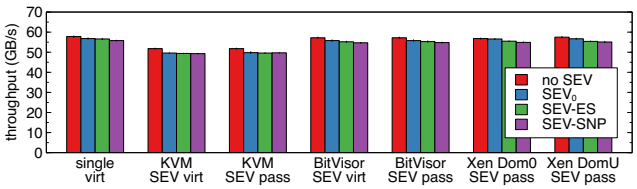

Figure 9: Performance of a memory-intensive workload.

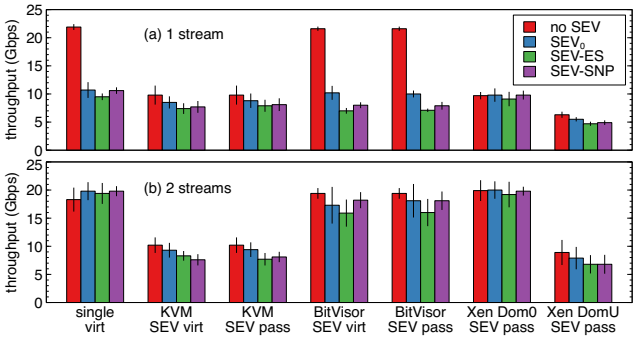

Figure 10: TCP/IP performance.

7.2 Memory Performance

We measured the performance of a memory-intensive workload using the STREAM 1.3.4 benchmark [31]. We performed a 2-GB memory copy so that the copy size was sufficiently larger than the CPU cache size. As shown in Figure 9, the overhead of nested virtualization was 0.4–3.6% in BitVisor and Xen, regardless of whether SEV was enabled. The performance decreased in the order of SEV disabled, SEV_0, SEV-ES, and SEV-SNP. In contrast, the overhead of nested virtualization was 10–12% in KVM. Since it was 10% even for an SEV-disabled L2 VM, this performance degradation is attributable to KVM's implementation rather than nested SEV.

7.3 Network Performance

We measured TCP/IP performance using the iperf 3.9 benchmark [12]. We ran the client in an L2 VM and connected it to the server running on the host. As shown in Figure 10(a), the throughput decreased by 51–53% due to SEV even in single-level virtualization. This is because the VM caused many VM exits and copied data between encrypted buffers and unencrypted bounce buffers to allow the hypervisor to access the data [27].

In nested virtualization with KVM, the throughput degraded significantly, even for an SEV-disabled L2 VM, due to the high overhead of VM exits. Enabling SEV further degraded performance, but the differences from the SEV-disabled L2 VM were relatively small. For BitVisor, the results were similar to those in single-level virtualization. The reason is that the L2 VM directly accessed the virtio-net device provided by the L0 hypervisor via PCI passthrough.

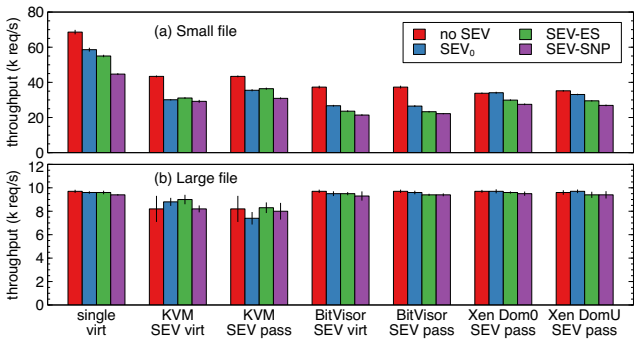

Figure 11: Performance of the Web server.

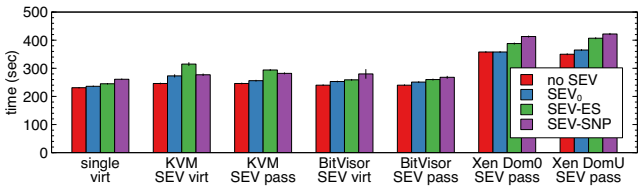

Figure 12: Build time of the Linux kernel.

Xen's Domain 0 also used PCI passthrough, but the performance of the SEV-disabled L2 VM was much lower. The throughput of Xen's Domain U was the lowest because of the split driver model.

Next, we ran two pairs of iperf3 clients and servers concurrently and measured their aggregate throughput. Figure 10(b) shows the total throughput of the two streams. The performance of the SEV-enabled VMs improved significantly in single-level virtualization, BitVisor, and Xen's Domain 0. Compared with single-level virtualization, the throughput decreased by at most 18% in BitVisor and 1.0% in Xen's Domain 0. This is because the overhead introduced by SEV was hidden by concurrent data transfers. In KVM, however, the performance improved only marginally. The throughput increased by only 12% in SEV-ES virtualization but decreased by 2.5% in SEV-ES passthrough. Although the throughput of Xen's Domain U improved by 39–45%, it remained lower than that of KVM.

Surprisingly, the performance of SEV-SNP was higher than that of SEV-ES in nested SEV. One reason is that VM exits are faster in SEV-SNP, as shown in Section 7.1. Since many VM exits occur under I/O-intensive workloads, SEV-ES suffers more from the higher overhead of VM exits. Another possible reason is the immaturity of the implementation of nested SEV. For example, SEV-ES virtualization uses our custom memory manager for L2 VMs, while SEV-SNP virtualization uses the standard `guest_memfd` provided by KVM. This could contribute to the relatively better performance of SEV-SNP virtualization with KVM.

7.4 Performance of the Web Server

We measured the performance of Apache HTTP Server 2.4.62 [44] using the bombardier 1.2.6 benchmark [13]. First, we repeatedly requested a small 45-byte HTML file from the remote host. Figure 11(a) shows the request processing rate with 200 concurrent connections. Even in single-level virtualization, SEV-SNP degraded performance by 35%. The overhead of nested virtualization was 31–58% with or without SEV. Unlike the iperf3 benchmark, the performance in BitVisor degraded significantly. This is because the transferred data was small, making the processing overhead relatively more significant than the I/O overhead. In contrast, the performance in Xen was 24–29% better than that in BitVisor when nested SEV was enabled. In KVM, the performance was up to 15% better with SEV passthrough than with SEV virtualization. One reason is that SEV passthrough eliminates the need for bounce buffers in the L2 VM.

Next, we repeatedly requested a large HTML file of approximately 100 KB. As shown in Figure 11(b), the overhead of nested virtualization became much smaller with or without SEV. This is because the network bandwidth became a bottleneck. In BitVisor and Xen, the performance was almost identical to that of single-level virtualization. In KVM, however, the performance degraded by 6.3–23%. These results are similar to those of the iperf3 benchmark.

7.5 Performance of the Kernel Build

We measured the time required to build Linux kernel 6.1.0 with the default configuration. We used as many virtual CPUs as assigned to an L2 VM. As shown in Figure 12, SEV increased the build time by up to 12% even in single-level virtualization. In nested virtualization with KVM, the SEV-disabled L2 VM increased the build time by 6.1%, while the SEV-enabled L2 VMs increased it by 5.8–22%, compared with single-level virtualization. Notably, the slowdown was greatest in SEV-ES virtualization and smallest in SEV-SNP virtualization. The reasons are likely the same as those for the iperf3 benchmark because the kernel build generated intensive disk I/O. In BitVisor, the slowdown in nested SEV was only 2.6–6.8%. This is because the L2 VM directly accessed the virtual disk via PCI passthrough. In contrast, the build time was much longer in Xen. The slowdown was 34–40% in the SEV-enabled L2 VMs and 34–36% even in the SEV-disabled L2 VMs. Since building a large Linux kernel spawned many processes, the L2 VM needed to modify the page tables frequently. This overhead was higher because a paravirtualized L2 VM in Xen issued a hypercall whenever it modified a PTE.

7.6 Boot Performance

We measured the time required to boot an L2 VM. We defined the boot time as the interval between the creation of the L2 VM and the point at which the SSH server became available

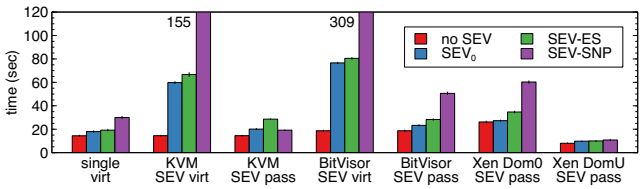

Figure 13: Boot time of an L2 VM.

in the VM. In KVM, OVMF or the custom firmware executed GRUB2, which loaded the Linux kernel and the initial RAM disk. Note that, for BitVisor and Xen's Domain 0, we included the boot time of the L1 VM. This is because the L2 VM was automatically booted immediately after the L1 hypervisor booted, making it difficult to isolate the boot time of the L2 VM.

Figure 13 shows the boot time of an L2 VM. In KVM, SEV_0 virtualization was 4.1x slower than nested virtualization without SEV. This is because the cost of NPT virtualization was high. Since the shadow NPT initially had no entries, a VM exit occurred whenever the L2 VM accessed a memory page for the first time. Then, the L0 hypervisor updated the shadow NPT through complex interactions with the L1 hypervisor, as described in Section 4.3. In the current implementation of SEV_0 virtualization, the L1 hypervisor cannot assign huge pages to the L2 VM. As a result, the L2 VM generated a large number of NPT violations and VM exits during boot.

For BitVisor, in contrast, the overhead of NPT virtualization was smaller because BitVisor could assign 2-MB huge pages to the L2 VM. However, it encrypted a 10-MB Linux kernel image and a 100-MB initial RAM disk using the relatively slow AMD-SP. Therefore, the boot time was 4.1x longer in SEV_0 virtualization. If BitVisor encrypts only the hash values of the kernel and the initial RAM disk using the AMD-SP and lets the firmware verify them, as implemented in KVM [34], this overhead could be reduced.

SEV-SNP slowed down the boot of the VM because the VM had to validate assigned memory using the `PVALIDATE` instruction. OVMF validated approximately 2 GB of memory in advance, while the Linux kernel validated the remaining memory on demand in 2-MB units. In this experiment, the kernel validated approximately 800 MB of memory. As a result, SEV-SNP virtualization significantly degraded boot performance. In particular, BitVisor exhibited the longest boot time. The reason is that BitVisor validated the entire memory of the L2 VM during boot. In addition, the custom firmware did not assign huge pages to the L2 VM, which further increased the overhead of NPT virtualization.

In contrast, SEV passthrough was comparable to single-level virtualization. In KVM, the boot time increased by only 12% and 49% for SEV_0 and SEV-ES, respectively. This is because the L1 hypervisor could assign 2-MB huge pages to the L2 VM, thereby reducing the overhead of NPT virtualization.

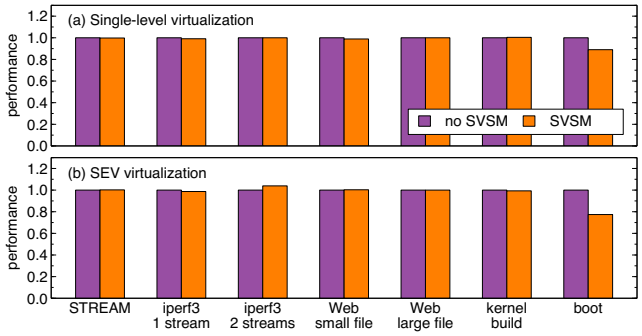

Figure 14: Performance with SVSM enabled.

For SEV-SNP, the boot became 1.6x faster than in single-level virtualization. The reason is that the L1 hypervisor could use 1-GB huge pages, which further reduced the overhead of NPT virtualization.

7.7 Impact of SVSM

We conducted experiments on SNP-enabled VMs running SVSM under single-level virtualization and SEV virtualization with KVM. Figure 14 shows the relative performance in the five experiments described above, using performance without SVSM as the baseline. Except for the boot time, SVSM had little impact on performance. In contrast, the boot performance degraded by 12% and 29% in single-level virtualization and SEV virtualization, respectively. The reason is that the guest OS needed to invoke SVSM to validate memory in VMPL0. The overhead was larger in nested virtualization because each SVSM call required a VM exit to the L0 hypervisor and the execution of `VMRUN` to enter the L1 VM.

7.8 Discussion

SEV virtualization assumes a stronger threat model in which neither the L0 nor the L1 hypervisor is trusted, while SEV passthrough assumes a weaker threat model in which only the L0 hypervisor is untrusted. SEV passthrough consistently performs better for VM exits and the boot time of L2 VMs. For the other workloads, however, a faster mechanism depends on the SEV variant and the L1 hypervisor. Note that SEV passthrough remains useful even when its performance is lower than that of SEV virtualization. This is because several features, such as VM introspection [15], are possible only with SEV passthrough.

For SEV variants, the threat model becomes stronger in the order of SEV_0, SEV-ES, and SEV-SNP, but performance does not necessarily decrease in this order. Since a stronger threat model does not always result in lower performance, users need to select an appropriate SEV variant based on their workloads. For example, they may prefer SEV-SNP for network-intensive workloads. Although SEV-SNP generally outperformed SEV-

ES, the boot time was much longer in SEV-SNP virtualization. When users need to boot L2 VMs frequently, they may choose SEV-ES virtualization if its threat model is acceptable.

Hecate's threat model is similar to that of SEV passthrough. Compared with the performance results reported in the literature [16], SEV passthrough incurs lower overhead for VM exits, while Hecate achieves better performance in network communication and Web access. Direct comparison is difficult because the experimental conditions differ, but Hecate could reduce overhead by supporting only a single L2 VM. The threat model of Microsoft's patch is similar to that of SEV virtualization, except that the L1 hypervisor must trust the L0 hypervisor. Therefore, its threat model is weaker than that of SEV virtualization. The performance results for Microsoft's patch have not been reported, but it is expected to outperform SEV virtualization because the L0 hypervisor can directly access the memory and register state of the L1 VM to virtualize the L1 hypervisor. However, the additional overhead in SEV virtualization is necessary to protect the L1 hypervisor and ensure the correct execution of L2 VMs.

8 Related Work

Microsoft's patch [40] runs KVM as the L1 hypervisor on top of Hyper-V and enables only SEV-SNP for L2 VMs. Like SEV virtualization, the L0 hypervisor provides a virtual AMD-SP and a virtual RMP to the L1 VM. However, the patch cannot protect the L1 hypervisor against the L0 hypervisor because it cannot apply SEV-SNP to the L1 VM. Therefore, it assumes that the L0 hypervisor is trusted. Since the L0 hypervisor can directly access the memory of the L1 VM, support for SEV-enabled L2 VMs can be implemented more easily.

Hecate [16] also runs KVM as the L1 hypervisor on top of Hyper-V but enables SEV-SNP for both L1 and L2 VMs. Its purpose is to run a legacy guest OS without SEV-SNP support in an L2 VM. Unlike nested SEV, Hecate can support only SEV-SNP because it is implemented using VMPLs. In addition, it cannot run multiple L2 VMs in an L1 VM due to the lack of support for MMU virtualization in VMPLs. Since the L1 hypervisor runs at the highest privilege level, L2 VMs cannot be protected from the L1 hypervisor. This trust model is the same as that of SEV passthrough, but Hecate cannot support the stronger trust model assumed by SEV virtualization. OpenHCL [37] is similar to Hecate and offers various services, such as device emulation, via paravisor running in VMPL0. It supports not only SEV-SNP but also Intel TDX [25].

SGX virtualization [22] has been proposed to use Intel SGX [32] in VMs. SGX is another TEE and enables a process to securely execute code in a protection domain called an enclave. SGX virtualization exposes only a portion of the enclave page cache to a VM and emulates the `CPUID` instruction and MSRs. However, SGX cannot be used in confidential VMs protected by TDX. NestedSGX [46] enables applications to use SGX-compatible enclaves in confidential VMs protected by SEV-SNP. It securely runs enclaves in VMPL0 while running the untrusted parts of the application and the OS at a lower privilege level. vSGX [48] emulates SGX-compatible enclaves in a VM by leveraging another SEV-enabled VM.

Nested enclave [39] can run inner enclaves in an SGX enclave. An outer enclave cannot access its inner enclaves, while an inner enclave can access its outer enclave. Each inner enclave is isolated from other inner enclaves. For example, nested enclave can be used to protect an application from untrusted third-party libraries in an enclave. Unlike nested SEV, it requires extensions to SGX hardware.

Ryoan [23] creates an SGX enclave in clouds and constructs a sandbox inside it using Google NaCl [18]. NaCl verifies the code executed in the sandbox and performs runtime checks to securely run cloud services. Similarly, AccTEE [17] constructs a bi-directional sandbox inside an SGX enclave using WebAssembly [20]. Like NaCl, WebAssembly enables code to run inside the sandbox. In nested SEV, an SEV-enabled L2 VM can be used as a sandbox to isolate untrusted code.

9 Conclusion

This paper proposed nested SEV to provide secure and generic SEV support for nested virtualization. Nested SEV supports two trust models that differ in whether the L1 hypervisor is trusted. To support these trust models, it provides two mechanisms: SEV virtualization and SEV passthrough. These mechanisms rely on two techniques called emulation-less multiplexing and SEV context decoupling. Nested SEV supports three SEV variants and enables users to balance security and performance. We implemented nested SEV using KVM, BitVisor, and Xen (paravirtualization) as L1 hypervisors. We conducted experiments to evaluate the overhead of nested SEV and showed that the average performance degradation ranged from 0.9% to 30% across SEV variants and L1 hypervisors.

One direction for future work is to improve the performance of nested SEV, particularly its network performance. Another is to extend our approach to Intel TDX and validate the generality of the design of nested SEV.

μUSB: Practical and Safe USB Driver Reuse for Arm TrustZone

Abstract

TrustZone isolates device access with secure I/O, yet lacks support for USB devices, which constitute the most diverse peripherals. Existing approaches to integrate USB drivers into the TEE are impractical due to the complex USB protocols, high-frequency DMA accesses, and varying vendor implementations.

In this paper, we present μUSB, a system that derives a functional, *micro* USB driver for TrustZone from the observable concrete execution traces of a full-fledged, complex USB driver, an approach we dub *record, lift, and replay*. Based on the key insight of kernel specialization and the deterministic nature of USB FSMs, μUSB proposes a lightweight mutational recorder and a novel program analysis technique, addressing two challenges: how to record USB execution sufficiently and analyze the traces deeply?

Across four major USB classes and six diverse devices, μUSB generates performant, ready-to-use USB drivers for TrustZone, enabling in-TEE apps to, for the first time, leverage complex USB devices with near-native performance while still enjoying full TrustZone protection.

1 Introduction

TrustZone is the Trusted Execution Environment (TEE[1]) for Arm devices, widely deployed on mobile/embedded System-on-Chips (SoCs) [29, 7, 1]. TrustZone partitions the execution environment into two hardware-isolated worlds – the normal and secure world, with the latter executing a fully shielded baremetal kernel (e.g., OPTEE-OS [54]), independent of the normal world OS. Beyond CPU, secure world's protection further extends to I/O, providing a security feature known as *secure I/O*. It allows the TEE software to interact directly with I/O devices for data harvesting and processing, while ensuring confidentiality and integrity even under a compromised OS. This capability underpins security-critical, in-TEE *trusted apps* [20] demanding stringent protection of sensitive data such as biometric authentication [1, 25], credential management [29, 90], data analytics [85], and model inference [63].

*These authors contributed equally to this work.
✉: Liwei Guo (lwg@uestc.edu.cn) is the corresponding author.
[1]This paper refers to the TEE as TrustZone, which is our focus.

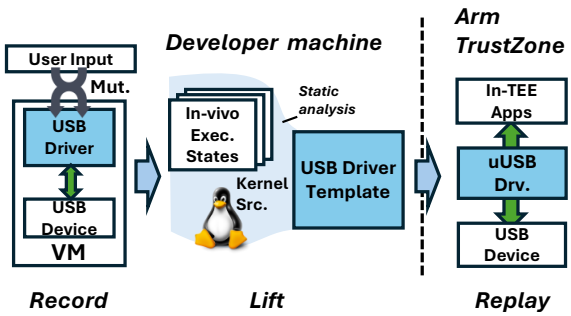

Figure 1: The overview of μUSB.

Secure I/O, however, lacks critical support for USB devices. As the most diverse class of I/O peripherals, they handle data *virtually* from all sources, e.g., from various sensors (including keypads and mice) to multimedia devices such as cameras and microphones; supporting them would bridge existing trusted apps on a Commodity-Off-The-Shelf (COTS) mobile SoC to a much broader range of *trusted* data sources, and empower more trusted apps. For instance, with TEE-protected USB sensors, a trusted app at the edge executing stream analytics [85] directly operates on trusted raw ingress sensor data; it does not relay any requests to an untrusted normal world OS, which is buggy [77, 66, 72] and may be malicious [14].

Yet to close the gap, the key missing link is USB device drivers inside the TrustZone TEE. To the best of our knowledge, no commodity TEE OS supports them to date: 1) commercial TEE OSes such as Android Trusty [29], Qualcomm QSEE [7] and Huawei iTrustee [1] scope their secure I/O support to a few selected proprietary devices, e.g., RPMB storage [47], fingerprint sensors [1]; 2) open-source TEE OSes (e.g., OPTEE-OS [54]), which are incorporating more emerging I/O device drivers (e.g., GPIO [4], SPI [5]), still have no plans for USB despite the first USB feature request dating back to 2017 [6]. As we will show in Section 2.2, it is likely due to a combination of large efforts required to support them and their security implications to the TEE.

How to bring USB drivers into the TEE? One may reuse existing Linux driver code, either wholly (e.g., porting [87, 44]) or partially [31, 110]. Nevertheless, this approach misfits USB drivers which are diverse, complex, and with deep kernel dependencies: porting incurs non-trivial manual efforts, bloats the Trusted Computing Base (TCB), and infects TEE with

kernel bugs which we quantitatively analyze in Section 6.2; partitioning [110, 31] needs to reason about the partitioning boundary which spans over a few thousand kernel functions of major kernel subsystems, and is known challenging [48, 14, 35, 53]. Instead of code, one may opt to reuse driver/device interactions by recording the low-level interaction events induced by a given I/O job and replaying them at run time [32, 83, 106, 56]. This route, however, is difficult too. First, recording by *manual annotations* [83, 106, 56] is tedious and error-prone, where USB drivers exploit in-memory data structures and massive pointer accesses for device interactions; a single missed annotation may result in incorrect results. Second, recording by *symbolic tracing* [32, 16] is unsuitable, because many USB devices interact with drivers through high-frequency (e.g., over 100K per I/O job) *isochronous transfers* bound by strict timing intervals. The high tracing and analysis overhead incurred by a complex symbolic/concolic execution engine (e.g., S2E [17]) is intolerable to such devices and triggers persistent time-outs, as we will discuss in detail in § 2.

Our approach. In light of these, we ask a natural question: can we record USB driver/device interactions *concretely*, and later generalize them for runtime reuse, purely based on these concrete interactions? To answer it, our key insight is that while a full USB driver is complex, its low-level interactions for a specific I/O function follow a highly deterministic *beaten* path, which allows us to sidestep its full complexity.

To this end, our approach adopts a simple idea – *record, lift, and replay*: for a desired USB I/O function, we *in vivo* record the *concrete* low-level USB driver/device interactions, *ex vivo* lift them into a *symbolized* USB driver template, and replay the template with dynamic input at run time to realize the same I/O function. Figure 1 shows the approach overview.

Benefits. Our approach enables *practical* and *safe* USB driver reuse: the developer only needs to specify the desired USB I/O function (e.g., audio record/playback) and corresponding inputs, just as she would expect to use the USB device in TEE, and our system instantly generates the corresponding ready-to-use driver template, faster than driver porting or refactoring, as will be shown in § 6.2; the driver template dictates sequential, replayable low-level driver/device interactions, which precludes kernel code and potential vulnerabilities contained within it (e.g., 0-days).

Challenges. To *record, lift, and replay*, we face two major challenges. First, how to record necessary and sufficient *in-vivo* execution states from USB driver executions? As mentioned earlier, USB driver/device interactions are dominated by high-frequency DMA accesses, where many allocated addresses/parameters vary dynamically over time. A successful recording must capture such accesses completely and promptly: it does not disrupt USB execution; it preserves sufficient information to allow faithful reconstruction of the USB I/O function which tolerates runtime variations. Second, how to lift the concrete traces into templates which accept dynamic inputs at run time? The process essentially recovers the dependencies and constraints missed from concrete traces back to their symbolic and programmatic form. Doing so soundly requires high-fidelity and deep static analysis. However, such analysis is known difficult for the complex kernel code [112, 12], which exploits wild pointer conversions and recursive data structures (e.g., a self-referencing page struct).

μUSB. Towards practical and safe USB driver reuse, we present μUSB, a system which has addressed the aforementioned challenges by employing a suite of novel techniques. For recording necessary and sufficient execution states, μUSB employs a *mutational recorder* in a lightweight VM that captures complete hardware I/O traces without disrupting the timing-sensitive USB protocol. In addition to user-supplied concrete input, the recorder automatically mutates these inputs using a set of mutation rules designed to make mutated inputs closely approximate the *valid* inputs of the recorded I/O function. With the new inputs, it then re-records the I/O function to gather more traces, until they converge structurally (i.e., isomorphically) with the same I/O function.

For automatically lifting concrete traces into templates, μUSB integrates and extends two successful program analysis techniques and proposes *symbolic trace differential analysis* and *qualified taint tracking*. With simple heuristics, the former effectively filters out and symbolizes concrete values that *may* change during execution (e.g., a virtual address), whereas the latter is a form of trace-guided analysis that leverages the recording as an oracle path qualifier to make a deep, high-fidelity (i.e., context-, path-, flow- and field-sensitive) data-flow analysis on complex kernel code scalable and precise. The two novel techniques harmonize in exploiting the inherent invariance and variability of the deterministic USB FSM to produce the USB driver template used for replay, which at a high level specifies the behavior of the USB driver – *when* should *which* data go *where* in *what* format.

Results. We apply μUSB to four important USB classes (i.e., Mass Storage, Audio, Video, HID) encompassing six different devices from five different vendors, whose drivers were considered too complex for Arm TrustZone [110, 32]. With light efforts and basic knowledge of USB device internals, μUSB successfully produced eight diverse templates; each template comprises a vastly different number of events (e.g., from 1K to over 400K) and encodes necessary and sufficient dependencies and constraints to achieve its designated I/O functions. The resultant μUSB drivers have decent performance: on Raspberry Pi 5, a popular COTS Arm development board, and for the first time without a normal OS, the TEE software can read/write USB storage at 10-20 MiB/s (close to a full-fledged native driver), stream video at 30FPS, record audio reliably in real time, and receive keyboard/mouse inputs at low latencies.

Contributions. Our contributions are as follows:

• The design and implementation of μUSB, a novel *record, lift, and replay* solution to reusing mature USB device drivers for TrustZone. μUSB demonstrates: by combining concrete USB driver execution traces with simple static analysis, it is possible to reproduce and reuse complex USB I/O functions.

• Qualified taint tracking, a novel trace-guided static analysis technique that makes high-fidelity dependency recovery in complex kernel code practical and fast.

• A comprehensive evaluation of μUSB. By deploying μUSB on various USB devices (e.g., streaming webcam, speaker) on real Arm TrustZone-enabled hardware, we demonstrate the practicality and scalability of μUSB.

• Ready-to-use, performant μUSB drivers for TEE. To the best of our knowledge, it is the first time for complex USB device drivers to enjoy end-to-end TrustZone protection.

For a TrustZone TEE, μUSB [2] opens a new door to trusted apps accessing diverse USB devices.

2 Background & Motivations

2.1 A Primer on USB

USB protocol. Universal Serial Bus (USB) is the dominant peripheral interconnect standard, evolving from USB1.0 [102] to USB4.x [103]. To standardize peripheral-to-host communication, it provides two key abstractions. *Endpoints* represent data sources or sinks on a device and communicate with the host via logical channels called pipes. *Transfers* encapsulate communication between endpoints and the host, with four types defined according to data content and purpose: *1) control transfers* for device setup and configuration; *2) interrupt transfers* for regular, low-latency communication such as keyboards; *3) bulk transfers* for reliable, high-throughput exchange as in storage devices; and *4) isochronous (ISOC) transfers* for time-sensitive streaming with bounded latency, essential for multimedia devices. Through these transfer types, USB abstracts diverse peripherals into 25 device classes, e.g., Human Interface Device (HID), Video, Audio, Mass Storage.

eXtensible Host Controller Interface (xHCI). A host controller interface (HCI) implements the interface specified by the USB protocol for device interaction, including OHCI/EHCI, UHCI, and xHCI. This paper mainly focuses on xHCI, as it is the most recent and widely adopted standard [101]. Mandated by the specification, xHCI is architecture-independent and exposes a large group of memory-mapped registers for host configuration. These include *capability registers*, which report protocol information, and reference *operational registers* and *runtime registers*. The latter configure USB data transmission parameters at run time, e.g., data page size, and commands. Beyond registers, xHCI mainly manages USB transfers with in-memory data structures. It employs *Transfer Descriptors (TDs)*, each containing one or more *Transfer Request Blocks (TRBs)* depending on the transfer size and type, which refers actual data pages. All TRBs are organized within a ring buffer, the *Transfer Ring (TR)*.

[2]The code is at https://github.com/SECG-UESTC/uusb/

2.2 The USB Secure I/O Dilemma

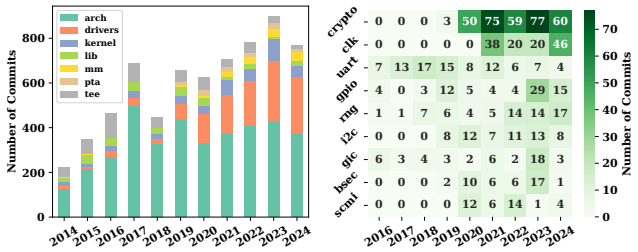
What USB devices matter for TEE? Following example trusted apps [20] motivate our design and benefit from TEE-protected USB devices: *1) Secure storage*: trusted apps manage sensitive data such as credentials [90], authentication tokens [29], and biometric data [1, 25]. They acquire/persist the data on storage. *2) Trusted perception*: they acquire sensor data [110, 56] for executing stream analytics [85] and NN inference [109, 97]; notably, multimedia data are often unencrypted thus cannot be exposed to normal OS. *3) Trusted UI*: they render privacy-sensitive contents, e.g. bank account; the UI reads in user inputs such as presses from a keypad or movements from a mouse. TEE needs to isolate input devices for confidentiality and integrity [82, 107].

Why TEEs lack USB support? Despite their strong use cases, USB support remains untapped by existing TEEs. We examine OPTEE-OS [54], TrustZone's reference secure OS, analyzing its development and commit history over the past decade (Figure 2(a)). The data reveals a clear upward trend in driver-related commits, which have doubled in recent four years, and now account for 35% of total commits. However, closer inspection shows that the majority (73%) target relatively simple character devices such as CRYPTO, UART, and GPIO which provide only basic I/O services (Figure 2(b)).

Why has USB remained overlooked by TEE, with no indication of future development? Our conjecture is twofold: *1) USB couples with heterogeneous and diverse standards.* Supporting different device classes (i.e., 25 in total) demands compliance with heterogeneous standards and class-specific encodings, e.g., video and audio codecs; bringing them into TEE is unwarranted. *2) The large USB software stack deters developers.* Existing in-TEE drivers are compact and simple (under 77k SLoC shown in Figure 2(b)). A single USB audio driver spans 245K SLoC (Linux v6.13), compared to only 300K SLoC for the entire OPTEE-OS; its dependencies span over 600 header files of tens of kernel subsystems (e.g., IRQ, DMA, file systems) accounting for additional 560K SLoC.

Why are existing approaches inadequate? We examine existing approaches which may bring USB drivers into TEE.

1. *Porting.* One may port the full or partial USB driver and shift them to the TEE, e.g., as a library OS [44]. This approach is unfit for the TEE, as it introduces a large and unwarranted USB driver along with its deep kernel dependencies to TEE (as discussed earlier). As will be shown quantitatively later, it incurs large manual efforts (§ 6.1), and inherits existing kernel bugs [67, 71, 75] (§ 6.2), which makes the TEE susceptible to attacks from malicious USB devices [57, 79].



(a) Yearly commits grouped by kernel subsystems from 2014.

(b) A breakdown of OP-TEE driver commits from 2016.

Figure 2: OP-TEE OS commits over the past decade.

2. *Partitioned execution.* Prior works [110, 22, 36] partition the existing drivers and execute only the security-sensitive code inside the TEE while leaving the rest to normal OS. Despite having less in-TEE code, it has two security issues. First, reliance on non-secure OS code expands TCB and exposes the TEE to Iago attacks [14], which compromises data confidentiality and integrity as USB devices commonly lack end-to-end encryption. Second, defining partitioning boundaries is challenging [48], as it requires extensive auditing of interfaces and data structures (e.g., USB TRBs, DMA descriptors, kernel pages) that may handle USB data, which likely results in a major overhaul of USB drivers and kernel code.

3. *Record-and-Replay (RnR).* As old wisdom among software testing [26, 111] and bug finding techniques [23, 33], it recently proves effective for TEE driver reuse, e.g., for simple I/O devices [32, 106, 56], GPUs [83]. Its key idea is to record the driver/device interactions in a commodity OS and replay them in TEE. To record, they either manually annotate the kernel driver to instrument software/hardware interactions [83, 106] or symbolically trace these interactions using a symbolic/concolic execution engine [32, 16].

However, both recording methods are inadequate for USB devices. As mentioned earlier, USB primarily uses fine-grained DMA accesses for driver/device interactions [41], which does not retrofit kernel register accessors (e.g., `readl`, `writel`) and differs from GPUs [83] and other I/O devices [56, 106]. Manually instrumenting these DMA accesses hence is tedious and fragile, and incurs prohibitive efforts when scaling across diverse USB devices and classes. Conversely, symbolic tracing alleviates this instrumentation burden but is too heavyweight for the USB protocol – the USB device times out and halts if an interaction misses its timing (e.g., 1ms interval of isochronous transfers), which is hard, if not impossible, for a symbolic/concolic execution engine to keep up with. Therefore, driverlet [32] as a notable representation of this approach, only supports USB bulk transfer which tolerates analysis delays but does not work for other transfer types. Furthermore, even for USB storage, it needs to explicitly disable Start-of-Frame as a workaround for EHCI protocol's timing control, stated in its § 7.2.2.

2.3 Goals, opportunities, and choices

Design goals. To extend TEE protection to USB for COTS SoCs at a low cost, we set the following goals.

- **Practical.** It is our top concern. The system shall scale to major classes of USB devices (e.g., audio/video) which have important I/O functions with little to no manual effort.
- **Safe.** USB drivers execute entirely inside the TEE to leverage secure I/O, and remain safe against a malicious USB device.
- **Performant.** Multimedia devices often have real-time data transmission, e.g., microphones stream audio samples at constant rates for sound quality. The system and the drivers must deliver deployable and usable performance.

Observations. We have exploited the following observations.

– The beaten USB FSM state transition path. The USB FSMs are by design deterministic and largely data-independent [104, 102, 103]. For a given I/O function and fixed inputs, the USB device's internal FSM follows the same, *beaten* state transition path; conversely, driving the device to go through the same path reproduces the same I/O function.

– Architecture-independent USB driver/device interactions. Operating a USB device entails driver–host controller (xHCI) interaction via MMIO, DMA and interrupts, with architecture-independent data structures and register specifications designed for scalability across platforms.

– Limited dynamism of trusted apps. Trusted apps (§ 2.2) are statically bound to TEE, constraining the USB usage: the TEE expects persistent USB device connection (e.g., no hotplug); they demand I/O data, which can be served with corresponding I/O functions without complex and dynamic device features, e.g., power management.

Design choices. The above observations and goals motivate our design choices: (1) prioritize specific USB I/O functions over full device features for practicality; (2) decouple analysis from USB driver execution by *in vivo* recording concrete execution states, and by *ex vivo* analyzing concrete recordings exploiting the deterministic, beaten USB FSM path.

3 Design Overview

3.1 System model

Threat model. We follow the threat model of TrustZone and USB security [31, 42]. We trust the Arm SoC hardware, including TrustZone Address Space Controller (TZASC) and TrustZone Protection Controller (TZPC), and firmware enforcing the secure/normal world isolation. We trust the secure world software, including the TEE kernel and trusted apps. We do not trust the normal world OS, which may probe or tamper with USB data. Physical attacks [45, 34] are out of scope.

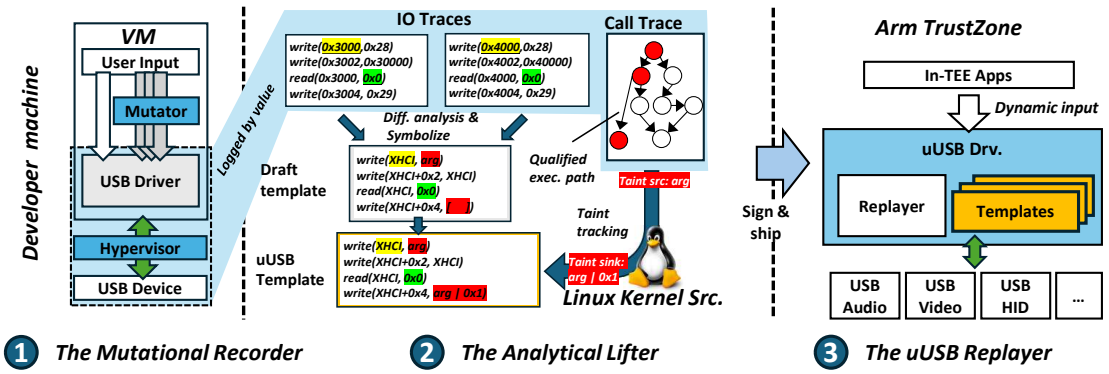


Figure 3: Overall workflow of μUSB

We assume software and hardware on the developer's machine used for recording are trustworthy, including the OS, USB devices and drivers. We also assume that the recorded USB drivers are *gold*: they implement sufficient driver/device interactions, so that it can assess if the device has finished the state transitions needed by given requests. Our rationale is similar to other recording-based TEE drivers [32, 83, 84, 106].

Targeted USB devices and SoC hardware. We target mobile/embedded Arm SoCs with TrustZone enabled. We focus on USB I/O devices with strong TEE use cases (§ 2.2). These devices handle sensitive user data but lack end-to-end encryption at the protocol layer. We do not target USB networking or hub devices, as their safety can be complemented by protocol-level encryption [92]. We also do not consider USB gadgets due to unclear TEE use cases. The SoC has multiple instances of the USB host controller, which is a common practice in today's SoCs [21, 3]. By configuring TZPC and TZASC, the TEE exclusively owns one instance of the USB host controller.

3.2 μUSB overview

Our key idea is to specialize a TEE USB driver for specific I/O functions by ex vivo deriving a *micro USB* (μUSB) driver from the concrete in-vivo execution of a mature kernel driver. Figure 3 shows workflow. The core mechanism is as follows.

1. *Mutational Recording.* The developer invokes the USB IO function desired by trusted apps with concrete inputs, e.g., `read 10 blocks from sector 0`. μUSB mutates the inputs, invokes the same I/O function for multiple times, and logs complete interaction events from the USB driver, including register/DMA accesses, interrupts, and kernel inputs.

2. *Static Lifting.* μUSB processes traces logged from multiple concrete inputs into a template which adapts to dynamic inputs at run time: it detects variables and symbolizes them by differentially comparing their values across traces; it uses traces to *qualify* taint analysis for distilling dependencies and constraints between variables. The lifted template comprises a sequence of low-level hardware/software interaction events (e.g., MMIO, IRQs) required to complete the specific I/O function, which precludes the original kernel code.

3. *Runtime Replay.* μUSB signs and ships the template to TEE as the ready-to-use μUSB driver, which exposes a simple interface to trusted apps for requesting I/O data. Upon request, the μUSB driver replays the events in the template sequentially with runtime inputs, e.g., `read X blocks from sector Y`. A faithful replay fulfills the same recorded I/O function while adapting to various dynamic inputs.

Applicability to other TEEs. A μUSB driver relies on secure I/O provided by TrustZone for strong protection but is not strictly limited to it. It also supports other TEEs providing similar features. For instance, AMD SEV-SNP uses SEV-TIO (i.e., Trusted I/O) [9], similar to TrustZone's secure I/O; RISC-V's Keystone TEE [46] combines PMP (i.e., memory/register isolation) and processors M-mode to achieve secure I/O.

3.3 Why μUSB works

Understanding μUSB drivers at a high level. Based on our rationale of the USB device FSM (§ 2.3), a USB device generalizes as a set of deterministic FSM state transition paths, which collectively fulfill the I/O functions of the device. The corresponding full USB driver hence can be regarded as *traces* of low-level device interactions, i.e., MMIO, DMA, and IRQs; each trace 1) drives the device state transitions of a path, and 2) also assesses if the transitions are correct. A μUSB driver captures a subset of full traces by recording low-level interactions from demanded I/O functions; replaying the trace drives the device FSM to go through the same state transitions to fulfill the recorded I/O function. The appendix presents a sketch proof showing a μUSB driver achieves trace equivalence with its recorded USB driver under the same I/O function.

Replay correctness. The μUSB driver offers the same level of correctness guarantee as a kernel driver does: the μUSB replayer's assertion that a recorded I/O function (e.g., read/write a block, streaming audio for some interval) has completed successfully is as sound as the assertion from the kernel driver.

Our rationale is: the full driver continuously assesses if state transitions are correct via low-level interactions. By recording

Recorded Interaction Events and Formats			Description
I/O events	DMA/ MMIO	write(**addr**, **val**, **len**)	Write len bytes of val to addr
		val = read(**addr**, **len**)	Read len bytes of val from addr
	IRQ	on_irq(**n**)	Receive an IRQ at n-th interrupt line
Kernel Inputs	Clock Inputs	**ts** = ktime_get_real/raw/current()	Get current timestamp ts
	DMA Buffer Allocation	**addr** = dma_alloc_coherent (dev, **size**, handle, gfp)	Allocate size bytes of DMA buffer at addr
	Random number	**num**=random()	Generate a random number num

Table 1: Events recorded by μUSB. μUSB records **highlighted** fields by value.

and matching these interactions, the μUSB driver also asserts execution correctness of the I/O function. During replay, if it observes the same trace of interactions with all parameters matched, then to the best of the driver's knowledge, the USB device performs the same state transitions and completes the same I/O function, and the replay is correct.

At a higher level, μUSB resembles duck typing [55] for USB driver construction: upon user inputs, a μUSB driver executes as a USB driver; upon device inputs, it reacts as a driver; then it must be as correct as a driver.

4 μUSB Design

4.1 The Mutational Recorder

The recorder records the *in-vivo* execution states of the USB driver by value as the basis for the template. To this end, we have addressed two challenges: 1) how to capture *necessary* interaction events to faithfully reconstruct the execution states needed to recover USB driver execution? 2) how to obtain *sufficient* concrete values such that the lifter can distill data dependencies and symbolize them for dynamic inputs?

4.1.1 Record necessary in-vivo execution states

To initiate, the developer launches a *recording campaign* by invoking the entry function provided by the recorder on the developer's machine: `record(f, [arg...], [var...])`, where `f` is the desired USB I/O function (e.g., `read/write` for USB storage), `[arg]` is an array of concrete inputs needed by `f`, and `var` is a binary array indicating which arguments in `[arg]` accept dynamic inputs at run time. More I/O functions recorded by μUSB are in Table 4.

What to record? Two types of runtime traces are necessary: **1) I/O traces:** these include the low-level USB driver/device interaction events, i.e., xHCI register and DMA accesses, and interrupts; **2) Kernel inputs:** USB devices rely on inputs from a few kernel APIs to alter states. For instance, its device FSM expects a DMA buffer from kernel to initiate data transfer. The recorder logs their arguments and return values in the I/O trace; Table 1 summarizes all observed kernel inputs.

The recorder additionally captures call traces. Section 4.2 demonstrates existing static analysis is infeasible for the lifter to analyze kernel deeply and precisely without them.

How to record? The recorder must capture complete traces. It is challenged by USB's high-frequency pointer-based DMA accesses (e.g., 10KHz) whose strict timing must be respected. To address this, μUSB records the USB driver execution in a controlled, lightweight virtual machine, and traces I/O at the lowest level via stage-2 page faults. Specifically, the recorder compiles the guest kernel using tinyconfig and enables only necessary USB drivers. It configures the hypervisor to monitor: 1) interrupts and 2) memory regions belonging to USB host controller and 3) DMA pools allocated to USB; tracing extra regions adds overhead and may interfere with USB execution. The recorder thus transparently traps these I/O events and records them by value in the format given in Table 1.

An alternative is to trace via stage-1 page faults, which was our initial attempt. To our surprise, their latency exceeds the USB isochronous transfer interval, which is erroneous and causes the USB transfer to abort; we will show measurements in Section 6. During recording, the recorder logs the I/O events sequentially and segregates them into two contexts (i.e., the CPU and the interrupt context) to match the asynchronous USB job submission/execution.

4.1.2 Mutational recording

Relying on a single trace is brittle, as many values and events are timing- and input-dependent. To accommodate input and runtime variations, our idea is to reveal such dependencies and variability *proactively* by stress testing the given I/O function with *mutations* which approximate these variations.

Mutation strategy. In addition to recording using the user-supplied input, the recorder mutates inputs in two dimensions and re-records. *First, on user inputs*. The recorder mutates all inputs which the user expects to use dynamically at run time, i.e., specified by `[var]` of the recording entry. As explained earlier, the recorder does not aim for code coverage (i.e., desired by an OS fuzzer [42, 86]) but to approximate input variations under the same I/O function. It hence adopts simple, semantic-aware mutators in Table 2 to generate more user inputs for all `arg[i]`, if its corresponding `var[i]` is true (i.e., variable at run time). *Second, on kernel inputs*. The recorder exploits Kernel Address Space Layout Randomization (KASLR) default in today's kernel and restarts the VM between each re-run for a clean-slate kernel state. This helps expose those DMA addresses which appear identical across different runs but are in fact recycled.

Stop condition. During operation, the recorder gathers a *reference trace* from user-supplied input, and additional *mutated traces* from extra runs. The recorder decides to stop upon two conditions. *First, the traces converge*. It deems the exploration sufficient if after N runs, the majority of mutated traces are isomorphic (i.e., structural equivalence [15]) to the reference trace, where the trace lengths, the ordering and types of the events are identical. N is a user-configurable parameter and is at least 10. Larger N (e.g., 100) is fine but incurs longer

Type	Mutator	Example user input fields
Arithmetic (dec/inc)rement	(dec/inc)rement 1,2,3,…,10, 64,128,256,1024	**Storage**: sector, len **Audio**: record/playback duration **Video**: # of requested frames
Address shuffling	Shuffle address space & supply a new buffer	**Storage/Audio/Video/HID**: data buffer address
Random configuration	Randomly sample from valid configurations	**Audio**: sampling rate, audio encoding **Video**: resolution, video encoding

Table 2: Mutation strategy defined by μUSB recorder.

delays as the recording is sequential to ensure determinism; it does not bring additional benefits, for our evaluations in Section 6.3.3 show that as few as six runs is sufficient. *Second, recording times out*. The traces may never converge, due to excessive mutable inputs. For example, the developer specifies all arguments `[sector, blk, buf]` of `read` I/O function as mutable. This apparently will not converge, as allowing *all* inputs to be mutable requires exploring the full driver state space. To deal with such cases, the recorder sets the default timeout to 10 minutes. After timeout, it stops recording and prompts the developer to reduce the number of mutable input in $[var]$, i.e., reducing the size of state space to explore. In practice, we have not found a case where traces do not converge when the number of mutable input reduces to one. This is because in such a case, the mutable input has to be a runtime buffer address, changing which is expected by the USB FSM and still follows the same I/O transition beaten path (§ 2.3).

Recording outcome. Upon completion, the recorder gathers an enclave of runtime traces in a recording campaign, including a reference trace and several mutated traces. These traces capture concrete and varying values, but are structurally equivalent, suggesting a sufficient exploration of the USB device state transition path determined by mutable user inputs.

4.2 The Analytical Lifter

The lifter is the core to μUSB, which distills concrete recordings into a replayable template. To this end, we have addressed two challenges: *given a corpus of concrete execution traces, how to 1) identify the variants (i.e., values that change w.r.t. new inputs) and 2) recover their data dependencies?*

4.2.1 Symbolic differential trace analysis

To generalize to dynamic inputs, the first step is to locate *variants* from concrete I/O traces. A central difficulty is that invariants and variants in I/O traces can appear identical. For instance, a SCSI `read(10)` CMD (0x28) appears no different than a block count or sector number.

To address this, our observation is that invariants capture the constants (e.g., commands) and substructures (e.g., linked lists) preserved across traces, while the variants reflect the input-induced divergences. The lifter thus exploits such inherent dichotomy by differentially comparing the traces.

First, symbolizing addresses and inputs. For a concrete trace, the lifter instantiates three symbolization rules for i-th event $v_i = E_i(args, ...)$ of the trace:

Rule 1 (indexed symbols). Base addresses of USB host controller and allocated DMA buffers are assigned unique symbols w.r.t. their sizes and respective indices i; user inputs, and all v_i returned by kernel inputs and DMA/MMIO reads are assigned unique symbols w.r.t. their indices i.

Rule 2 (address matching). All concrete addresses, i.e., DMA/MMIO read/write addresses, are symbolized by relatively addressing their closest base address.

Rule 3 (argument matching). Concrete values $args$ consumed by MMIO/DMA writes are symbolized by relatively addressing known symbols which prioritize addresses.

To justify, rule 1 first addresses four intuitive sources of variants: device/DMA addresses, inputs from kernel, device, and users (Table 1); the naming allows unique references from other variants within the trace and differential analysis across traces. Rule 2 associates values *known* to be virtual addresses (e.g., USB MMIO read) with already symbolized base addresses. Rule 3 handles the tricky case where a kernel input or address is used as an argument, by conservatively assuming all arguments are variants and associating them with existing symbols. The rationale for the value matching heuristic is that a USB device often uses kernel inputs (i.e., timestamps, random numbers) *as-is*. This may introduce false positives (e.g., a static encoding or a timestamp coincides with a DMA address) but the key is not to leave out true positives. The lifter filters false positives as follows.

Second, detecting invariants differentially. The lifter sequentially scans each I/O trace and creates key-value pairs `<var, [val]>`, where `var` is a symbolized variant and `[val]` is a list of symbols and concrete values (i.e., not symbolized by rule 1-3) associated with the variant in a DMA/MMIO read/write. It detects invariants by differentially comparing the reference trace with all mutated traces: a `val[i]` is an invariant *if and only if* its counterparts of mutated traces are symbolically or numerically equivalent. Figure 4 shows an example: `var_4k_2` and 0xd0 are invariants corresponding to `var_4k_1` and `var_4k_1+0x8` if and only if `var_4k_1` and `var_4k_1+0x8` *always* writes `var_4k_2` and 0xd0 across all traces. It also resolves false positives: as the recorder restarts VM and leverages KASLR (§ 4.1.1), it is unlikely for kernel inputs to persistently coincide with address reads/writes.

At first glance, this approach may appear ad hoc or unsound, i.e., dependent on number of traces, may miss some variants, etc. We highlight the lifter's goal is not to identify *all* variants but only those observable under variable inputs. We argue that these values subject to change would have changed and been captured during the mutational recording (§ 4.1.2). In practice, we find the strategy effective and fitting for USB I/O

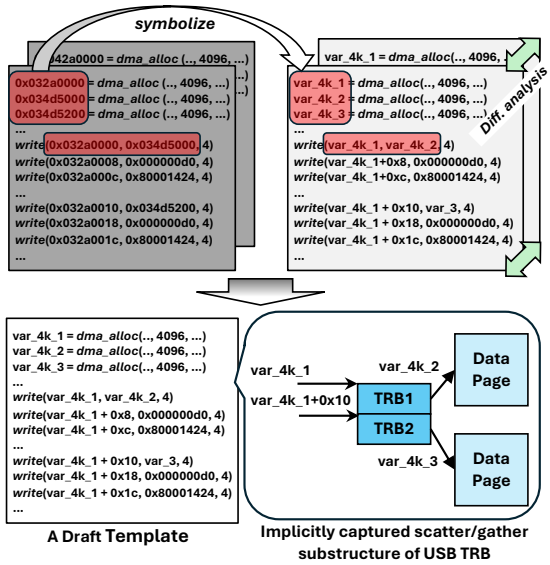

Figure 4: µUSB reconstructs the scatter/gather substructure of TRBs via differential analysis with the simple heuristics.

events, which are highly deterministic. Figure 4 demonstrates this by showing that the actual USB driver sets up TRBs in the TR for submitting I/O jobs with a sequence of DMA writes. With our technique, the lifter identifies the invariants and preserves the substructure, which implicitly reconstructs the same scatter/gather topology of TRBs when being replayed. Section 6.3.3 quantitatively shows the impacts of the number of traces.

Third, generating a draft template. The outcome is a draft template built upon the reference trace: addresses are symbolized canonically; the invariants are preserved as-is, either as symbols or concrete values; kernel inputs are symbolized with best efforts and remaining variants are marked as placeholders for further analysis.

4.2.2 Qualified taint tracking

Variants in the draft template are critical to the USB driver execution, which often involves data transformations (e.g., DMA address alignment) dictated by the driver and hardware specifications. The lifter must resolve their dependencies with user/kernel inputs and bind them with path constraints conforming to the driver behavior. While a high-fidelity static data-flow analysis (i.e., path-, context-, flow-, and field-sensitive) could theoretically resolve the issue, this method is unscalable for complex kernel code due to state explosion[112, 17].

To overcome this, our insight is to specialize the data flow analysis using the call traces collected along with I/O traces (§ 4.1.1) as the sharpest data flow information to *qualify* possible data flows of kernel code paths, i.e., a unique solution to the qualified data flow problem [37]. We present *qualified taint tracking* as follows.

The lifter sets all inputs (i.e., mutable arg of the recording entry, kernel inputs, and read from device states) as taint sources and the driver code which consumes them as sinks. For taint rules, the lifter adapts existing standard rules from [58] and introduces two crucial extensions: 1) since existing taint rules only concern taint propagation in the kernel space, it extends them to allow taints to propagate in field level across the user/kernel boundary through kernel utility functions such as `copy_from_user`; 2) to maintain field-sensitivity for recursive data structures like linked lists (a known challenge for static analysis [112]) for chaining URBs (i.e., the upper-layer kernel abstraction for TRB), the lifter introduces trace-guided alias analysis. Essentially, the improved alias analysis leverages the draft template as an oracle and determines if an object (e.g., URB) is an alias of another from its symbolized address encoded in the draft template. To track taint propagation, the lifter navigates the analysis with the call trace as a path qualifier: at control-flow branches (e.g., `if` statements), it chooses the path suggested by the call trace, and checks if the corresponding path condition is dependent on a tainted value. If so, the lifter collects the path condition as a constraint of the tainted input, which ensures the execution stays on the USB state transition beaten path. Since the analysis is static, the lifter saves these constraints symbolically in the final template. Alongside the taint propagation, the lifter accumulates the taint operations and saves them to generate the final template. We discuss the security implication in Section 6.2.

By design, a taint sink (i.e., a variant) corresponds to at least one taint source. However, if a variant depends on kernel inputs unlisted in Table 1, it cannot be correlated to a taint source and is untagged. To address this, the lifter marks the variant as a taint source, consults the call trace to perform *backward* qualified taint tracking, and adds the taint sink (i.e., a kernel input) to Table 1. The lifter then prompts the recorder to re-record leveraging the newly discovered kernel input. This efficiently and effectively recovers the dependencies and constraints missed from the draft template. For common USB devices (e.g., storage/video/audio/HID), the lifter does not conduct backward taint tracking, as the events in Table 1 are sufficient; nevertheless, we design the mechanism to cover emerging USB devices that may require more events to trace.

4.2.3 Generate the final template

To generate the final template, the lifter simply assigns a symbolic expression to each taint sink (i.e., a variant). The symbolic expression programmatically captures the series of computational operations originated from the variant's original taint sources (e.g., user or kernel inputs), as a result of qualified taint tracking.

Optimization: Loop re-rolling. Multimedia devices use high-frequency isochronous transfer which guarantees high-bandwidth (e.g. 160Mbps for 1080p capture) but bloats the

template, e.g., over 400K events for capturing 10 frames. Directly using the uncompressed template is possible but neither practical nor efficient. Observing the USB TR ring structure and repeated memory access pattern, μUSB leverages peephole optimization with a peephole size of 30 for detecting the pattern(s) and re-rolling the accesses into fixed-iteration loops. After re-rolling, the template size reduces by a few orders of magnitude, which we show quantitatively in Table 4.

4.3 The μUSB Replayer

Running inside Arm TrustZone, the replayer and templates are statically linked with the TEE OS, which incarnates as the **μUSB driver**. It provides a unified and easy-to-use API for in-TEE apps to invoke, executes the events of the template corresponding to the API, and handles possible failures.

The API. The replayer provides one unified API for in-TEE apps to request for USB I/O services. The API has two key arguments. The first specifies the template identified by its I/O function, and the second points to the arguments of the I/O function, which are mutable inputs specified at the recording entry. The design abstracts away the complexity of kernel abstraction (e.g., devfs) in the original recording and allows the in-TEE app to focus on the I/O functions. Figure 10 shows an end-to-end example.

Template execution. Upon API invocation, the replayer instantiates the template and then sequentially executes its events. To instantiate, the replayer configures TZASC/TZPC to isolate and map xHCI for memory accesses and reuses the interrupt handler of the TEE OS for top-half IRQ management. It redirects the events in Table 1 of the template to the TEE OS. Note these events are commonly provided by TEE OSes [54] or can be emulated, e.g., `malloc` of OPTEE-OS already allocates physically contiguous pages which emulates `dma_alloc_coherent`. The replayer maintains two contexts (CPU and interrupt), each holding only a pointer to the next event (like a PC). For writes, it re-applies the accumulated taint operations and writes dynamic values to corresponding addresses, which are mediated and checked to be valid DMA/MMIO addresses and non-executable; for reads, it matches the invariants while ignoring variants. It does not pace the replay, e.g., by injecting any artificial delays, because the USB protocol allows faster driver responses but not late ones. When execution finishes, the replayer frees up the allocated resources from the TEE OS, e.g., DMA.

Handling replay failures. The replayer handles two failure conditions. First, incorrect API invocation. This case includes selecting wrong templates and/or supplying arguments which do not satisfy the path constraints. In this case, the replayer directly returns an error code. Second, reading unexpected values. During replay, the replayer matches interaction events (i.e., IRQs and values read from the USB device) against those recorded in the template. If the lifter deems a value read from the USB device as an invariant but appears different or an unrecorded IRQ emerges, it suggests the USB FSM has gone off the beaten path. For instance, the USB device is unplugged or reboots unexpectedly due to a firmware crash amid execution, which causes spurious IRQs and deviations from the recording. In this case, the replayer halts, resets the device, and re-executes the template. If the error persists, the replayer reports an error code back to the app and releases the allocated resources (e.g., DMA pages), without executing any device-specific recovery logic. The replayer does so because a deviation is precisely the condition under which the original driver itself would not have proceeded; therefore failing is not just safe but is the same decision the original driver would have made (§ 3.3). Doing so also fully confines the μUSB driver execution inside TEE to ensure the confidentiality and integrity of the μUSB driver code and data, which are protected by TEE and never leave TEE memory; Denial-of-Service (DoS) (e.g., unplugging the USB device as mentioned above) is possible but cannot persist, as the replayer detects such deviations from the recording. In practice, no such case was found. See more in Section 6.

5 Implementation and Experiences

μUSB comprises about 4K SLoC across C, C++, and Python. Its core components are detailed below.

The recorder. We built it atop QEMU and KVM (Linux v6.8) in 2K lines of C code. We use QEMU as the frontend to manage the virtual machine which also runs Linux kernel v6.8. For I/O trace, we modify KVM to trap and record them by leveraging the `PT_ACCESS_MASK` to cause EPT page fault and IRQ virtualization to intercept USB interrupts. For call trace, we retrofit the existing kernel tracing facility, i.e., `ftrace` and `kprobe`. We implemented our own mutator and draw valid configurations from device utilities (e.g., `V4L2` for Video).

The lifter. We have implemented the lifter based on SUTURE [112] in 500 lines of C++ code and 1K lines of Python code. We choose it as it is the state-of-the-art kernel static analyzer, which integrates mature taint rules. To implement qualified taint tracking, we modified its taint tracking module to allow the traces to 1) direct the taint propagation upon branches, to 2) collect the corresponding path constraints, and to 3) qualify alias analysis upon recursive data structures.

The replayer. We have implemented the replayer as a simple executor of the events of the template in 500 lines of C code based on OPTEE-OS v4.4. For DMA/MMIO accesses, the replayer implements them as uncached pointer accesses and insert memory barriers for cache coherence. For call events, the replayer redirects them to existing services already provided by OPTEE-OS, e.g., `dma_alloc_coherent` to `malloc` of OPTEE-OS which allocates physically contiguous pages.

Table 4: The USB devices, recorded I/O functions, and number of events in the generated templates. Underlined args are mutable at run time.

5.1 USB devices and I/O functions

We test µUSB with four classes of USB devices which have important use cases in TEE but commonly lack protocol-layer end-to-end encryption: **1) USB Mass Storage:** it extends secure storage from on-chip RPMB [2] to a diverse range of external commodity storage devices, e.g., a thumb drive; **2) USB Video/Audio:** it enables TEE to obtain *trusted* images/audio for provable video authenticity [56]. We choose two distinct cameras with different rates (1080P@5FPS and 480P@30FPS) to demonstrate cross-vendor practicality; **3) USB HID:** it enables TEE to process privacy-sensitive human inputs, e.g., passwords. We choose keyboards and mice as they are the most common HID devices. We record their typical I/O functions and device initialization. The setup and I/O functions are in Table 3 and 4.

5.2 Recording outcome and post analysis

We report the recording outcome for each of the devices in Table 4 in interaction events, including raw recorded events and the events after lifting.

USB Mass Storage. µUSB recorded two SCSI commands: `read(10)` and `write(10)`. For each data transmission round, three interrupts are received, for sending SCSI command, transporting data and receiving status respectively. The number of TRBs scales linearly with transfer data size, which suggests each TRB carries a fixed amount of data.

USB Video/Audio. To configure them, both drivers allocate DMA buffers, encode configurations, and write buffer addresses to xHCI, which is exactly recovered by µUSB, with the buffer symbolized and configurations correctly preserved as invariants, e.g., the audio sampling rate specified in user input (i.e., 44100) is encoded and preserved as 0xbb80 (i.e., 48000). Unsurprisingly, both devices stream raw data with ISOC transfers; without the secure I/O's end-to-end protection, they would have been easily intercepted and exploited by a malicious OS. We are surprised to find camera 2 (480P) requests data buffers of the same size (i.e., 96KB) as camera 1 (1080P), which greatly exceeds its actual needs and is likely an implementation defect. Figure 5 illustrates a fragment of the template for USB Audio playback, where configurations are encoded as invariants, and variants (e.g., buffer addresses) are correctly symbolized.

```
#define S16_LE  0x0001
// mutable input: buffer
void Playback(2, 10, S16_LE,
              44100, void *buffer)
{
    val = read(xhci_base+0x44, 0x4);   //read xHCI
    // matching invariants for correctness
    if (val != 0x0) goto replay_error;
    // write a 4-byte invariant to xHCI
    write(xhci_base+0x0044, 4, 0x8);
    ......
    // alloc DMA
    tmp = dma_alloc(0x3);
    // UAC_SET_CUR
    write(tmp, 3, 0xBB80);  //Resample to 48 kHz
    write(trb_base+0x67f8, 0x8, tmp);
    write(xhci_base+0x2004, 4, 0x1);  //ring doorbell
    ......
    // alloc DMA
    tmp = dma_alloc(0xc0);
    // transfer user data
    write(tmp, 4, buffer);
    write(tmp + 0x4, 4, buffer + 0x4);
    write(tmp + 0x8, 4, buffer + 0x8);
    ...
    // send data to xHCI
    write(trb_base+0x7a50, 0x8, tmp);
    ......
    on_irq(10);          // wait for irq line 10
    ......
}
```

Figure 5: An example of a µUSB template for audio playback, which specifies a sequence of MMIO, DMA, and IRQ events to complete a single isochronous transfer of USB audio. Comments are added for readability.

USB HID. It only uses interrupt transfer for data and is highly deterministic. Exactly one TRB is transferred to report each movement of the mouse and a keystroke. More interestingly, all address/value fields remain identical within one trace. By simply observing its concrete trace, a less-seasoned developer would have treated them as invariants. Yet, µUSB's lifter detects the addresses and symbolizes them as variants.

6 Evaluation

We answer the following questions w.r.t. our goals (§ 2.3):

1. Why is µUSB practical? (§ 6.1)
2. Why do µUSB drivers work correctly and safely? (§ 6.2)
3. What is the performance of µUSB and its drivers? (§ 6.3)

6.1 Analysis of developer efforts

We compare three approaches to implementing the same I/O functions as described in Section 5.

Build from scratch. Developing a USB driver from scratch demands thorough knowledge of the device specification, core functions, configurations, and data structures. We quantify such knowledge required to realize same I/O functions and summarize it in Table 5. For each USB class, we estimate the development typically takes at least several months.

Port. Compared with **Build from scratch**, porting requires less manual effort, yet developers still need to analyze the essential USB functions that implement the desired functionality. From μUSB's recorded call trace, a single USB I/O function involves at least 100 diverse functions from over 10 subsystems, e.g., the device framework, block layer, power and memory management. Porting them and emulating kernel frameworks takes at least 5K SLoC and several months.

μUSB. In contrast, we needed much less developer work. The essential USB-specific knowledge is the xHCI memory layout and interrupts, which took us a few days to familiarize. Building the framework took a couple of weeks, which is a one-time effort. Using our framework is easy, with basic knowledge of USB drivers (e.g., the specific I/O functions and respective arguments): the developer simply prompts μUSB with an input and gets a ready-to-use template; if she demands other I/O functions, she simply re-records, which often takes within a minute. Note that, while **driverlet** [32] also generates drivers, its support for USB is limited to storage (as explained in § 2.2), which took 1-3 days, much longer than our approach.

6.2 Security and correctness analysis

6.2.1 Security Analysis

The key security benefits of μUSB are from removing the large kernel dependencies and to lock USB driver execution on a beaten path inside TEE [52].

Thwarted attacks. μUSB mitigates existing attacks which exploit memory bugs and race conditions of kernel dependencies [71, 75] and USB drivers [68, 70, 73] by design: μUSB does not incorporate kernel dependencies and driver code (§ 4.1); templates accept limited inputs and have no dynamic memory allocation (§ 4.2); μUSB does not allow fine-grained sharing between in-TEE apps (§ 4.3). We show more CVE examples in Table 6. Note that [76] was disclosed *after* μUSB development, which μUSB also defends against as it does not incorporate the code. By confining the execution fully inside the TEE, μUSB drivers also defend against software attacks from the malicious OS through memory [77], interrupt [78], or untrusted RPCs [14]. For logic bugs, e.g., resource exhaustion due to incorrectly handled inputs [8], μUSB mitigates them: 1) incorrect executions will be exposed by mutational recording with user-supplied inputs (§ 4.1); 2) μUSB soft-resets the device for a clean-slate replay (§ 4.3). A corner case is when μUSB might inherit taint-style vulnerabilities encoded in input *constraints* (e.g., integer overflow) which μUSB preserves. However, these are fundamentally difficult to exploit: 1) inputs from in-TEE apps are trusted and limited (1-2), which are validated by the template and audited manually; 2) malformed inputs from devices fail to replay and are immediately rejected; 3) all memory writes (as replayable events) are mediated to ensure they hit valid DMA/MMIO addresses which are non-executable.

Attacks against μUSB. 1) Template fabrication or tampering is unlikely, as the trusted lifter signs them. 2) Attacks from malicious USB devices are defended. They may be mounted against μUSB at both the recording and the replay stage. During recording, they are defended by complementary USB protection measures [40] on the developer machine (§ 4.1). During replay, they may cause the replay to fail due to constant divergence from the template, which can be detected and does not compromise data confidentiality and integrity; they cannot inject malicious payloads (e.g., shellcode) to TEE because the template only supports the pre-recorded I/O function but not other features such as dynamic interface discovery needed by BadUSB-like attacks to emulate HID devices [81]. Exploiting the replayer is also hard, due to its small codebase (500 SLoC) and the simple logic.

	Opcode	Spec.	Conf. Desc.	Data Struct
xHCI	17	645	**Nah**	421
USB Stor.	13	554	3+	50
USB Video	8	169	93+	31
USB Audio	11	239	18+	36
USB HID	8	97	2	3

Table 5: The knowledge required to build a driver from scratch. Conf. Desc. refers to configuration descriptor.

6.2.2 Correctness

We statically vet the templates by cross-checking them with the call traces, drivers, and specifications; we experimentally verify their functional correctness and continuously stress test them for robustness for over two weeks which confirms sustained throughput. An ideal guarantee requires full formal verification of the recordings, which we leave as future work.

USB Mass Storage. We verify the templates encode correct SCSI commands; we generate 1K read/write requests and have verified that 1) they are either rejected by the replayer due to invalid input arguments, or 2) the data read by the μUSB driver match native drivers and that writes reach the storage.

USB Video/Audio. We verify the templates encode correct configurations (e.g., sampling rate, resolutions), following the same control transfers mandated by the respective specification. We dump and manually examine the captured data. For audio, we utilize the μUSB driver to playback the recorded audio to verify record and playback both works correctly; Figure 8 shows their waveforms. For video, we check video frames for correctness (e.g., no missing content, abnormal

µUSB's Design	Example CVEs	Description	Effect	Vuln.

`I: Integrity; C: Confidentiality; A: Availability`

Table 6: µUSB mitigated common vulnerabilities and exposures (CVEs) in the USB stack by design. Vuln.: vulnerabilities.

color, or jagged edges). To stress test, we streamed video and audio by repeatedly executing `capture` templates and have verified both endured for over 24 hours.

USB HID. We manually verify them. For keyboard, we verify the µUSB driver captures the same key code as we pressed specified in the usage table [100]. For mouse, we verify the coordinates are identical to those reported by native drivers.

The corner case. Despite the above manual verification, one corner case is when the µUSB driver successfully replays an I/O function (i.e., no error codes, and all interactions match the recording) but the data is silently lost. However, this means the recorded driver itself does not implement sufficient driver/device interactions for inferring and handling device states and errors, contrasting our assumption of a *gold* driver (§ 3.1).

6.3 Overhead

6.3.1 Methodology

Our recording machine, test platform, and USB devices are listed in Table 3. We assign one of the two xHCI controllers of the platform to TrustZone and connect the USB devices with the corresponding ports. We reserve 8MB of TEE RAM for DMA allocation.

Benchmarks. We choose benchmarks specific to USB classes and their I/O functions in Table 4. 1) **Storage:** we use FIO, a famous open-source I/O testing tool [11]. We vary transfer block sizes, and report the throughput on 64M of data. 2) **Camera (OneShot/ShortBurst/LongBurst):** we request the cameras to capture 1, 10, 100 image frames at the highest resolution. We report the latency of each request. 3) **Audio (Recording):** We request the microphone to record audio clips from PEASS, a widely used benchmark in audio processing [24], for 10 seconds. We use cosine similarity of MFCC as the measure for audio similarity, a common metric in signal processing [18]. We also report the request latency. 4) **HID (Keyboard/Mouse):** We randomly press the keyboard and move the mouse, and report the latency between receiving an interrupt and obtaining the keystrokes or coordinates.

Comparisons. We compare µUSB drivers with two baselines. 1) **native**: we run the same benchmarks on Linux v6.4 invoking the full-fledged native drivers. 2) **circle**: we run the benchmarks on USB drivers of Circle [93], a baremetal USB driver for Rpi which supports USB Mass Storage and HID, but not Audio/Video. We additionally consider **Driverlet** [32] as it also supports storage and video devices; we use it as a theoretical reference point and do not compare quantitatively, as it is unable to support same USB devices as we do.

6.3.2 µUSB driver performance

Storage. As shown in Figure 6, µUSB storage driver achieves excellent performance. On average, its read/write throughput is 16.26/11.01 MiB/s, close to **native** (17.42/6.68 MiB/s), and higher than **circle** (7% and 35% higher for read, write respectively). µUSB's good performance comes from its simplistic design, which *de-indirects* kernel and has most benefits for CPU-bound workloads (e.g., small random block writes) – both µUSB and **circle** outperform **native** by 5× and 2.5× respectively, where µUSB has better performance due to an even shorter execution path. SSDs have also observed a similar result [113].

Camera. Figure 7(a) and 7(b) show the results. On two distinct cameras, µUSB drivers achieve the lowest per-frame latency, i.e., 2964 and 87 ms, 3% and 20% faster than **native**, respectively. Their performance is consistently close to or better than **native** in **ShortBust** (7.8% better) and **LongBurst** (13.5% better). Noticeably, on camera 2 (480P), the µUSB driver is up to 26% faster than **native** (i.e., **LongBurst**). This is because transmitting lower-resolution images is CPU-bound, which benefits most from µUSB's simplistic design.

Audio. Figure 8 shows audio similarity of two samples and Figure 7(c) shows the latency. As can be seen both visually and quantitatively, µUSB captures almost identical audio with **native** without distortion or packet loss during the 10-second recording. Its latency appears little to no difference with **na-**

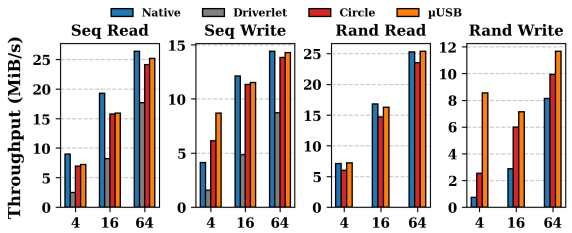

Figure 6: FIO benchmarks for USB Storage. X-axis: transfer block size in KiB. **Driverlet** [32] is kept as a theoretical reference point.

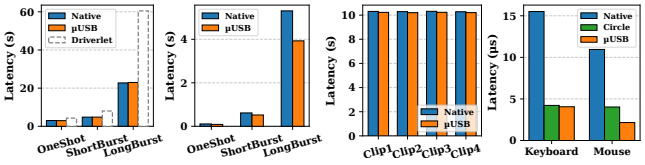


(a) Camera 1 (b) Camera 2 (c) Audio (d) HID

Figure 7: The latency for USB Video, Audio and HID. **Driverlet** [32] is kept as a theoretical reference point.

tive because of a constant audio sampling rate.

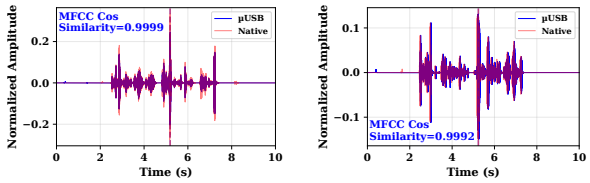
HID. Figure 7(d) shows the results. On average, µUSB is 4.5× faster than **native** and is 1.3× faster than **circle**, which are the best results µUSB have achieved. It is because this class is most latency-sensitive (i.e., µs-level), where each instruction counts. For it, µUSB only executes several (8-12) events in sequence without branches or jumps.

Memory overhead. Table 7 compares the sizes of µUSB driver executables with **native**. µUSB driver sizes range from 15 to 400 KB, which are one to two orders of magnitude smaller than native drivers. µUSB achieves the substantial reduction since it reuses driver/device interactions instead of the driver code and kernel dependencies.

6.3.3 µUSB overhead

End-to-end results. We use one I/O function of each device class in Table 4 and show the template generation time in Figure 9. µUSB is efficient and lightweight: on average, generating a template takes 56.9 seconds, up to 135.1 seconds (**Capture(10s)**). For **Audio** and **Video**, most time is spent on recording which takes 84.9% and 70.6% respectively, since they need to stream data for a fixed duration. **Storage** and **HID** have brief I/O functions thus taking more time to lift, i.e., 44.6% and 54.3% respectively. We highlight the offline analysis does not affect runtime performance of a µUSB driver.

Tracing overhead. The recorder delays USB driver execution by 2.3%, which is negligible. The overhead mainly comes from tracing via KVM: we add 0.03ms to each DMA/MMIO event, and 0.009ms to each interrupt; `ftrace` is fast, as it is static. In comparison, tracing via stage-1 page fault costs



(a) Clip 1 (b) Clip 2

Figure 8: Waveforms of audio clips recorded by µUSB and the native driver. All cosine similarities of MFCC are >0.99.

Dev. Class	Ours	Native	Size Reduction
Storage	24KB	2.5MB	107×
Video	400KB	4.6MB	12×
Audio	160KB	7.1MB	45×
HID	15KB	1.7MB	116×

Table 7: The sizes of µUSB drivers compared to corresponding native USB driver kernel modules.

0.14ms which is 4.5× slower and disrupts USB execution. This significant difference is likely due to a much heavier kernel exception handler than a lightweight one used by the hypervisor, backing our decision for the recorder (§ 4.1).

Static analysis overhead. Symbolic differential trace analysis is fast, whose execution time is linear to the recorded `<var, [val]>` pairs. For **Video** which has the most events (i.e., over 400K), it takes only 3.29 seconds and can be further optimized through SIMD instructions. It effectively detects variants of most I/O functions with just two traces, except for camera 1 which needs six; all are covered by the recorder which mutates at least 10 times (§ 4.1). We also tried continuing mutation, which did not yield more variants. We show the detailed results in Table 8. Qualified taint tracking takes slightly more time. On average, each I/O function takes 11.6 seconds, with **Audio** being the slowest (i.e., 18.14 seconds) due to the longest code path. The results are not surprising, as the lifter only analyzes a *specialized, beaten* kernel code path. In comparison, without the call trace to qualify static analysis, the lifter experiences serious state explosion and does not finish execution within 12 hours, whose intermediate states consume over 64GB of disk space.

6.3.4 End-to-end use case

To showcase the real-world practicality of µUSB, we construct an end-to-end trusted surveillance app inside the TEE, as shown in Figure 10. This app uses the USB devices from Table 3, where each device owns its dedicated ports while coarsely sharing the host controller. Invoking µUSB APIs to select different templates (i.e., `VID_CAPTURE`, `WRITE_64`), this app continuously captures image frames from the camera and dumps them to storage. With µUSB drivers, it runs fully inside TEE to enjoy the strong protection for data confidentiality and integrity, despite the lack of end-to-end data encryption from these USB devices. As we have measured,

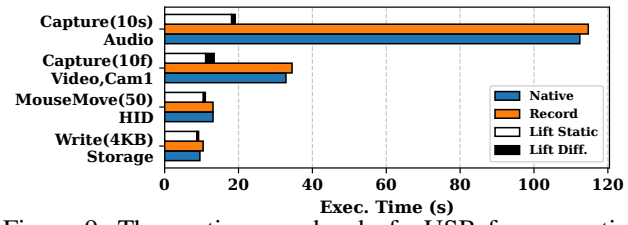


Figure 9: The runtime overhead of µUSB for generating µUSB driver templates.

	Min. # of mut. → 1	2	3	4	5	6	8	10
Capture (10s)	18376	18376	18376	18376	18376	18376	18376	18376
Audio	/165384	/165384	/165384	/165384	/165384	/165384	/165384	/165384
Capture (10f)	41348	41348	41348	41348	41348	**41364**	41364	41364
Video, Cam1	/372132	/372132	/372132	/372132	/372132	/372116	/372116	/372116
Write(4KB)	446	446	446	446	446	446	446	446
Storage	/3568	/3568	/3568	/3568	/3568	/3568	/3568	/3568
MouseMove(50)	100	100	100	100	100	100	100	100
HID	/800	/800	/800	/800	/800	/800	/800	/800

Table 8: Detected variants with more traces after mutation.

µUSB sustains 1.92 FPS on the 1080P camera and 11.6 FPS on the 480P camera for over a day, which achieves comparable performance with native drivers, i.e., 1.94/10.7 FPS on 1080P/480P cameras respectively. The performance is practical since industry webcams often use low (2-15) frame rates to reduce storage costs [108].

7 Related Work

Device drivers. They have been extensively studied [43, 28, 60, 91]. For better security and reliability, pioneering works propose new architectures [27, 98]. µUSB is inspired by them with a focus on USB and reuses mature drivers for derivation. RevNIC [16] and driverlet [32] also derives from mature drivers but both rely on symbolic execution which is impractical to USB; LDR [110] reuses the original driver through partitioning, which only supports simple I/O drivers.

Program analysis. It examines static program structure and or dynamic runtime behavior to detects errors [58, 112, 99]. Among the techniques, fuzzing analyzes programs via semi-random inputs [64, 114]; differential analysis compares behaviors across versions or environment [105, 49]. µUSB builds upon them, and extends them by leveraging kernel I/O/call traces as path qualifier for precision and efficiency, which is a new form a trace-guided analysis [10, 62].

Notably, the techniques can be used to *debloat* software [89, 39, 30, 38] reduces the attack surface by trimming unused driver code while retaining original functionality. However, debloated drivers still depend on large portions of the original implementation, preserving large TCB and vulnerabilities.

Trusted execution environment. It is widely adopted to isolate sensitive operations from hostile OSes [31, 80, 63]. For I/O, existing solutions often rely on normal OS [51, 50] or only support simple sensors [106]. µUSB complements them, providing USB support the TEE critically lacks.

```c
#include <uusb.h> // uUSB API
void trusted_surveillance_app() {
  // 1. Allocate DMA buffer in TEE
  void *buf = dma_malloc(FRAME_SIZE);
  int sector = 0;
  while (true) {
    // 2. Replay frame capturing; buf is mutable arg.
    int ret = uusb_replay(VID_CAPTURE, buf);
    if (ret != SUCCESS) { handle_err(); }
    // 3. Dump to USB Storage
    int blk = FRAME_SIZE/SECTOR_SIZE;
    int rounds = blk/64;
    for (int i = 0; i < rounds; i++) {
      // recorded 64-blk write, with 2 mutable args.
      ret = uusb_replay(WRITE_64,
                        sector, //1st arg
                        buf+i*64*BLK_SIZE); //2nd arg
        if (ret != SUCCESS) { handle_err(); }
    }
    sector += 64;
  }
}
```

Figure 10: An end-to-end trusted surveillance app built atop µUSB inside TrustZone.

Driver synthesis. One may synthesize drivers from scratch and deploy them inside the TEE using DSL [19, 61, 96] and considering execution context interfaces [94, 60, 95]. While synthesis can theoretically yield safe TEE drivers, it requires correct specifications and synthesizers, which is challenging due to the manual effort and error-prone nature of register-level specification development [65]. Notably, µUSB echoes with the pioneering Synthesis OS [88] which collapses kernel layers for flat execution and factors out invariants. Differently, µUSB takes a lightweight recording approach which *ex vivo* synthesizes USB drivers for simplicity and safety.

8 Concluding remarks

We present a novel record, lift, and replay approach to deriving USB drivers for TrustZone. We design and implement µUSB, a system to record USB driver/device interactions with mutations, lift the concrete traces into a template which accepts dynamic inputs while ensuring correctness. We show µUSB drivers have decent performance on USB Storage, Audio, Video and HID. For the first time, µUSB opens a door for TEE software to access complex yet essential USB devices.

A Appendix

We retrofit Labelled Transition System [13, 59] to show μUSB drivers are as correct as a USB driver for a recorded I/O function.

A.1 Definitions

Definition 1: Labelled Transition System. Labelled Transition System (LTS) [13, 59] uses a tuple $(S, A, \rightarrow, s_0)$ to describe the states of system and a set of transitions between those states, where S is a finite set of states, A is a finite set of actions, $\rightarrow$ is a transition relation (i.e., $s \xrightarrow{a} t$ denotes state s transfers to t with action a), and s_0 is the initial state of system.

Definition 2: Trace and Trace Equivalent. We use A^* to describe all possible finite action sequences of A. An element of A^* is a concrete finite action sequence and is called a *trace*, denoted as $\sigma = a_0 \dots a_n$. Formally, for a given LTS $(S, A, \rightarrow, s_0)$, a set of all possible traces from s_0 is:

$$\mathrm{Tr}(s_0) = \{\sigma \in A^* | \exists t \in S, s_0 \xrightarrow{\sigma} t\}$$

Based on the above, given two LTSs, $T = (S, A, \rightarrow, s_0)$, $T' = (S', A', \rightarrow', s_0')$, we say that they are trace equivalent *iff* $\mathrm{Tr}(s_0) = \mathrm{Tr}(s_0')$.

Example. We give the intuition behind trace equivalence in Figure 11. Suppose to configure a USB device, drivers need to read its capability first to decide the exact configuration. While the two LTSes implement the behavior differently, they are trace equivalent, i.e., $\mathrm{Tr}(s_0) = \mathrm{Tr}(s_0')$, containing two traces {read_usb_cap, write_config_a} and {read_usb_cap, write_config_b}.

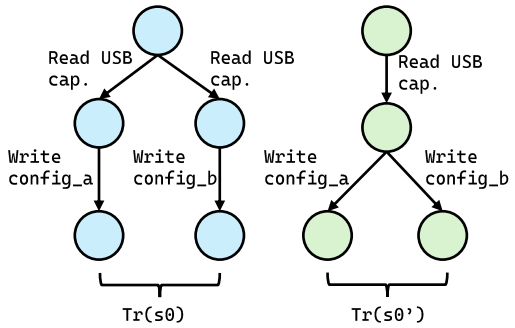

Figure 11: A minimum example of two trace equivalent LTSes.

Definition 3: Minimum Trace. We define state-changing actions as an action set D which when observed by the LTS changes its current state s to t:

$$\forall d \in D,\ \exists s, t \in S.\ s \xrightarrow{d} t \wedge (s \neq t)$$

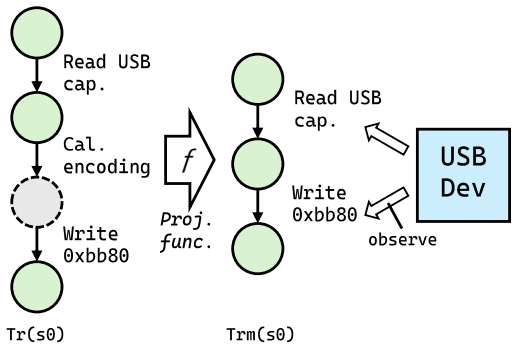

Figure 12: An example of Tr vs. Trm, where calculating encodings are oblivious to a device.

$\mathrm{Trm}(s)$ is minimum trace if all actions are state-changing: $\mathrm{Trm}(s) = \{\sigma \in D^* \mid \exists t \in S,\ s \xrightarrow{\sigma} t\}$. We further define a projection function $f : A^* \rightarrow D^*$, which filters out non-state changing actions of a trace σ. A key corollary is that any trace in Trm is itself after projection:

$$\forall \sigma_m \in \mathrm{Trm}(s_0),\ f(\sigma_m) = \sigma_m$$

The function represents how the device observes actions, where a driver's *internal* actions (e.g., calculating command encodings, allocating slab caches) are oblivious to the device. An example is shown in Figure 12.

A.2 Lemma

With minimum traces, we land on an interesting lemma – if any traces of two LTSes, after projection f, belongs to the other LTS'es minimum trace, then these two LTSes' minimum traces are equivalent. Formally:

$$\begin{aligned} & (\forall \sigma \in \mathrm{Tr}(s_0), f(\sigma) \in \mathrm{Trm}(s_0')) \\ \wedge\ & (\forall \sigma' \in \mathrm{Tr}(s_0'), f(\sigma') \in \mathrm{Trm}(s_0)) \\ \rightarrow\ & \mathrm{Trm}(s_0) = \mathrm{Trm}(s_0') \end{aligned}$$

We prove the lemma by contradiction. Suppose the two minimum traces are **not** equivalent under the same premises, i.e., $\mathrm{Trm}(s_0) \neq \mathrm{Trm}(s_0')$ while $\forall \sigma \in \mathrm{Tr}(s_0), f(\sigma) \in \mathrm{Trm}(s_0')$ (***Pa***) and $\forall \sigma' \in \mathrm{Tr}(s_0'), f(\sigma') \in \mathrm{Trm}(s_0)$ (***Pb***). That is, there exists an outstanding minimum trace σ_x in either Trm:

$$\sigma_x \in \mathrm{Trm}(s_0) \quad \wedge \quad \sigma_x \notin \mathrm{Trm}(s_0')$$

or

$$\sigma_x \in \mathrm{Trm}(s_0') \quad \wedge \quad \sigma_x \notin \mathrm{Trm}(s_0)$$

We first prove the former: as Trm is minimum trace, we have $\sigma_x \in \mathrm{Tr}(s_0)$ and $f(\sigma_x) = \sigma_x$ from corollary. Combined with ***Pa***, we further have $\sigma_x \in \mathrm{Trm}(s_0')$, which apparently contradicts the condition that $\sigma_x \notin \mathrm{Trm}(s_0')$; such a case hence does not exist. By duality, the proof of the latter is symmetric

to the former: we again obtain $\sigma_x \in \mathrm{Tr}(s'_0)$ and $f(\sigma_x) = \sigma_x$ from corollary. By ***Pb***, it follows that $\sigma_x \in \mathrm{Trm}(s_0)$, which also contradicts the condition that $\sigma_x \notin \mathrm{Trm}(s_0)$. Therefore, this case cannot hold either. As both cases do not exist, the predicate $\mathrm{Trm}(s_0) \neq \mathrm{Trm}(s'_0)$ is false and that $\mathrm{Trm}(s_0) = \mathrm{Trm}(s'_0)$ is therefore true ■.

A.3 The Proof

Without loss of generality, we consider the USB device with one single I/O function and initial state s_0. For USB devices, the state-changing actions are low-level driver/device interactions. We thus define $D = \{\mathrm{MMIO}, \mathrm{DMA}, \mathrm{IRQ}\}$. For the native kernel driver, its LTS T has an action set $A = D \cup I$, where I are driver-internal, e.g., slab allocation, encoding calculation. Its trace $\sigma \in \mathrm{Tr}(s_0)$ is mixed with both D and I, We next define the LTS T' for a μUSB driver with action D and trace σ': by recording the low-level interactions of a native driver T, it effectively applies the projection function f to σ and logs $f(\sigma)$; by replaying, it re-executes its own actions σ' which is essentially $f(\sigma')$.

Based on the above, T and T' further have two properties tied to our design.

Property 1. *For the recorded I/O function, T''s converging traces σ' (i.e., after mutational recording) capture sufficient traces σ from T. In other words, the projection of traces σ of T constitutes minimum traces of T'. That is,*

$$\forall \sigma \in \mathrm{Tr}(s_0), f(\sigma) \in \mathrm{Trm}(s'_0)$$

Property 1 is not derived here; it follows from the convergence criterion of § 4.1.2 together with the gold-driver assumption of § 3.1.

Property 2. *A μUSB driver does not make up actions; all σ' replayed by T' come from actual recordings of T for the I/O function which are minimum traces. That is,*

$$\forall \sigma' \in \mathrm{Tr}(s'_0), f(\sigma') \in \mathrm{Trm}(s_0)$$

With the previous lemma, we conclude $\mathrm{Trm}(s_0) = \mathrm{Trm}(s'_0)$■. To understand more intuitively, from the perspective of a USB device, it only observes and reacts to state-changing actions which form *minimum traces*; whether such traces are emitted by a native driver T or a μUSB driver T', they are trace equivalent to the device and equally correct.

Achieving Cloud-Grade SLOs for Local Mixture-of-Experts Inference through CPU–GPU Hybrid Design

Abstract

Local deployment of large Mixture-of-Experts (MoE) models falls short of the service quality achieved in cloud-scale environments, even under low-concurrency workloads. We identify four key gaps in local MoE inference: reliance on capacity-reduced models (quantized, distilled, rerouted), inability to meet 30-second TTFT for long prefills (>12K), sub-baseline decode throughput (<20 tokens/s), and poor concurrency under mixed prefill–decode and batched decode workloads. We present a CPU–GPU hybrid system that achieves cloud-level SLOs on dual-socket commodity CPUs and consumer GPUs by (1) stream-loading prefill (SLP), boosting prefill throughput to 1,200 tokens/s and enabling 32K prompts within 30 seconds; (2) distributed SLP (DSLP) with SmallEP expert parallelism, reaching 1,800 tokens/s and 45K prompts in 30 seconds on two RTX 5090s; (3) intra-node prefill–decode disaggregation with zero-copy shared weights and a dual-batch attention–MoE overlap scheme, sustaining concurrency with <15% latency increase and 50% throughput gains; (4) an AVX-512–optimized FP8 GEMV kernel, enabling native CPU FP8 inference while delivering 4–5× lower CPU latency; and (5) fine-grained CPU parallelism that attains 28 tokens/s on INT4 DeepSeek-V3 and 21.5 tokens/s on intact FP8 V3. Evaluations show our system delivers cloud-level QoS for flagship MoE models on consumer CPU–GPU platforms, reshaping local deployment with intact, original-precision inference and enabling high-quality, cost-effective access without datacenter infrastructure.

1 Introduction

Large-scale Mixture-of-Experts (MoE) architectures have become a central design point for state-of-the-art language models, enabling their parameter counts approaching the trillion scale while sustaining practical training and inference costs through sparse expert activation [17, 28, 38, 44]. This sparsity reshapes the deployment landscape. On one end, massive cloud deployments—often serving tens of thousands of concurrent requests—benefit from the highly overlapped expert activation, which drives hardware utilization toward peak levels [55, 59]. On the other end, local or low-concurrency deployments benefit from the sparse activation from small batch sizes, which significantly cuts down memory traffic, reducing the cost of accessing expert parameters and enabling efficient inference on resource-limited hardware [8, 23].

Significant engineering effort has gone into scaling MoE inference in large cloud environments, where service-level objectives are well established [12, 51] and system designs have converged on robust tradeoffs among throughput, latency, and cost. But these methods won't apply to local scenarios, where the hardware landscape and workload characteristics differ substantially. In contrast, local deployment of MoE models remains underexplored. A promising approach for local deployment is CPU–GPU hybrid inference, which alleviates the constraints of limited local VRAM by storing the majority of model parameters in larger and more affordable system memory.

Prior systems follow the arithmetic-intensity principle: compute-heavy layers—such as attention and shared experts—are assigned to the GPU, whereas lower-intensity, parameter-heavy components—such as routed experts—are offloaded to the CPU. The state-of-the-art system, KTransformers [8], demonstrates that careful CPU–GPU orchestration can yield superior performance. By adopting quantized model and altering routing, KTransformers achieves an acceptable 22 tokens/s decoding throughput on an INT4-quantized, rerouted DeepSeek-V3/R1 model.

However, compared to service quality achievable in cloud-scale systems, current local deployment systems still lag substantially. This gap manifests along several dimensions. (1) **Model quality**. Local deployments typically rely on quantized, distilled, rerouted, or otherwise capacity-reduced models, imposed by tight VRAM and memory-bandwidth budgets. Consequently, users cannot access the full-precision, unmodified MoE models commonly available in cloud services, leading to a pronounced gap in model quality. (2) **Prefill Latency (time-to-first-token, TTFT)**. TTFT is critical

for emerging agent workloads and document QA or summarization. Cloud services target a 30-second TTFT [37]. In contrast, prior local systems—despite using advanced matrix units in high-end CPUs—struggle to meet the 30-second target for 12K-token or longer prefills on the DeepSeek-V3 INT4 model [8]. (3) **Decode Latency (time-per-output-token, TPOT; or tokens-per-second, TPS)**. Cloud systems typically deliver >20 tokens/s per-request decoding as a responsiveness baseline [12, 51]. Prior local systems, even with quantized models, fall short (e.g., 16 tokens/s on DeepSeek-V3 INT4 [8]), leading to noticeably reduced responsiveness relative to cloud deployments. (4) **Concurrency**. Two gaps emerge under concurrency even considering the inherent low concurrency requirements in local deployments. First, prefilling and decoding are often mutually exclusive on local systems, producing either impaired TPOT for decoding under prefill-first scheduling or long TTFT under decode-first scheduling. Second, concurrent decode requests—even at small batch sizes—can substantially degrade per-request latency (TPOT), as expert activations effectively multiply with each additional request.

Throughout the paper, we use these cloud-level targets as local QoS reference points. Our key insight is that local MoE inference should be co-designed around the resources available on commodity nodes: large CPU DRAM capacity and bandwidth, consumer-GPU compute, limited VRAM, and PCIe-class interconnects. Based on this principle, our system reorganizes prefill, decode, parallelism, and concurrency to close the four SLO gaps locally. Our contributions include:

- **Stream-loading prefill.** We introduce a stream-loading prefill (SLP) execution model that overcomes consumer GPU VRAM limits, maximizes GPU utilization. SLP increases prefill throughput to up to **1,200 tokens/s** and supports prefilling 32K-token prompts within a 30-second TTFT budget.
- **Distributed stream-loading prefill.** Building on the SLP model, we develop a parallelism strategy that enables multi-GPU prefilling in local settings, with a SmallEP optimization for expert parallelism tailored to regimes with small expert-parallel sizes. The distributed stream-loaded prefill (DSLP) design delivers over **1,800 tokens/s** prefill throughput and supports prefilling **45K-token** prompts within a 30-second TTFT budget using only two consumer-grade RTX 5090 GPUs—offering better cost efficiency than CPU-prefill approaches relying on high-end CPU matrix units.
- **Concurrency via intra-node prefill–decode disaggregation and dual-batch attention–MoE overlap.** For prefill–decode concurrency, we perform prefill–decode disaggregation within a node atop the SLP execution model, and employ zero-copy, shared model weights, enabling concurrent prefill and decode with minimal interference—less than 15% latency increase. For batched decode concurrency, we introduce a dual-batch attention–MoE parallelism scheme that interleaves attention and MoE computations across two microbatches, increasing system throughput by 50% with limited impact on per-sequence QoS.
- **High-performance FP8 GEMV kernel.** We develop an AVX-512–optimized FP8 GEMV kernel tailored for native FP8 MoE inference, achieving 4–5× lower latency and higher bandwidth utilization compared to existing BLAS libraries. This enables practical original-precision inference on CPUs.
- **Fine-grained CPU Parallelism for MoE Inference** We design fine-grained synchronizations, minimize inter-socket communication and synchronization overheads, and fuse quantization-specific operations on CPUs. This improves decode latency for both full-precision and quantized inference, delivering a 28 tokens/second decode rate on INT4 DeepSeek-R1 model (1.25× improvement over KTransformers) and 21.5 tokens/second on the intact FP8 DeepSeek-R1 model.

We evaluate our system on a dual-socket low-end server-class CPU platform with 1–2 consumer GPUs, against mainstream CPU inference frameworks (KTransformers, llama.cpp, ik_llama.cpp) and state-of-the-art CPU BLAS libraries (OpenBLAS, AOCL-BLAS). Our results demonstrate that such consumer-grade CPU–GPU platforms can serve flagship large MoE models at cloud-level quality of service, at a fraction of the cost of GPU-centric supernode or cluster deployments. We further discuss the expected behavior on lower-end hardware, including single-socket CPUs, different CPU SKUs, and lower-VRAM GPUs in Section 6.

2 Background and Motivation

2.1 Background

Mixture-of-Experts (MoE) architectures introduce conditional computation into transformer models by replacing dense feed-forward blocks with large pools of expert networks [40]. A learned gating mechanism selects a small subset of experts—typically top-k or grouped top-k—for each token, enabling the model to scale its total parameter count without proportionally increasing compute per token. Modern designs such as DeepSeek [13, 28] series augment this with additional shared experts that are always active, providing a common representation path aside token-specific specialization.

To sustain inference throughput for models with large parameter counts, serving systems must deliver both high memory capacity and high effective memory bandwidth. Figure 1 surveys recent models and situates their capacity and bandwidth requirements against contemporary device trends. With

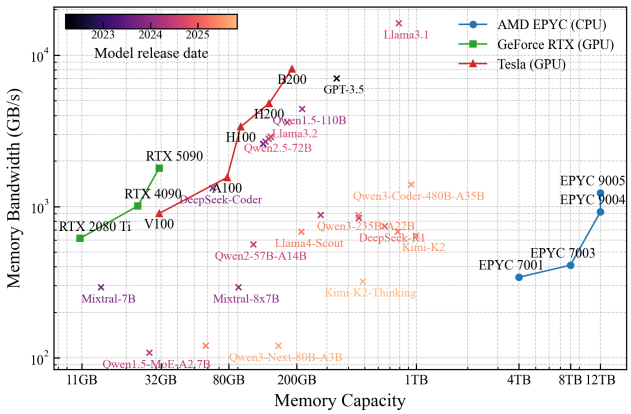

Figure 1: Models' memory demands and device comparison. Model memory capacity reflects parameter size at original weight dtype; memory bandwidth reflects activated weight accesses under a 20 tokens/second service-level objective (i.e., 20 serial activated-weight reads per second). Devices shown include NVIDIA GeForce RTX, NVIDIA Tesla data center GPUs, and AMD EPYC CPUs.

brighter colors indicating more recent releases, a clear trajectory emerges: total parameter capacity continues to climb (approaching 1 trillion parameters, or roughly 1 TB in raw weight size), while activated weights per token are reduced via selective activation. This shift lowers the bandwidth pressure for inference to approximately 1 TB/s, as evidenced by recent large MoE deployments [28, 44].

As Figure 1 illustrates, modern multi-socket CPU systems can deliver aggregate DDR5 bandwidth in the same ballpark as prior GDDR or HBM solutions for the activated-weight access patterns typical of large MoE inference. Combined with substantially lower memory cost (about $3 per GB for DDR5 versus about $30 per GB for HBM) and improved system-level power efficiency, CPU-based deployments become particularly attractive for low-concurrency inference scenarios, where capacity per node and cost/performance at moderate bandwidth are the dominant considerations.

Leveraging modern CPU platforms, hybrid systems such as KTransformers [8] report approximately 16 tokens/second for decode and up to 500 tokens/second for prefill on the DeepSeek-V3 Int4 model—yielding around 20 seconds TTFT for an 8K prompt and an estimated 30+ seconds for 12K or longer. Nonetheless, a substantial gap remains between local inference performance and cloud-level service quality. In the next section, we dissect this gap and its root causes.

2.2 Motivations

Below, we dissect the gap between state-of-the-art local deployment systems and cloud-level service quality across five dimensions—decode, prefill, multi-GPU parallelism, concurrency, and FP8 kernel support—and, based on this analysis, introduce targeted improvements for each. These challenges are not isolated. In local deployment, decode is limited mainly by CPU-side bandwidth efficiency, prefill by how much compute can be exposed under tight VRAM budgets, parallelism by commodity PCIe interconnects, and concurrency by whether these resource pressures can be separated and reorganized rather than forced onto a fixed execution path. This coupling motivates the key principle of our design: local MoE inference should be co-designed around CPU DRAM capacity/bandwidth and consumer-GPU compute, rather than directly inheriting cloud-style assumptions.

2.2.1 Decode

To accommodate limited VRAM in local deployments, hybrid inference systems employ computation offloading [8, 15, 20, 23]: MoE layer weights are persisted in CPU memory and their expert computations execute on the CPU, while densely activated weights and corresponding kernels remain resident and execute on the GPU. Building on this split, KTransformers [8] specifically targets decode-phase bottlenecks—CPU–GPU synchronization and kernel launch overheads—achieving state-of-the-art decode throughput compared to prior local systems such as llama.cpp and Fiddler.

Despite these improvements, decode performance remains short of cloud-level responsiveness: KTransformers delivers approximately 16 tokens/second on the Int4 quantized model, whereas cloud services running full precision models commonly target $\geq$20 tokens/second as a responsive baseline [12, 51]. Decode in local deployment of large MoE models is predominantly memory-bandwidth bound. Using the published figures—74% CPU time and 20.4B activated MoE parameters—KTransformers' decode throughput implies an effective memory bandwidth of roughly 221 GB/s. On the reported dual-socket Xeon DDR5 system, this is only about 50% of the nominal aggregate DDR5 bandwidth. This breakdown highlights significant hardware underutilization and motivates our work to close the gap to cloud-level service quality, as elaborated in Section 3.5.

2.2.2 Prefill

In popular hybrid systems, sparsely activated MoE computations run on the CPU while densely activated components such as attention execute on the GPU. During prefill—where compute intensity rises—computation increasingly dominates end-to-end latency. As sequence length grows beyond roughly 512 tokens, CPU-side MoE execution saturates available compute, and its latency becomes the primary contributor to time-to-first-token (TTFT).

To mitigate CPU limitation, KTransformers leverages Intel's Advanced Matrix Extensions (AMX) instruction set with carefully specialized CPU GEMM kernels, achieving state-of-the-art peak prefill throughput of over 500 tokens/second at a 2048-token prompt, surpassing prior hybrid approaches.

Nonetheless, the approach remains bounded by CPU arithmetic throughput: CPU-centric pipelines cannot match GPU-resident dense GEMM performance. As prompt lengths grow to 8K, 16K and 32K (common in agent, document Q&A and text summary tasks [5, 6]), CPU-side MoE computation becomes the dominant bottleneck, driving time-to-first-token upward to around 20, 40 (estimated) and 100 (estimated) seconds.

Conversely, to exploit GPU compute, weight-offloading systems [4, 18, 19, 42, 43] prefetch model weights to the GPU prior to kernel launches, using predictive scheduling, quantized or compressed weights and reordered pipelines to reduce reactive latency. These designs typically (1) apply a unified optimization strategy to both decode and prefill that prioritizes minimal transfer latency and proactive fetching, and (2) target edge deployments of small- to mid-scale models with lower compute intensity. Consequently, they are optimized for latency rather than throughput, making them ill-suited for compute-heavy prefill on large MoE models and deliver suboptimal prefill performance compared to contemporary computation-offloading approaches.

These limitations motivate a different direction: keep the benefits of weight offloading to avoid CPU-bound compute, but focus explicitly on prefill and optimize for throughput on large MoE models across both weight transfer and computation. In Section 3.1 we introduce a fine-grained stream-loading prefill (SLP) mechanism that pipelines and fully overlaps expert weight transfer with GPU kernel execution at sub-layer granularity. SLP eliminates reactive stalls without prediction overhead, quantization, or rerouting—preserving model quality while sustaining low TTFT at scales.

2.2.3 Multi-GPU Parallelism

To accelerate prefill, large-scale GPU deployments rely on context, sequence, tensor, pipeline, and expert parallelism [7, 22, 26, 29, 37, 41, 53, 55, 57]. Local deployments, however, operate at a different point: low concurrency with strict latency targets, PCIe-only interconnects often lacking GPU–GPU P2P, and constrained VRAM. Under these constraints, many cluster-oriented schemes do not translate directly. We implement a communication-lean hybrid of context and expert parallelism to distribute long-context prefill; yet, even with reduced exchanges, PCIe dispatch/combine remain significant, leaving communication as the primary bottleneck.

Figure 2 illustrates StripedAttention (CP=2, Pass-KV) [7, 58] combined with standard expert parallelism (EP=2) [26, 55]. StripedAttention splits input tokens evenly across two ranks. Each rank first computes causal attention over its local KVs (Attn P1, ①), then performs a ring Pass-KV to exchange the remaining KVs, with which each rank completes the causal attention (Attn P2, ②). In the expert-parallel stage, tokens on each rank are gated and sorted to form per-expert token lists (③). An All-to-All Dispatch exchanges tokens so each GPU receives the tokens assigned to its local experts.

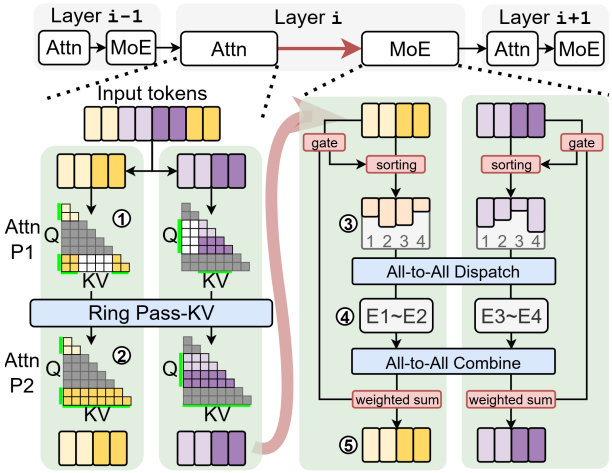

Figure 2: Example workflow: zigzag StripedAttention (Pass-KV, CP=2, left) followed by expert parallelism (EP=2, right). Tokens are split across two ranks; each rank attends locally (phase 1), performs one ring Pass-KV exchange, then completes attention (phase 2). Outputs then flow through MoE gating, dispatch/compute/combine, and weighted aggregation.

Local experts execute on those tokens (④), after which an All-to-All Combine returns the expert outputs for the originating tokens. A final weighted sum produces the per-token outputs (⑤).

Implementing StripedAttention with standard expert parallelism confirms that distributed prefill can effectively reduce computation time. As shown by the top-down microbenchmark of a 20K-token prefill on a single decoder layer in Figure 3, standard CP2+EP2 reduces end-to-end layer latency by 21% over the single-GPU baseline. However, EP still incurs substantial PCIe traffic: Dispatch and Combine account for roughly 31% of the layer time in local deployments without GPU–GPU P2P support. To mitigate this bottleneck, in Section 3.2 we propose SmallEP, which redesigns the expert-parallel exchange and reduces transferred MoE communication volume by approximately 50%. This further lowers end-to-end layer latency by 18% over standard EP in the same 20K-token prefill microbenchmark. With SmallEP, the 2-GPU distributed stream-loading prefill (DSLP) achieves a 1.64× throughput gain over single-GPU SLP.

2.2.4 Concurrency

Local deployments face markedly different concurrency profiles from what is evaluated and optimized for on cloud platforms [25, 27, 41, 56]. Given inherently low parallelism, two common strategies help—but with trade-offs: (1) Chunked prefill [2] partitions long prompts so prefill and decode can interleave, which reduces mutual blocking between a lengthy prefill and concurrent decodes on hybrid CPU–GPU systems. However, segmentation induces frequent kernel transitions and short compute windows, destabilizing per-token

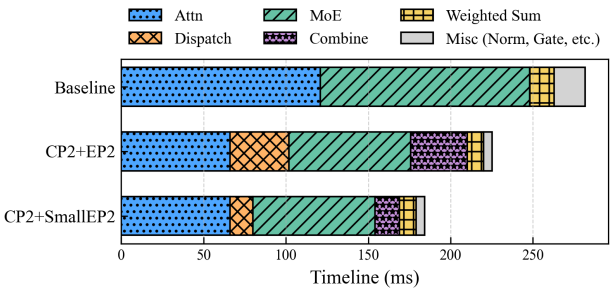

Figure 3: Top-down comparison of parallelism designs on a 20K-token prefill for a single decoder layer (one Attention + one MoE). Baseline: single-GPU sequential. CP2+EP2: StripedAttention (CP=2) with standard expert parallelism (EP=2). CP2+SmallEP2: StripedAttention with our optimized expert parallelism that reduces inter-GPU communication by roughly 50%.

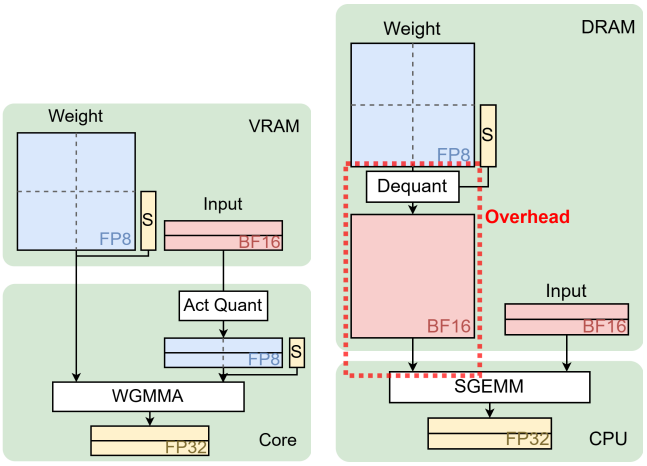
latency (TPOT) for decode and often increasing time-to-first-token (TTFT) for prefill versus isolated execution due to altered scheduling. (2) Batched decode and continuous batching [54] coalesce decode steps across requests to execute jointly. While highly effective in the cloud—large batches saturate expert-activation paths and raise compute utilization—the gains diminish locally. With small batch sizes and sparse expert activation, batching multiplies the number of active experts per step, amplifying memory-bandwidth pressure; consequently, each request experiences worse TPOT compared to non-batched local execution. In Section 3.3 we provide intra-node prefill-decode disaggregation and dual-batch attention-MoE overlap to overcome these two types of contentions.

2.2.5 FP8 Block Scaling Format

Modern models increasingly train and serve with native low-bit formats such as FP8 and FP4 [30, 31, 52], expanding parameter capacity while reducing memory pressure and preserving capability and generality [14, 17, 28, 32, 36, 44]. FP8 typically uses per-tensor or per-block scaling to map BF16 ranges into E4M3 (4-bit exponent, 3-bit mantissa), restoring dynamic range via shared FP32 scales. On modern GPUs, hardware support [34] and optimized kernels [11] enable a straightforward FP8 GEMM path (Figure 4a): FP8 weights and scales are loaded from VRAM, activations are quantized to FP8, and WGMMA executes native FP8 GEMM with FP32 accumulation.

In contrast, CPUs lack native FP8 units; hybrid systems run quantized [48,50] or upcasted BF16 models [47,49] to execute on CPUs [8]. Quantization can degrade precision and stability, while upcasting doubles memory requirements. As shown in Figure 4b, FP8 weights must be dequantized to BF16 before SGEMM, inflating DRAM capacity and memory traffic—the red boxed region marks this dequantization overhead.



(a) Example FP8 GEMM execution path on a modern GPU.

(b) Example FP8 GEMM execution path on a CPU.

Figure 4: FP8 GEMM execution on GPU versus CPU. "S" denotes per-tensor or per-block scale factors. On CPU, FP8 weights and scales are dequantized to BF16 prior to GEMM; the dequantization and doubled memory footprint are highlighted by the red box.

To overcome these limitations and enable original-precision FP8 inference on CPUs, we develop an AVX-512–optimized FP8 GEMV kernel tailored for online FP8 MoE serving, As detailed in Section 3.4. Our FP8 kernel delivers 4–5× lower latency and higher effective memory bandwidth than existing BLAS libraries, making native CPU FP8 inference practical without quantization/dequantization.

3 System Design

Hardware and model target. Our goal is to meet cloud-level SLOs on a single, cost-efficient local node. The system prioritizes price/performance: dual-socket, value-tier server CPUs (e.g., AMD EPYC 9355–class) supplies enough DRAM capacity and bandwidth, while 1–2 consumer GPUs (e.g., RTX 5090–class) provide the bulk of compute at low cost per TFLOP. On the model side, we primarily target intact, original-precision large MoE models whose full weights fit in host DRAM, especially DeepSeek-V3-class models and similar state-of-the-art public MoE models.

3.1 Stream-loading Prefill

To maximize GPU utilization and reduce TTFT, we prefill exclusively on GPUs with a computation–communication overlap design inspired by weight-offloading systems. Unlike prior approaches that rely on modified routing or compression, our design targets overlapping operations and maximizing prefill throughput for intact large MoE models.

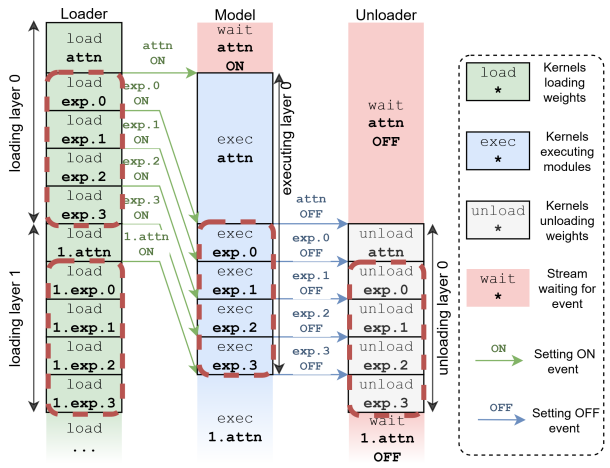


Figure 5: Stream-loading prefill pipeline with three concurrent threads. The loader (left, green) loads weights for modules (attn & exp.i) and sets ON events. The model thread (center, blue) wait ON events, executes modules and set OFF events. The unloader (right, gray) wait OFF events then unloads weights to free GPU memory. Arrows indicate event signaling and dependency ordering. Dark red boxes indicates weights that are managed by experts ring buffer.

Stream-loading prefill scheme. We implement prefill as a three-thread (as well as three CUDA streams) pipeline—loader, model, and unloader—coordinated at a sub-layer granularity, with event tuples that each pairs a CUDA event (device-side) with a host threading event (CPU-side). The loader runs concurrently with the model thread, proactively staging module weights from DRAM into GPU global memory. For each module, the loader signals readiness by setting its ON events, which the model thread waits on before executing that module. After a module finishes, the model thread sets the corresponding OFF events to indicate its weights can be released. The unloader waits on OFF events and, once signaled, evicts the associated weights from GPU memory. This design overlaps weight I/O with computation and minimizes stalls in computation, and bounds VRAM use by actively reclaiming weights after their execution.

Mitigating frequent memory operations. A key engineering challenge is the sheer number of weight tensors. In DeepSeek-V3, 58 MoE layers × 256 experts × 3 FP8 linear modules yields 44.5K tensors; naïvely allocating and freeing them incurs substantial cudaMalloc/cudaFree overhead. We therefore use a manually managed experts ring buffer shared across layers, as marked in dark red boxes in Figure 5. Its length adapts to the compute–communication balance and the peak memory footprint of long-context prefill. For short prompts (transfer-dominated), we set the length to the number of experts of a layer to maximize preload lookahead and saturate host–device bandwidth. Beyond a prompt-length turning point (e.g. 50K), computation becomes the bottleneck and intermediate tensors dominate VRAM; we shrink the length to 2 (ping–pong) to maintain overlap while capping memory use.

Loader and unloader strategy. The loader must decide whether the next module's weights fit in VRAM. For tensors not covered by the ring buffer, we probe available device memory before loading. These tensors are relatively small; a fixed budget of about 1 GB suffices to stage one layer's dense weights. The loader streams weights until that budget would be exceeded, then blocks until the unloader frees space. The unloader follows different policies for different tensor classes. For expert weights managed by the ring buffer, the authoritative copy always remains in host memory, so unloader simply frees or reuses the corresponding GPU-side ring-buffer slot rather than copying the weights back to the CPU. For other tensors, such as the QKV projection weights, which are few in number and irregular in shape and are therefore not managed by the experts ring buffer, the unloader simply releases their temporary GPU allocations after use.

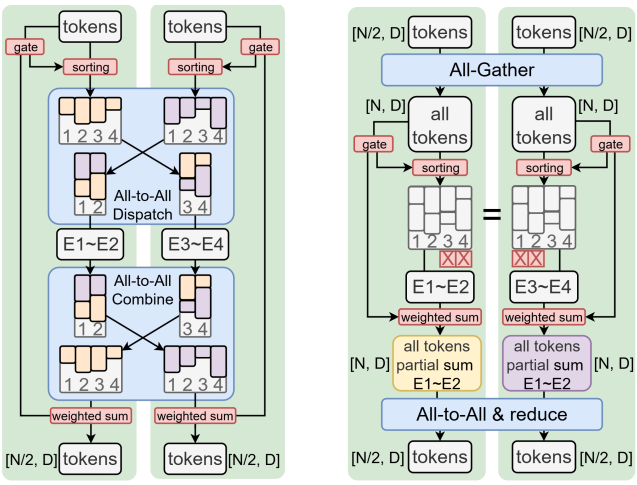
Compared with more implicit memory-management and prefetching mechanisms such as CUDA Unified Virtual Memory and `cudaMemPrefetchAsync`, our design uses explicitly orchestrated loader/model/unloader threads to obtain predictable memory usage and precise control over computation-transfer overlap. This choice does introduce additional engineering complexity, but the added logic is mostly confined to reusable ring-buffer management and synchronization primitives, making the design straightforward to adapt across different large MoE models.

3.2 Distributed Stream-loading Prefill

In few-GPU settings typical of local deployments, we distribute prefill with a combination of context parallelism (CP) and expert parallelism (EP) across GPUs to maximize hardware utilization and shorten time-to-first-token (TTFT); we refer to this distributed version as DSLP. The design targets low parallelism sizes and inferior interconnect regimes by carefully balancing computation and communication, co-optimizing data layout to reduce inter-GPU transfers.

For attention, we adopt the zig-zag variant of striped attention [7, 58], which achieves load balance across GPUs while simplifying implementation.

We optimize EP for small EP sizes to reduce communication overhead on our few-GPU scenario with commodity interconnects. In the standard EP workflow (Figure 6a), tokens are routed by the gate, sorted by expert, and then exchanged via an All-to-All dispatch so each device gathers the tokens for its local expert group. The expected volume communicated per device pair is $\frac{N \cdot A \cdot D}{S}$, where N is the total number of tokens across devices, A is the number of activated experts per token, S is the EP size, and D is the hidden-state size; the



(a) Standard EP workflow.

(b) SmallEP workflow.

Figure 6: Workflow comparison between standard expert parallel and SmallEP optimization under an EP size=2 configuration. N is the number of tokens on all devices, D is hidden size.

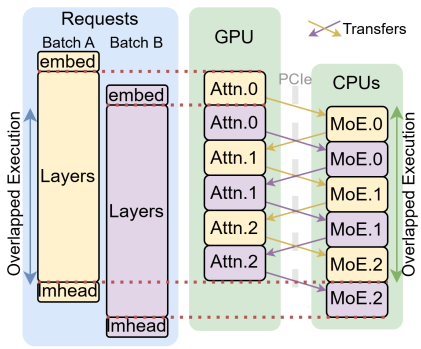


Figure 7: Dual-batch attention-MoE parallelism scheme for simultaneous inference of two batches A and B. "embed" stands for input token embedding linear layer; "lmhead" stands for output language model head linear layer.

combine phase mirrors this cost. When S is large, traffic is evenly spread across links and latency can be effectively overlapped. However, with small S—typical in local deployments without high-bandwidth interconnects like NVLink—the per-link volume becomes concentrated and the transmission cost dominates, as depicted in Figure 3.

SmallEP design. To reduce communication in small EP regimes, we first All-Gather the unsorted tokens so that every rank holds a full copy of all tokens, then perform gate evaluation and token sorting locally on this replicated batch. Each rank retains tokens assigned to its local experts and discards the rest before expert computation. After experts finish, we apply a per-rank partial weighted sum to produce a reduced tensor of shape $[N, D]$, perform an All-to-All on these partial results, and then complete the local reduction to obtain the final output.

This scheme fixes the All-Gather traffic at $N \cdot D$ bytes per link and limits the All-to-All to the partially reduced $N \cdot D$-sized tensors. Compared to standard EP's communication volume $\frac{N \cdot A \cdot D}{S}$, we deduce that when the EP size S is no larger than the number of activated experts A, SmallEP reduces peak per-link bandwidth and improves end-to-end communication efficiency.

This tradeoff is favorable in the small-EP regime we target, especially for long-context prefills over PCIe-class interconnects, where dispatch/combine communication becomes a dominant cost. SmallEP does incur redundant local gating and sorting because each rank processes a full copy of all tokens before discarding non-local expert assignments. However, our profiling shows that this overhead—included in the "misc" component of Figure 3—remains below 10 ms per layer ($< 5\%$ of end-to-end latency), and is therefore small relative to the communication overhead that SmallEP eliminates.

Expert load imbalance is a well-known concern in large-scale EP deployments. However, in our target small-EP regime, each device serves a relatively large set of experts rather than only a few, so routing skew is averaged out more effectively within each device. This makes stragglers from expert imbalance much less severe than in traditional large-EP settings.

3.3 Concurrency-Targeted Optimizations

3.3.1 Dual-Batch Attention-MoE Overlap

Batched decoding presents a fundamental bottleneck on CPU-centric systems due to independent MoE activation patterns. As the number of concurrent requests increases, the set of activated experts expands multiplicatively, creating proportional increases in memory bandwidth demand that quickly saturate available resources.

On the other hand, hybrid CPU-GPU inference reveals a sequential execution pattern where CPU and GPU components alternate but cannot overlap due to compute dependencies. When the CPU processes MoE layers, the GPU remains idle, and vice versa. Our measurements show that attention processing requires approximately 350µs while MoE computation takes 450µs per layer, creating significant idle time that represents wasted computational capacity.

To address both the concurrency limitations and hardware underutilization, we propose a dual-batch interleaving execution scheme. As illustrated in Figure 7, we create two threads as well as two CUDA streams (A and B, execution flow represented by arrows) for concurrent request processing. The execution pattern interleaves two streams of attention (on the GPU) and MoE computation (on the CPU), creating a tightly coupled pipeline that minimizes idle time. The only synchro-

nization bottlenecks occur during GPU-exclusive operations such as token embedding and model head computation, but these contribute minimal overhead (<5ms) compared to the 61 decoder layers that dominate execution time (approximately 50ms per token).

3.3.2 Intra-node Prefill-Decode Disaggregation

Building on stream-loaded prefill, we push prefill compute fully onto the GPU with minimal CPU time consumed. This enables disaggregation within a single node: we dedicate one GPU to prefill while the other handles decoding or chunked prefill, thereby isolating prefill tasks from decode ones, increasing concurrency and reducing contention impacts.

To avoid duplicated storage of weights in DRAM, we share a single resident copy of model weights in our system with the SLP or DSLP pipelines. Inter-process communication uses the experts ring buffer to achieve zero memory copies and minimizes DRAM bandwidth consumption. During disaggregated SLP+decode, Although weights still necessarily traverse the CPU–GPU path over a PCIe 5.0 x16 link, this cost is modest relative to the >1 TB/s DRAM bandwidth and does minimal impact on decode performance.

Intra-node prefill–decode disaggregation, combined with DSLP, expands the scheduling design space beyond plain chunked prefill. Our policy is: use chunked prefill for short requests (e.g., <2K tokens). For long prefill requests, if there are no decode requests within a short window (e.g., 5 minutes), route to DSLP to maximize throughput; otherwise, route to disaggregated SLP to preserve decode latency. Prefill requests are served first-come, first-served, while decode requests are dynamically batched up to a target size (e.g., Y=6) to balance latency and efficiency.

3.4 AVX-512 FP8 GEMV Kernel

At the core of our system lies an FP8 matrix-vector (GEMV) kernel optimized for modern AVX-512 CPUs where modern GPU-style FP8 units are not available. The design targets MoE inference workloads, where extreme throughput and memory efficiency are critical.

3.4.1 FP8 Format and Dequantization Strategy

DeepSeek-V3 adopt the E4M3FN format—1 sign bit, 4-bit exponent, and 3-bit mantissa without NaNs—as the FP8 variant for weight storage [28]. Unlike GPUs, CPUs lack native FP8 processing units [21]. Therefore, we implement E4M3FN dequantization via integer bit manipulations.

We implemented a standard FP8-BF16 dot-product kernel, as illustrated in Figure 8, it requires:

1. Expanding FP8 to FP32 (without fixing exponent bias diff),
2. Applying FP32 scale inverse and exponent bias fix,

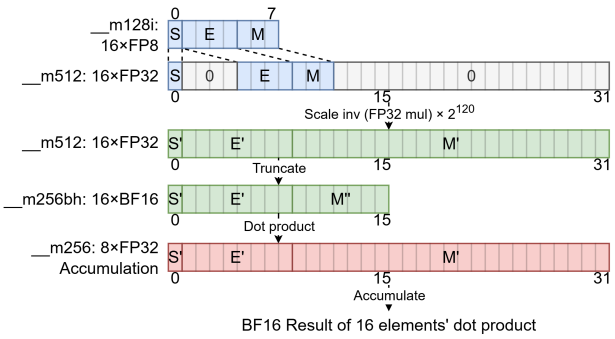

Figure 8: Baseline FP8-BF16 dot-product kernel in AVX512.

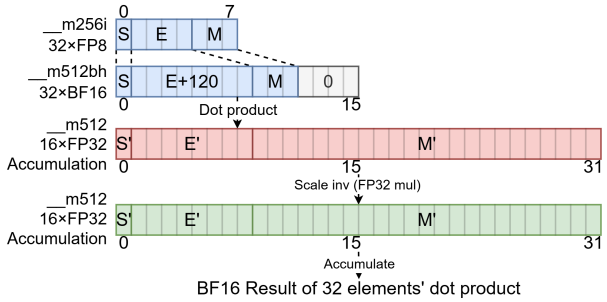

Figure 9: Our post-scaling kernel of FP8-BF16 dot product.

3. Truncating to BF16,
4. Performing BF16 dot-product.

This approach is inspired by the one that is adopted by Chitu engine [45]. Although precise, it involves over 15 vector instructions and suffers from pipeline pressure due to FP32 register density (16 FP32 elements per 512-bit register). On AVX-512, this limits vectorized throughput and results in an estimated latency of ∼36 cycles, and throughput of 12 cycles per iteration (per 16 elements).

Our optimized post-scaling design avoids FP32 in the hot path. As illustrated in Figure 9, we:

1. Expand FP8 weights directly to BF16,
2. Load BF16 activations into `__m512bh`,
3. Execute `vdpbf16ps` for fused BF16-BF16 dot products into FP32 accumulators,
4. Apply post-scaling to the accumulated FP32 result.

This optimized execution path circumvents the register pressure caused by frequent FP32 use. By working directly in BF16 for both weights and activations, we effectively double AVX-512 vector slot utilization—from 16 FP32 to 32 BF16 elements per register—maximizing instruction throughput and widening the execution pipeline. An estimated latency of 27 cycles and throughput of 4.96 cycles per iteration (per 32 elements) are deduced.

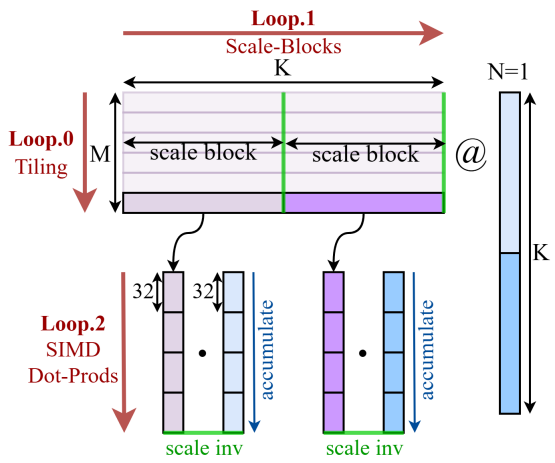

Figure 10: Hierarchical structure of the FP8 GEMV kernel. Computation is organized into **Tiling** along the M-axis, **Scale-Block** iteration along the K-axis (128 elements per block), and **SIMD Dot-Prods** that pipeline accumulations within each block. A single scale factor is loaded per block and applied after all accumulations, reducing scaling overhead and sustaining high bandwidth.

The numerical impact of this transformation is minimal: the end-to-end GEMV operation exhibits only 0.0017 as the 95 percentile of the L1 differences of all elements when compared to PyTorch's reference BF16 GEMV implementation on GPUs. This suggests the BF16 intermediate format is sufficient to preserve inference fidelity for most workloads. Beyond this kernel-level result, Section 4.7 further evaluates end-to-end model quality.

Measured on a our dual-socket AVX-512 CPU platform, the post-scaling kernel achieves 815 GB/s memory bandwidth. Supporting CPU FP8 inference even in the absence of dedicated FP8 hardware.

3.4.2 Tiling and Scale-Block Optimizations

Building upon the post-scaling optimization that lifted bandwidth to 815 GB/s, we further refine the GEMV kernel by restructuring the loop hierarchy. Specifically, we decompose the computation into three nested levels (see Figure 10): (1) *Tiling* (M-axis): the matrix is partitioned into tiles that do not cross scale-block boundaries, ensuring clean alignment between data layout and scaling granularity. (2) *Scale-Blocks* (K-axis): the K dimension is iterated in fixed-size blocks (typically 128 elements), each governed by a single FP8 scale factor. Instead of applying the inverse scale per sub-iteration, we accumulate all partial dot-products first and apply the scale_inv once per block—reducing the number of multiplications by 4× compared to the baseline post-scale kernel. (3) *SIMD Dot-Prods*: within each block, unrolled inner loops perform fused multiply-accumulate operations in SIMD registers, pipelining partial sums before applying the shared scale factor.

This hierarchy minimizes redundant scaling operations while retaining numerical accuracy, maximizing bandwidth utilization. As a result, the optimized kernel sustains up to 947 GB/s memory bandwidth—surpassing both the baseline and prior post-scaling design.

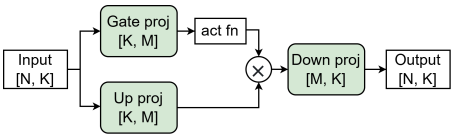

Figure 11: MoE expert compute graph: each expert has gate, up, and down projections. Gate and up can run concurrently; their outputs synchronize before down. N is batch size (N=1 for single-request inference).

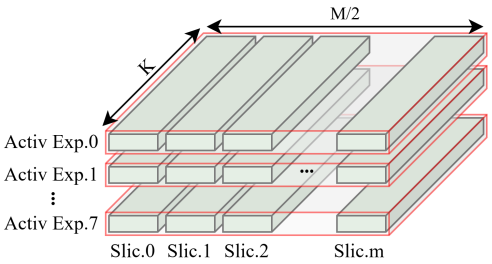

Figure 12: Task partitioning of gate/up on a NUMA node. Output dim M is sliced into m segments per expert, yielding m×8 independent tasks (8 activated experts). Each thread runs a vectorized FP8–BF16 kernel. Red borders mark per-expert barriers that satisfy dependencies for down projection while minimizing synchronization.

3.5 Fine-grained CPU Parallelism for MoE Inference

3.5.1 Fine-Grained Synchronization Design

In MoE layers [28, 38], each expert comprises gate, up, and down projections with the dependencies in Figure 11. Gate and up are embarrassingly parallel and execute concurrently; their results synchronize before down.

In KTransformers' CPU backend, stage 1 computes gate and up. As shown in Figure 12, each GEMV is sliced into m segments along the output dimension M, deepening tensor parallelism on the gather axis, while activated experts are evenly distributed across cores within each NUMA node. Because gate and up must be combined (activations and multiplications) before down, naive global barriers could be adopted but are costly. Instead, we use fine-grained per-expert barriers and fuse the combine ops into stage one, cutting synchronization overhead and improving scalability.

3.5.2 Operator Fusion for Quantized Inference

In quantized MoE models, expert weights (gate, up, down) use low-bit formats (e.g., Q4_K_M, a mixed blockwise GGUF quantization format with per-block scales/metadata). In the KTransformers configuration we study, `Q4_K_M` is a mixed K-quant storage scheme: `gate_proj` and `up_proj` use `Q4_K`, while `down_proj` uses `Q6_K` [3]. The expert inference path can be summarized as

$$\text{input conversion:} \quad \texttt{hidden_type} \rightarrow \texttt{Q8_K},$$

$$\text{gate/up:} \quad \texttt{Q4_K} \times \texttt{Q8_K} \rightarrow \texttt{F32},$$

$$\text{activation and elementwise multiply:} \quad \texttt{SiLU}(\cdot) \odot (\cdot) \rightarrow \texttt{F32},$$

$$\text{down-input conversion:} \quad \texttt{F32} \rightarrow \texttt{Q8_K},$$

$$\text{down:} \quad \texttt{Q6_K} \times \texttt{Q8_K} \rightarrow \texttt{F32},$$

followed by router-weighted accumulation in `F32` and conversion back to `hidden_type`.

This requires converting activations among FP32, Q8_0, and BF16 to preserve precision for SiLU and expert aggregation. We fuse these conversions into surrounding kernels: input conversions for gate/up and down are fused into the parallel gate/up projections (stage 1); output conversion is fused into down (stage 2). The result reduces launch overhead and limits synchronization to two global barriers per MoE layer—after gate/up combination and after down.

4 Evaluations

Our evaluation is organized compositionally around the targeted deployment setting. The claimed SLOs apply to flagship MoE models on the dual-socket CPU plus 1–2 consumer-GPU class of hardware described in Section 4.1. We then isolate the major components of the system: Section 4.2 evaluates SLP/DSLP and SmallEP for long-context prefill; Sections 4.3 and 4.4 evaluate fine-grained CPU parallelism and dual-batch attention–MoE overlap for full-precision and quantized decode; and Section 4.5 shows how these components interact under concurrent requests in a single-node deployment. Finally, Section 4.6 isolates FP8 kernel performance, while Section 4.7 reports end-to-end model quality.

4.1 Evaluation Platform Setup

Hardware Configuration Overview Our primary evaluation platform is a hybrid inference node built for cost-effective large-scale model serving. Our platform is equipped with two AMD EPYC 9355 processors, 24 DDR5-6400 48GB memory modules distributed across 24 memory channels, yielding a total system memory capacity of 1.15TB and a theoretical aggregate bandwidth of 1228GB/s. Complementing the CPU is two NVIDIA RTX 5090 GPUs with 32 GB of GDDR memory and up to 419 FP8 TFLOPS (with FP32 accumulation). Unless otherwise noted, all experimental results for both our engine and KTransformers are measured on this platform; we also cite KTransformers' published numbers when comparing against their original reported setup. Our empirical evaluation therefore primarily covers this dual-socket, PCIe-attached commodity CPU–GPU node. For lower-end or otherwise different configurations, such as reduced effective DRAM bandwidth or lower-bandwidth PCIe interconnects, we provide discussion in Section 6.

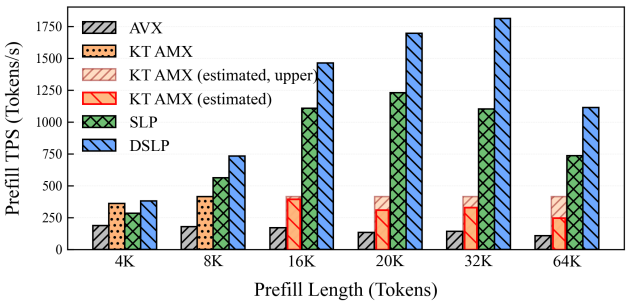

Figure 13: Prefill throughput (tokens/s) for different configurations. We compare CPU AVX baseline (FP8), KTransformers (KT) AMX (INT4), Stream-Loading Prefill (SLP, FP8), and 2-GPU Distributed SLP (DSLP, FP8). KT AMX values for prefill lengths >8K are shown as estimates: "estimated" is obtained by linearly scaling the AVX baseline based on the ratio observed at $\leq$8K tokens. "estimated, upper" is an optimistic projection of the measured KT AMX results by assuming both attention time and MoE time scale linearly with prefill length.

Model Benchmarks Our primary benchmark target is the full-precision FP8 DeepSeek-R1 [17] and Kimi-K2 [44] model, with the Q4_K_M quantized DeepSeek-R1 [48] evaluated alongside them to contextualize the tradeoffs and benefits of our optimizations.

4.2 Prefill Performance

Figure 13 reports prefill throughput as a function of sequence length for different configurations. On our platform, we evaluate our engine on the original FP8 model with three prefill modes: baseline CPU prefill (AVX), Stream-Loading Prefill (SLP), and its 2-GPU distributed variant (DSLP). For comparison, we also cite KTransformers' published AMX-based prefill results (KT AMX), which were obtained on their own platform rather than ours. Across the long-context regime (8K–64K), SLP and DSLP substantially outperform both AVX and KT AMX. For short contexts (4K), weight transfer dominates SLP and DSLP latency, thus no dominant advantage over KT AMX. As the prefill length increases into the long-context regime (16–64K), the advantage of SLP be-

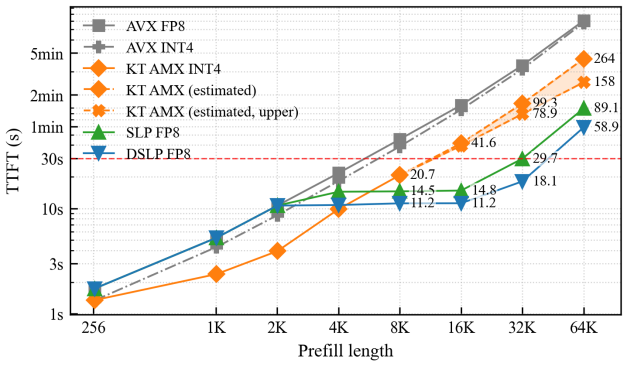

Figure 14: Time-to-First-Token (TTFT) comparison across prefill lengths from 256 to 64K tokens. We report CPU baselines using AVX FP8 and AVX INT4, KTransformers on AMX (KT AMX INT4), and our Stream-Loading Prefill (SLP, FP8) and 2-GPU Distributed SLP (DSLP, FP8). KT AMX results beyond 8K tokens are shown as estimates.

comes dominant. At 20–32K tokens, SLP delivers more than an order-of-magnitude speedup over AVX and a 2.8× improvement relative to the estimated KT AMX performance, while DSLP further increases throughput to 1.64× SLP. The "estimated upper" KT AMX bars, obtained by linearly scaling the measured KT AVX throughput, remain far below SLP and DSLP, implying that even an ideal AMX implementation that scales linearly with sequence length cannot match the gains from our SLP and DSLP.

For a more comprehensive comparison, we evaluate TTFT across a wider range of prefill lengths. Because SLP and DSLP incur additional latency from weight transfer and stream setup, they are disadvantaged at very short prefixes. Consequently, we use the AVX FP8 kernel for requests up to 4K tokens and switch to SLP/DSLP for longer contexts.

At small prefill lengths (256–2K), the CPU baselines are competitive: AVX FP8 and AVX INT4 track each other closely, and KT AMX INT4 achieves the lowest TTFT. Beyond 4K tokens, offloading with stream loading becomes clearly preferable. All CPU-only configurations quickly exceed the 30 s TTFT threshold, while SLP and DSLP grow much more slowly. At 4K–32K tokens, SLP and DSLP keep TTFT below the 30 s target. For very long contexts (32–64K), SLP and especially DSLP remain much closer to practical latency budgets than KT-AMX configuration.

4.3 Full-Precision Decode Performance

As shown in Figure 15, on our evaluation platform, the 671B-parameter DeepSeek-R1 model sustains 21.5 tokens/s on short prompts and maintains ∼20 tokens/s up to 32K context length. We observe similar performance with the Kimi-K2 model, which achieves comparable single-stream throughput of 22.4 tokens/s. With two equal-length, concurrent requests under

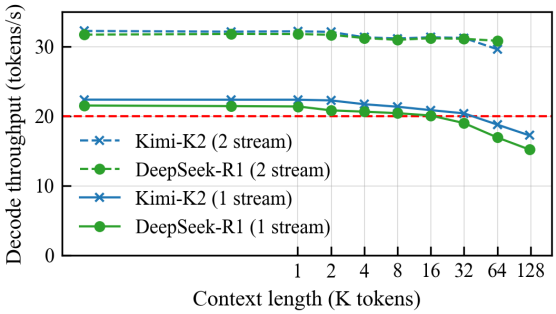

Figure 15: Decode throughput of the full-precision FP8 DeepSeek-R1 671B and Kimi-K2 1T model under single-stream and dual-stream execution across varying context lengths.

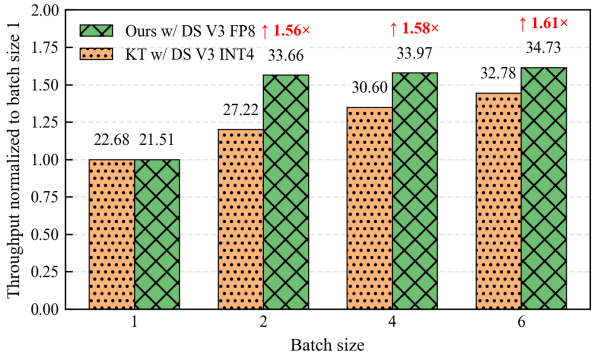

Figure 16: Decode throughput comparison of our engine running DeepSeek-R1 FP8 versus KTransformers (KT) running Q4_K_M (INT4) across batch sizes of 1, 2, 4, and 6. Bars are normalized to each engine's batch size 1 result; absolute system throughputs (tokens/s) are annotated. Red markers report our throughput gains relative to batch size 1.

our dual-batch parallel execution, total system throughput rises to 33.6 tokens/s and remains 31.1 tokens/s at 32K, ensuring each request still achieves ∼16 tokens/s. These results show that our design not only meets the single-stream QoS target but also scales gracefully under concurrency.

Figure 16 compares decode throughput as a function of batch size for our engine running DeepSeek-R1 FP8 and KTransformers (KT) with Q4_K_M. Normalizing to batch size 1 highlights scaling efficiency: our engine achieves 1.56×, 1.58×, and 1.61× throughput at batch sizes 2, 4, and 6 respectively, while KT scales more modestly.

Per-request decode speed, computed as system throughput divided by batch size, shows our dual-batch Attention-MoE parallelism preserves user-level fluency under small batches: at batch size 2, our engine sustains 16.8 tok/s per request, a 21.7% reduction from batch size 1, whereas KT drops from 22.7 to 13.6 tok/s (-40.0%). This narrower per-request degra-

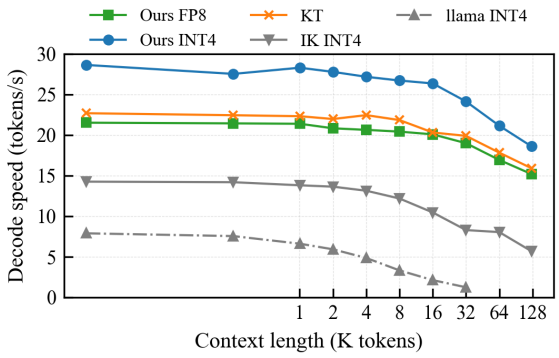

Figure 17: Decode speed comparison including Q4_K_M quantized DeepSeek-R1 671B model. IK: `ik_llama.cpp`; llama: `llama.cpp`.

dation indicates our design delivers better per-user responsiveness and higher aggregate throughput as concurrent requests increase.

4.4 Quantized Model Decode Performance

To contextualize our inference engine's performance and validate our optimizations on mixed-precision inference, we also benchmarked the Q4_K_M variant of the DeepSeek-R1. While lower in numerical precision and sacrifices model fidelity, Q4_K_M quantized DeepSeek-R1 requires only 404GB of RAM to run, displaying its role in resource-constrained deployment scenarios.

We conducted a head-to-head throughput comparison across varying context lengths from 1K to 128K tokens, evaluating: (1) Our engine, (2) llama.cpp, (3) ik_llama.cpp, (4) KTransformers.

As shown in Fig. 17, our design consistently leads across all context lengths. At short sequences (1K–8K), it sustains 28 tokens/s, nearly doubling the throughput of ik_llama.cpp (14 tokens/s) and outperforms KTransformers (22 tokens/s) by 25%. As the context grows, competing engines degrade sharply: KTransformers drops to around 15 tokens/s at 128K. In contrast, our engine declines gracefully, maintaining 19 tokens/s at the maximum length. KTransformers on INT4 quantized model reaches similar decode speed to our engine running the original FP8 model. These results highlight the impact of our tailored CPU backend and parallelism design.

4.5 Performance Under Concurrent Requests

We evaluate concurrency in four representative scenarios to measure engine performance under concurrent prefill–decode and batched decode workloads. For isolation, we construct requests that each lasts about 20 seconds when running alone. Considering the different prefill throughput of our disaggregated SLP and KT on the AVX platform, we set the prefill length to 4K tokens for KT and 24K tokens for our engine, with no shared prefixes and only a few decoded tokens. Decode requests use short 10-token prompts and are forced to generate 480 tokens. Under these settings, when requests arrive simultaneously (regardless of whether they are prefill or decode), their execution could largely overlaps in time, allowing us to minimize variability and focus on end-to-end latency metrics.

Workloads consist of: (1) a single prefill request (1P), (2) a single decode request (1D) (these two serve as baselines), (3) one prefill request plus one decode request (1P+1D), (4) two concurrent decode requests (2D), and (5) one prefill request plus two decode requests (1P+2D). Each workload is executed multiple times on each engine. For metrics, we report the average TTFT for prefill requests and the average TPOT for decode requests, and we also measure the total latency to complete all requests within each workload.

We summarize the results in three perspectives: prefill latency (TTFT), decode latency (TPOT), and total workload latency, as shown in Figure 18. Overall, our engine consistently handles concurrent workloads more robustly than KT. From the prefill perspective, TTFT remains stable for both engines under 1P and 1P+1D. For our engine, this is because prefill–decode disaggregation isolates the 1P request from concurrent decodes. Under 1P+2D, however, the additional DRAM traffic introduced by Attention–MoE parallelism slightly delays Stream-Loading Prefill's weight transfers, leading to an 18% TTFT increase. We expect this effect to become slightly more pronounced as the number of concurrent decode requests further increases, because denser decode-side DRAM accesses leave less bandwidth headroom for SLP weight streaming. For KT, TTFT behavior is governed by its scheduling strategy of executing one 256-token chunked prefill per decode step, effectively prioritizing prefill over decode; this tradeoff becomes clearer when we examine TPOT.

From the decode perspective, our engine maintains stable TPOT across all workloads, while KT's TPOT degrades significantly whenever prefill and decode coexist. KT's average TPOT increases by up to 2.45× over the 1D baseline, whereas ours increases by at most 1.54× and scales smoothly under various concurrency workloads.

Finally, in terms of total latency to complete all requests in each workload, our engine is consistently better than KT: our worst-case latency increase is 1.67× over the baseline, compared to KT's 2.53×, and we also exhibit more favorable scaling when serving multiple concurrent decode requests (2D and 1P+2D).

4.6 FP8 GEMV Kernel Performance

To isolate kernel performance from end-to-end system effects, we evaluate our FP8 GEMV kernels under real MoE workload and compare them against established CPU libraries. As shown in Table 1, our optimized kernel achieves a latency of

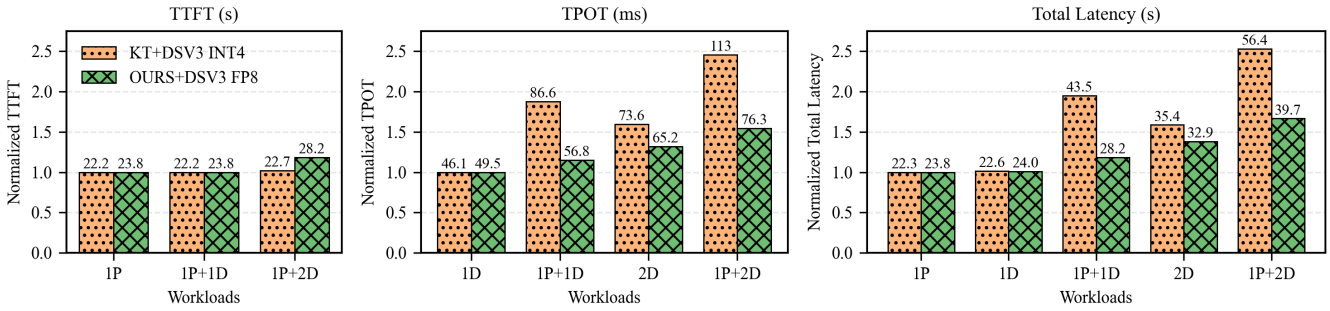

Figure 18: Microbenchmark of system latency under concurrent workloads. We compare KT with INT4 DeepSeek-R1 against our engine with FP8 DeepSeek-R1. All results are normalized to the first bar group in each subfigure, with the corresponding absolute values annotated on top of the bars. Workload labels: "1P" denotes one prefill request, while "1D" and "2D" denote one and two concurrent decode requests, respectively.

Table 1: Comparison of GEMV kernels on MoE workload. Our implementation is the only one supporting FP8 natively, while remaining competitive in bandwidth and significantly reducing latency.

Library	Format	Latency (μs)	BW (GB/s)
OpenBLAS	FP32	69.5	844.42
AOCL-BLAS	FP32	59.2	992.70
AOCL-BLAS	BF16	69.5	422.26
Ours (Std.)	FP8	21.7	678.0
Ours (Optim.)	FP8	**15.5**	**947.1**

15.5 µs and bandwidth utilization of 947 GB/s — surpassing the our standard kernel (21.7 µs, 678 GB/s) and significantly outperforming OpenBLAS [35], and AOCL-BLAS [1] across FP32 and BF16 formats in latency while matching or exceeding bandwidth utilization. These results demonstrate that our kernels unlocks 4–5× latency reduction over existing CPU libraries with native FP8 support and delicate design.

4.7 End-to-End Quality Evaluation

We evaluate end-to-end model quality on benchmark tasks. Table 2 reports Exact-Match results on MMLU-Redux [16] and MMLU-Pro [46] for our deployments of DeepSeek-V3.1 [28] and Kimi-K2-Instruct [3], compared against the officially published results of these models.

Overall, our system preserves end-to-end quality well: the measured scores are close to the official references, with degradations within about 1–1.2 percentage points across the evaluated benchmarks. We believe these differences are minor and likely stem from small mismatches in generation configuration, rather than from a systematic loss of model capability introduced by our system. These results therefore provide additional evidence that our design preserves the quality of the original models while improving local serving performance.

Table 2: End-to-end quality evaluation using Exact Match. Official results are taken from the corresponding model releases.

Model	Benchmark	Ours	Official
DeepSeek-V3.1	MMLU-Redux	91.00	91.8
	MMLU-Pro	83.41	83.7
Kimi-K2-Instruct	MMLU-Redux	91.53	92.7

5 Related Work

Cloud-service inference systems GPU-centric engines such as vLLM, SGLang and TensorRT-LLM are optimized for multi-GPU nodes and datacenters to sustain high concurrency and throughput [25,33,56]. They converge on KV cache management (paged or radix-indexed) [25,56], concurrency-aware scheduling (Chunked Prefill, Continuous Batching) [2,54], distributed inference across context, sequence, tensor, pipeline, and expert parallelism [22,26,29,37,41,53,55,57], and operator-level optimizations (kernel fusion, FlashAttention variants, new precisions) [9, 10, 39, 45]. While highly effective, these designs assume abundant GPU memory bandwidth, large aggregated VRAM, and fast interconnects, limiting flexibility and cost-efficiency outside GPU-first environments. Our work targets the local regime, adapting MoE-specific execution and parallelism to small-EP, low-concurrency settings on commodity CPU–GPU platforms while retaining cloud-level QoS.

Local inference systems for MoE models Mainstream frameworks [25,33,56] prioritize datacenters and are impractical under constrained VRAM and bandwidth. Consumer-first solutions like Llama.cpp [15], ik_llama.cpp [20], and KTransformers [8] enable CPU–GPU hybrid serving; KTransformers combines quantization, rerouting, advanced CPU instruc-

tions, and NUMA-aware orchestration to deliver competitive throughput on commodity platforms. We advance this trajectory by achieving cloud-level SLOs for intact, original-precision MoE models on consumer CPU–GPU systems. Compared with KTransformers, our work differs most clearly in target of achieving cloud-grade SLOs rather than enabling inference, and technically in three places: long-context prefill is made explicitly GPU-centric through stream loading instead of remaining CPU-centric; expert parallelism is redesigned for small EP sizes on PCIe-only local nodes; and concurrency is improved through intra-node prefill/decode disaggregation and dual-batch overlap rather than only through chunking and scheduling.

Expert offloading techniques. Serial expert-processing approaches such as ES-MoE [24] improve efficiency in memory-constrained settings by executing experts sequentially, avoiding zero-padding and large dispatch masks while improving load balance. However, ES-MoE differs from our target and design in three aspects. First, it targets training, where offloading and sequential processing enable larger microbatches and higher throughput, whereas our work targets latency-critical local inference, especially low-concurrency, long-context prefilling where TTFT is the primary objective. Second, ES-MoE plans expert transfer based on routing decisions, but this routing-dependent synchronization point leaves less opportunity to overlap transfer with the substantial pre-MoE computation on the critical path, which accounts for more than 40% of per-layer execution time on a 20K-token prefill. In contrast, our SLP strategy stream-loads expert weights at a finer granularity and overlaps transfer with dense-module execution as well as expert computation. Third, for multi-GPU local prefilling, we further introduce SmallEP to reduce communication overhead under small EP sizes, improving distributed-prefill TTFT in PCIe-class local deployments.

6 Discussion

Lower-end CPUs While prefill is largely addressed by our stream-loading prefill design, the main impact of lower-end CPUs is on decode. Small-batch decoding is well known to be heavily memory-bound. For the MoE computation executed on CPUs, the involved skinny GEMMs have an arithmetic intensity of roughly $2\times$ batch size. In local deployment, the batch size is typically small (1–4), which remains far below the compute-to-memory ratio of current CPUs (around 50 FLOPs/byte). As a result, for lower-end CPU configurations, the dominant concern is reduced effective DRAM bandwidth rather than raw compute capability. According to our profiling, CPU-side MoE execution accounts for about 60% of total decode time, with even greater exposure under dual-batch decode. We therefore expect decode performance to scale approximately linearly with available DRAM bandwidth, both in single-stream decoding and under dual-batch overlap.

Lower-VRAM or mid-range GPUs The main hardware sensitivity on the GPU side lies in SLP/DSLP. For moderate prefill lengths (e.g., 16K tokens), performance depends on a tradeoff between experts ring-buffer capacity in VRAM and the ability to overlap weight transfer with computation. Our default design uses a full ring buffer covering all experts in one layer, which best smooths intra-layer transfer/computation imbalance and maximizes overlap. For DeepSeek-V3 and Kimi-K2, this corresponds to 11.3–16.9 GB of ring-buffer space, or 5.6–8.5 GB per GPU when distributed across two GPUs. If a lower-VRAM GPU cannot support this buffer size, overlap becomes less effective, and TTFT for medium-length prefills may degrade. By contrast, at very long prefills (e.g., beyond 50K tokens), the workload is dominated more by computation than by transfer, so performance should depend more directly on the GPU's available compute throughput.

7 Conclusion

This work demonstrates that flagship large MoE models can be served locally with cloud-level quality of service on commodity CPU–GPU platforms. By introducing stream-loading prefill (SLP) and its distributed variant (DSLP) with SmallEP, we achieve 30-second TTFT for 32K–45K prompts. Our intra-node prefill–decode disaggregation and dual-batch attention–MoE overlap sustains concurrency with minimal interference, while an AVX-512–optimized FP8 GEMV and fine-grained CPU parallelism close decode latency gaps for both full-precision and quantized models. Evaluations against mainstream CPU frameworks and BLAS libraries show that our design attains >20 TPS decode responsiveness and high-throughput prefills at substantially lower cost than GPU-centric deployments. Together, these results reshape the local MoE deployment landscape, enabling intact, original-precision inference and robust QoS without datacenter infrastructure, and point to a path for broader, cost-effective access to state-of-the-art applications.

Abstract

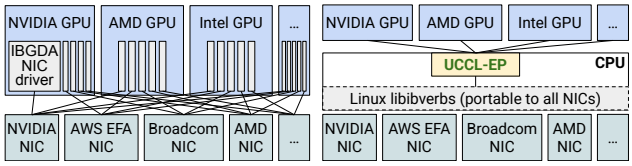
Modern Mixture-of-Experts (MoE) workloads rely on expert parallelism (EP) to achieve high GPU efficiency. State-of-the-art EP communication libraries, such as DeepEP, rely on GPU-initiated RDMA communication. Although performant, they have poor portability across heterogeneous GPU and NIC hardware. The poor portability is rooted in its architecture: GPU-initiated RDMA communication requires tight vertical integration between GPUs and NICs, e.g., GPU writing to NIC driver/MMIO interfaces.

We present UEP, a portable EP communication system that delivers high performance across heterogeneous GPU and NIC hardware. UEP replaces GPU-initiated RDMA with a high-throughput GPU-CPU control channel: compact token-routing commands are transferred to multithreaded CPU proxies, which then issue GPUDirect RDMA operations on behalf of GPUs. UEP further emulates various ordering semantics required by specialized EP communication modes using RDMA immediate data, enabling correctness on NICs that lack such ordering, e.g., AWS EFA. We implement UEP on NVIDIA and AMD GPUs with EFA and Broadcom NICs. On EFA, it outperforms the best existing EP solution by 2.1× for dispatch and combine throughput. UEP also improves token throughput on SGLang by up to 40% on the NVIDIA+EFA platform, and improves DeepSeek-V3 training throughput over the AMD Primus/Megatron-LM framework by up to 45% on a 16-node AMD+Broadcom platform.

1 Introduction

State-of-the-art large language models (LLMs), such as DeepSeek-V3 [12,30], OpenAI gpt-oss [45], Google Gemini-3 Pro [16], and Meta Llama 4 [2], are increasingly based on the Mixture-of-Experts (MoE) architecture. In a MoE layer, a gating network running on GPUs selects a small subset of experts for each token activation, dispatches the token activation to those experts, and then aggregates their output activations. Modern MoE models typically instantiate hundreds of experts that specialize in different input patterns, so that only a few experts are active for each token. This sparsity allows MoE models to achieve accuracy comparable to large dense models while using only a fraction of the per-token inference cost, making them the *de facto* choice for many frontier LLMs.

*This work does not relate to the position at Amazon.



(a) IBGDA-style. **(b)** UEP.

Figure 1: Assuming m GPU vendors and n NIC vendors, UEP enables $O(m)$ effort, instead of IBGDA's $O(m \times n)$, to support GPU-initiated token-level communication for expert parallelism.

Training and serving large MoE models require expert parallelism (EP), which places different experts on different GPUs and communicates token activations among GPUs in an all-to-all manner. By sparsely sharding experts on different GPUs, EP leaves enough GPU memory for matrix multiplication on large batch sizes (e.g., 4096 in DeepSeek-V3 [30]), thus enabling high GPU resource efficiency. Expert-parallel communication plays a pivotal role in the EP efficiency [30, 63], because token activations are small (e.g., 7KB), dispatch and combine operations are frequent (e.g., selecting 8 experts per token), and routing destinations are only determined at runtime in GPUs (§2.1).

GPU-initiated token-level (fine-grained) communication (§2.2) is an emerging and key communication pattern for efficient token dispatch and combine at runtime, where DeepEP [64] by DeepSeek is a popular communication system implementing it. Different from CPU-initiated bulk-transfer (coarse-grained) communication in NCCL/RCCL [3, 41], DeepEP leverages the advanced NVIDIA IBGDA (InfiniBand GPUDirect Async) [43] technique that enables GPUs to directly operate RDMA NICs (network interface cards) to write out small activations. DeepEP has been widely adopted by various training and serving frameworks such as Megatron-LM [6], vLLM [59], and SGLang [58] with state-of-the-art performance.

Although GPU-initiated token-level communication leads to high performance, its design unfortunately results in poor portability. There are two key reasons: GPUs directly issuing RDMA operations to NICs prevent interoperability across different GPUs and NICs, as it requires the GPU to write to NIC-defined MMIO interfaces typically requiring proprietary register layouts and tight hardware-level co-design between the NICs and GPUs [26, 44, 51]; GPU kernels also impose strict ordering and delivery semantics assumptions on the underlying network, which are often misaligned with the capabilities and semantics

of heterogeneous NICs. As shown in Figure 1a, ML infrastructure developers need to vertically integrate the GPU and NIC software ecosystems. This involves complex and subtle code migration and maintenance that are both NIC vendor-specific and GPU vendor-specific. Assume there are m types of GPU accelerators and n types of NICs. Developers need to pay $O(m \times n)$ effort to enable such communication on heterogeneous hardware. Because of this portability issue, the official DeepEP [64] only supports NVIDIA GPUs and NICs, creating severe vendor lock-in and high portability effort for alternative GPU and NIC devices. For example, at the time of writing, it remains impossible to run DeepEP on any AWS GPU instances with AWS EFA RDMA NICs; it is also challenging to run DeepEP on AMD GPUs with Broadcom NICs, the second-biggest GPU and NIC vendors, respectively. At a high level, such vertical integration is somewhat reminiscent of mainframe servers, which get replaced by less-coupled and more portable commodity servers from heterogeneous vendors in modern cloud computing.

This paper introduces a new portable expert-parallel communication architecture for GPU-initiated token-level communication with high performance. We envision that with our architecture, developers only need to pay m times effort to enable systems like DeepEP on heterogeneous GPU and NIC hardware, as shown in Figure 1b.

Our key insight is to leverage the host CPU to help break the tight coupling between GPUs and NICs, where the CPU is essentially portable to any GPUs and NICs via the `libibverbs` library [48] maintained by the Linux community and NIC vendors. Unlike traditional CPU-driven approaches, communication is still initiated by the GPU: the library passes only *small control information* from the GPU to the CPU, while the data payload is transferred directly between GPUs. GPUs and CPUs are connected through high-throughput, low-latency interconnects such as PCIe or even faster NVLink-C2C [42], which allows efficient transferring of small control data from GPUs to CPUs. By embedding the token dispatching information, such as source and destination address, into the control data, CPUs directly issue GPUDirect RDMA to write out the activations on behalf of GPUs. We note that modern GPU servers usually have hundreds of CPU cores, which are often heavily underutilized, e.g., 20%-45% CPU utilization reported by several industry companies in their GPU clusters [19, 23]; From discussion with a model training team inside a major GPU vendor, their model training using Megatron-LM [40] yields on average 14.5% CPU utilization.

Moreover, flexible host CPUs can help bridge the semantic gap between the guarantees required by specialized EP communication systems and the primitives actually provided by heterogeneous NICs. For example, EP communication libraries often require a specific write-then-atomic ordering to inform remote GPUs of data arrival, but such a requirement is typically not enforced by all RDMA NICs, such as AWS EFA NICs, which do not guarantee ordering.

To realize these insights, we need to address two challenges: i) how to efficiently transfer control data from GPUs to CPUs so that the CPU does not become the bottleneck. This is challenging, especially given the frequent token dispatch/combine operations as high as 7Mop/s/GPU under 7KB activations [30] and a 400G network. ii) How to use CPUs to express and enforce various delivery semantics (e.g., write-then-atomic) in CPU to accommodate heterogeneous NICs that do not support them on their own.

We present UEP, a portable expert-parallel communication system with GPU-initiated token-level communication. UEP decouples communication initiation from communication execution: it keeps GPUs initiating communication for fine-grained token transfer, and delegates the communication tasks to the host CPU. UEP addresses the first challenge with an efficient multithreaded, lock-free FIFO communication channel between GPUs and CPUs. This channel minimizes the PCIe traversing overhead and allows multiple CPU proxy threads to forward and execute the GPU-generated token routing decisions, achieving millions of messages per second from GPUs to CPUs. To address the second challenge, UEP leverages the immediate data feature that is widely available in RDMA NICs (this immediate data field has been standardized into the RoCEv2 packet header [1]). UEP embeds sequence information into this immediate data and lets the receiver hold messages (e.g., atomic updates) until all previous corresponding writes have finished. We show how host CPUs can flexibly bridge the delivery guarantees that GPUs require and the ones actually provided by the networking layer.

We have implemented UEP and enabled it on various heterogeneous platforms, including NVIDIA GPUs + AWS EFA NICs, and AMD GPUs + Broadcom NICs. On the NVIDIA+EFA platform, compared to the second-best EP solution PPLX [29], UEP achieved up to 2.1× higher throughput. On the AMD+Broadcom platform, UEP achieves comparable performance to the original DeepEP on the NVIDIA-only platform. UEP supports drop-in replacement for DeepEP-compatible applications without any line of code change. It speeds up serving throughput in the SGLang framework by up to 40% on the NVIDIA+EFA platform, and improves DeepSeek-V3 training throughput in the AMD Primus/Megatron-LM framework by up to 45% on a 16-node AMD+Broadcom platform. To the best of our knowledge, UEP is the first work that enables running GPU-initiated token-level communication on non-NVIDIA platforms. UEP is open-sourced.[1]

2 Background

2.1 Expert-parallel communication

Mixture-of-Experts (MoE) architectures have emerged as a leading architectural pattern for building state-of-the-art LLMs as they provide massive parameter capacity while keeping per-token compute low by activating only a small subset

[1] https://github.com/uccl-project/uccl/tree/main/ep

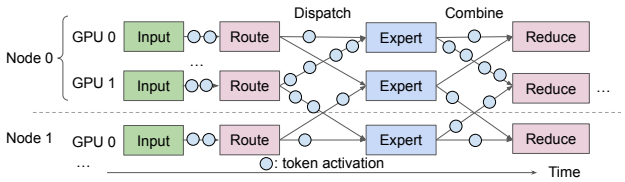


Figure 2: The MoE communication pattern consists of the dispatch phase and the combine phase. In the dispatch phase, the router sends each token's input activations to one or more selected experts. In the combine phase, expert activations are collected and aggregated back to the sender. The dispatch and combine phases feature *irregular*, *fine-grained* communication.

of experts. This sparsity enables specialization—experts learn domain-specific behaviors—while preserving general-purpose performance. As a result, many frontier models now adopt MoE designs, including OpenAI's gpt-oss [45], Google's Gemini-3 Pro [16] and GLaM [14], Mistral's Mixtral 8×7B [21], DeepSeek's DeepSeekMoE [8] and DeepSeek-V3 [12, 30] family, the Allen Institute's OLMoE [34], and Meta's Llama 4 [33], all of which use MoE to push model capacity and quality without the prohibitive compute costs of dense models. These systems power a wide range of applications—from interactive agents and large-scale pretraining to multimodal reasoning and domain-specialized tasks.

MoE models introduce a distinctive communication pattern that differs fundamentally from dense all-reduce or pipeline-parallel patterns found in other models. In a MoE layer, each input token activation is dynamically routed to a small subset of experts based on a learned gating function. This induces a sparse all-to-all pattern: Every GPU holds a subset of experts, so token activations must be dispatched from the originating GPU to the GPUs that host the selected experts and then gathered back to their origin (Figure 2). The destination GPUs are determined based on the learned gating function during runtime. Every MoE layer's forward pass has two communication phases: *dispatch*, where activations are sent to expert GPUs, followed by a *combine* phase, where expert outputs are returned and merged in the original token order. Expert-parallel communication has several new characteristics:

Fine-grained token-level[2] transfers. In MoE dispatch and combine, each token activation is small, on the order of 7KB (e.g., FP8, hidden size of 7168 [30]), so a naive implementation issues a large number of tiny GPU-GPU transfers. Unlike traditional collective communication (e.g., large, batched all-reduces or all-to-alls) that aggregates data into large bandwidth-efficient messages, MoE communication is naturally fragmented. Traditional approaches must therefore either push many small work-queue entries to the NIC, or first pack activations into contiguous per-expert buffers on the GPU, which consume SM cycles and add packing latency on the critical path.

[2]For simplicity, we use token and token activation interchangeably.

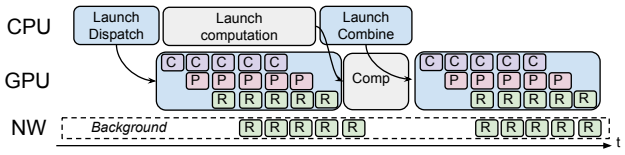

Figure 3: GPU-initiated token-level communication in DeepEP (High-throughput mode, single batch for illustration). *C* stands for intra-node data copying via NVLink, *P* stands for processing, and *R* stands for RDMA communication. Different phases (computation, communication, and copying) interleave.

Irregular communication. The number of tokens routed to each expert also varies every iteration, because routing decisions are computed at runtime by the MoE gating network. In contrast, traditional collectives assume a fixed set of participants and largely predictable, symmetric message sizes, which allows for static, precomputed communication schedules. However, MoE communication breaks these assumptions: dynamic routing creates significant load imbalance and introduces substantial overhead from fine-grained, data-dependent transfers [11, 15]. This irregularity makes it hard to precompute efficient communication schedules or reuse static buffer layouts, forcing implementations to dynamically size and route messages every step and amplifying the overheads of the already fine-grained transfers.

Communication is the bottleneck of MoE training and serving. Expert-parallel communication is already a major performance bottleneck in production systems: it can consume 43.6% of the forward pass and 32% of end-to-end training time on GPUs [24]. Serving faces the same challenge, with inter-device communication accounting for up to 47% of total execution time across popular MoE models and frameworks [61].

2.2 Expert-parallel communication requires GPU-initiated token-level communication

Given the central role of MoE communication, recent specialized systems—notably DeepEP [64]—have introduced *GPU-initiated token-level communication*, as illustrated in Figure 3. This design involves GPU threads *directly* submitting transfer commands to the NIC, using NVIDIA IBGDA (InfiniBand GPUDirect Async) [43].

GPU-initiated communication enables fine-grained and pipelined overlap *on a token basis*, where transfer for a single token or a chunk of tokens can overlap with other *phases* of communication, such as data copying (denoted "C") between application tensor buffers and RDMA transport buffers, token forwarding from the scale-out domain to the scale-up domain, and necessary computation (denoted "P") such as the reduce during the combine phase, or data type conversion such as from BF16 to FP8 to reduce communication volume. By breaking communication into these smaller GPU-triggered units (e.g., a few tokens), the system can better utilize both network and compute resources and significantly reduce end-to-end communication latency.

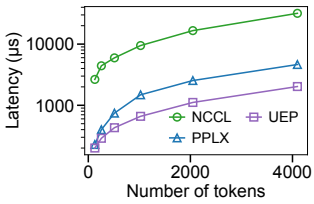

Figure 4: GPU-initiated token-level communication outperforms coarse-grained bulk transfer (e.g., packing tokens into a contiguous buffer on GPU then CPU initiating a single contiguous transfer) on NV_EFA3 (testbed details listed in Table 2). The overhead of packing becomes high as the number of tokens increases. The y-axis is in log scale.

GPU-initiated token-level communication also enables many optimization opportunities, such as message deduplication: if the token activation is routed to experts residing on multiple GPUs *on the same node*, the communication library can only send the token activation once with RDMA, and rely on intra-node forwarding to multiple experts for maximal speed. A second optimization enabled by GPU-initiated token-level communication is hierarchical reduce: an intra-node reduce (weighted sum) is performed on each node for a *chunk of tokens*, the result is sent back to the sender rank for another inter-node reduce: all of which is pipelined with background network transfer. Such optimization techniques were previously not feasible without GPU-initiated token-level communication, and have enabled a significant reduction in the amount of traffic needed to send over the network, and improvement in end-to-end performance.

To compare, some inference and training frameworks adopt coarse-grained transfer, such as with NCCL [41] or RCCL [3], or other general-purpose collective libraries. They require either the application packing tokens into a contiguous per-destination-rank transfer buffer or transferring small tokens one by one. The former incurs a high overhead of packing the token; the latter suffers from limited transfer throughput with small messages. For example, PPLX [29] adopts CPU-initiated communication with on-GPU token packing without fine-grained token deduplication and hierarchical reduce, and it does not scale as the number of tokens increases. The evaluation in Figure 4 shows that such approaches suffer from poor performance.

2.3 Existing GPU-initiated solutions couple GPUs and NICs, harming portability

While GPU-initiated token-level communication has been shown to improve performance, unfortunately, it compromises portability by *tightly coupling* GPUs and NICs. The reasons are two-fold:

Lack of hardware interoperability. The mainstream mechanism of GPU-initiated token-level communication is GPU threads directly posting to the RDMA NICs, or known as IBGDA [43]. IBGDA requires InfiniBand-capable NICs that support GPUDirect RDMA so the GPU can directly write to the NIC driver-defined MMIO interface. It also depends on a compatible software stack, typically including NVSHMEM and the necessary CUDA/RDMA drivers, to enable GPU-initiated network operations. Unfortunately, this makes it difficult, if not impossible, to support such communication patterns for non-NVIDIA GPUs or non-InfiniBand-capable NICs.

GPUs impose strict delivery semantics on NICs. While GPU threads are good for massive parallelism, they are limited in terms of the ability to control and manage the transfer. These communication libraries typically expect strict delivery semantics (e.g., "write-then-atomic" patterns, applying an atomic only after x number of writes have been delivered). This requires the networking layer to respect such delivery semantics, such as providing ordering guarantees. Furthermore, GPU threads lack the flexibility to manage communication. For example, DeepEP issues one-sided writes and relies on the receiver to busy poll a flag to detect incoming transfer. Flow control (such as pacing the sender's rate of communication) becomes an issue since the sender is unaware of the message delay or any potential congestion.

Taken together, this means that the GPU-initiated communication introduces strict requirements on the underlying networking layer, relying on it to provide reliability, ordering, as well as efficient network control. Unfortunately, maintaining them not only restricts a narrow selection of networking devices, as well as increasing the necessary fixed cost of enforcing these guarantees in hardware.

As a result, GPU-initiated token-level communication cannot be supported on cloud NICs (e.g., AWS EFA [52] with SRD transport [54]) that lack ordering guarantees, as well as non-NVIDIA GPUs, which lack a hardware mechanism to directly issue commands from the GPU to NICs. As GPU threads have little visibility into transfer delays and network congestion, this also poses significant challenges to practical deployment, as the networking environment needs to be carefully tuned to ensure congestion does not occur [64].

Importance of portability. Portability is essential for cost efficiency and avoiding vendor lock-in. Prior works have demonstrated significant performance and cost benefits of using heterogeneous hardware [17, 20, 22, 28, 32, 62]. Contemporary large-language-model systems increasingly rely on heterogeneous hardware: different data-centers and cloud providers deploy different NICs with distinct transport protocols (e.g., RC vs. SRD) and capabilities. As such, achieving portability in the communication layer is critical to reduce cost and improve performance, simplify integration into existing inference or training engines, and make efficient expert-parallel communication usable for a wide range of users.

2.4 The challenges of designing a portable and performant expert-parallel communication system

Designing a portable expert-parallel communication system requires breaking the coupling between GPUs and NICs. We describe the main challenges in the following.

	Support hete GPUs	Support hete NICs	Token dedup&reduce	High perf w/ small tokens
NCCL/RCCL [3,41]	✓	✓	✗	✗
PPLX [29]	✗	✓	✗	✓
DeepEP [64]	✗	✗	✓	✓
Mori-EP [50]	✗	✗	✓	✓
ROCm-DeepEP [49]	✗	✗	✓	✓
CPU-asst IBGDA [38]	✓	✗	–	–
UEP	✓	✓	✓	✓

Table 1: Comparison of major existing EP communication systems. "Hete." denotes support for heterogeneous (multi-vendor) GPUs or NICs.

Heterogeneous GPUs and NICs. Both GPUs and NICs are heterogeneous, coming from different vendors with different software ecosystems, e.g., NVIDIA, AMD, AWS EFA, Broadcom, Intel. To enable the GPU to directly initiate communication to the NIC (without involving the CPUs) often requires GPU knowing and accessing proprietary register layouts and tight hardware-level co-design between the NICs and GPUs. This is, at best, error-prone and difficult to do cross-vendor, and more often simply not supported.

Delivery semantics guarantees. Hardware transports differ in whether they guarantee in-order delivery of messages. For example, the ConnectX [37] RC transport offers in-order semantics, while the EFA SRD protocol offers reliable but unordered delivery. When the GPU kernel assumes ordering guarantees from the networking layer (for instance, issuing operations in a strict sequence without additional synchronization) or requiring a certain group of messages to arrive before a control message is delivered, moving to a transport that delivers out-of-order breaks correctness. A portable communication architecture, therefore, must assume minimal guarantees on the networking layer, or better, allow easy configuration in the software layer to adapt to the heterogeneous networking layer.

Existing solutions remained specific to each GPU-NIC. We observe that existing GPU-initiated communication libraries have remained largely ad hoc and involve one-time solutions on a particular combination of GPUs and NICs. We summarize existing systems in Table 1. Concurrent works MORI-EP [50] and the ROCm port of DeepEP [49] are specialized libraries for RDMA and GPU integration that work primarily on AMD GPUs with NVIDIA NICs. CPU-assisted IBGDA [27] relies on a single CPU proxy to relay transfer commands from NVIDIA GPUs, suffering from scalability issues, and it can only work on NVIDIA NICs that provide strict ordering guarantees. These solutions require a ported solution for each GPU and NIC vendor pair, inflating the development cost. We provide a more exhaustive discussion on related work in §7. Existing systems either preserve portability by falling back to coarse-grained CPU-initiated communication (e.g., Perplexity Kernels [29] pack tokens on the GPU into contiguous per-destination buffers and issue one RDMA transfer per destination rank), or achieve state-of-the-art performance by specializing to a specific GPU-NIC stack.

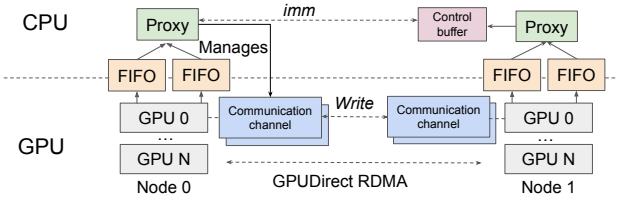

Figure 5: UEP-architecture. Control buffer temporarily buffers control messages (e.g., atomics) until the conditional check specified by the message is passed, upon which the values carried by these control messages are applied. Multiple communication channels are used for moving the data payloads (e.g., tokens) via GPUDirect RDMA.

We argue that the expert-parallel communication system should be portable by *design* - and UEP is based on a set of simple *primitives* that ease portability across various hardware, as well as supporting new future GPUs and NICs with minimal additional overhead.

3 Design

The key observation of UEP is that the GPU only needs to initiate token-level transfers for maximal performance with fine-grained overlapping with other phases of communication (e.g., data copying and computation), while the responsibility for monitoring and managing those transfers does not need to remain on the GPU. CPU, on the other hand, is portable to any GPUs via CUDA/ROCm and any NICs via the `libibverbs` library [48] maintained by the Linux community and NIC vendors, and CPU is also flexible in terms of enforcing various delivery semantics expected by the GPU.

In UEP (Figure 5), GPUs initiate the *fine-grained* data-movement (e.g., of expert token activations) by delegating the transfer tasks to CPU proxies. In effect, GPU threads issue lightweight control messages over PCIe to the CPU; the CPU proxies then intercept these control messages and issue token-level data communication on behalf of the GPU threads. This separation gives us the best of both worlds: the GPU retains token-level and pipelined data communication necessary for high performance, while the CPU proxy abstracts away heterogeneous NIC semantics with portability across platforms.

We discuss two high-level primitives proposed in UEP—an efficient CPU-GPU communication channel (§3.1) and a multi-threaded CPU proxy to delegate and manage GPU-initiated communication (§3.2 and 3.3).

3.1 Efficient CPU-GPU communication channel

UEP employs a lightweight, fixed-size command descriptor, termed `TransferCmd`, that the GPU threads enqueue into shared, lock-free FIFO channels with the CPU proxy as consumers (Figure 6). The GPU acts as the producer: it reserves space by advancing the head and then writes the command into the queue. The CPU proxy acts as the consumer: after processing a command, it advances the tail to make the entry available for reuse. After the GPU side writes to the head of the FIFO

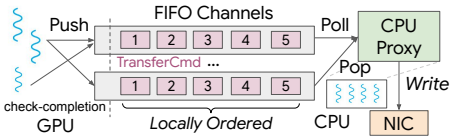

Figure 6: CPU-GPU FIFO channel. The FIFO channel transmits 128-bit `TransferCmd`. The GPU threads (left) enqueue commands to the FIFO channel. The CPU proxy threads (right) either read the commands with `Poll` or dequeue the command with `Pop`. UEP employs multiple FIFO channels per GPU, and each CPU proxy uses multiple threads to read from FIFO channels for scalability.

channel, it then proceeds with data packing and forwarding, while the CPU side reads from the tail of the FIFO buffer and issues the corresponding RDMA work request to the NIC.

Each `TransferCmd` bundles control information necessary for initiating GPU-direct communication, such as destination peer, buffer address, length, and sequence number. This leaves the data payload still residing on the GPU memory. This approach decouples communication initiation (by the GPU) from communication execution (CPU posting the actual RDMA commands).

UEP FIFO channels. Inspired by MSCCL++ [53], UEP uses a 128-bit (16 bytes) descriptor per command to improve the speed of each transfer, as 16 bytes can be written with a single GPU instruction and MMIO doorbell, aligning with PCIe's natural transaction and payload granularity. Since MSCCL++ does not target EP and it assumes strict ordering for the NICs, UEP is significantly different: UEP uses multi-threaded proxies and multiple parallel FIFO channels to make it scalable for small messages (§5.4); UEP further leverages the CPU proxy to enforce delivery semantics among `TransferCmd`s among a subset of FIFO channels as specified by the GPU threads (§3.3) for heterogeneous NICs.

The CPU-GPU channel exposes both CPU-side APIs and GPU-side APIs. UEP bounds the channel size with a parameter `kMaxInflight`. A message can be enqueued from the GPU only if there is space in the buffer (the number of outstanding messages is equal to or smaller than `kMaxInflight`) – otherwise, it will have to wait for the message to be dequeued by the CPU. Therefore, the channel size serves as a way to enforce *control* onto the GPU-initiated communication; this is important for pacing the GPU sender rate. The GPU threads can also, through checking the FIFO channel, know the completion of a prior message (e.g., important for implementing a barrier).

UEP's CPU-GPU communication channel is *one-sided*: communication only flows from GPU to CPU. However, the CPU can rate-limit the GPU by controlling how quickly the messages are consumed from the FIFO buffer. Delaying consumption of the transfer command will make the buffer full, making the GPU thread pause on enqueueing more messages onto the FIFO channel.

The communication channel is split between the host and GPU memory to place each portion of the metadata (e.g., head of the FIFO channel on CPU and tail of the FIFO channel on GPU) where it is most frequently read: the head is set by the GPU but polled by the CPU. The tail is set by the CPU but polled by the GPU. An alternative design is placing both head and tail on either GPU memory or host memory. However, one side (e.g., CPU or GPU) has to incur repeated access over PCIe when busy polling, incurring multiple PCIe crossings and hence heavy latency cost.

Memory consistency. Memory consistency is a key challenge for an efficient CPU-GPU communication channel. If the GPU sees stale data, this can lead to incorrect decisions (e.g., being stalled on a barrier). If the CPU sees stale data, it might read a stale value in the channel (leading to incorrectness). UEP ensures that when the GPU accesses the channel, it will bypass its hardware caches. CPU-side also ensures that the writes are flushed to the host memory rather than buffered in its L2 cache. Alternatively, the cache-coherent C-C interconnect (e.g., in GH200 [42]) can mitigate this issue (Figure 13 in evaluation).

Impact of GPU-side contention. Due to the large number of GPU threads, multiple threads of the same GPU SM naively pushing commands into the same FIFO channel can cause severe contention. To reduce contention, UEP uses multiple FIFO channels and carefully routes each GPU thread to push to the relevant FIFO channel. Cross-FIFO channels ordering is not guaranteed, though commands enqueued within the same FIFO channels are guaranteed to be ordered as they are read sequentially. UEP ensures that the sequence of messages that the GPU kernel requires ordering from the GPU side is mapped to the same FIFO channel.

Channel APIs. We next discuss APIs exposed at both the CPU-side and GPU-side to enable GPU-initiated token-level expert-parallel communication.

CPU-side:

- **Poll**: CPU proxy reads the `TransferCmd` from the channel, without dequeueing the command from the channel.
- **Pop**: CPU proxy removes the `TransferCmd` from the channel, indicating that the `TransferCmd` has been consumed.

GPU-side:

- **Push**: GPU thread enqueues a `TransferCmd` into the FIFO channel and gets a `Idx` for the command.
- **Check-completion(Idx)**: The GPU thread checks whether the `TransferCmd` with `Idx` has been popped from the CPU side.

UEP decouples between initiating the transfer and finishing the transfer. The proxy first becomes aware of the transfer when calling `Poll`, reading the message from the FIFO queue. This allows the CPU proxy thread to initiate a particular operation. For example, the CPU proxy thread can issue an RDMA write after polling a `Write` `TransferCmd` (described later).

The FIFO queue exposes an API for the GPU thread to check completion. This is important for GPU-side operations. For example, the GPU-side might need to wait for a prior dispatch or combine operation to finish to proceed (so as not

to overwrite the transport buffer); this logic often requires the communication layer to initiate a barrier across a subset of participating ranks. In this example, the GPU-side needs to wait for the barrier operation to finish by checking completion on the Barrier `TransferCmd`.

Types of TransferCmd. We added four types of `TransferCmd`s to support GPU-initiated token-level communication. These types are not meant to be an exhaustive list for expert-parallel communication. However, they suffice in our example to support expert-parallel communication in both training and serving.

Write: GPU thread delegates a write request to the CPU proxy thread to execute. We pass in the `addr offset` on the source rank, `addr offset` on the destination rank, the number of bytes to transmit, and the destination rank. Only offsets are needed, rather than a global address, as UEP CPU proxies exchange each other's base address during initiation (§3.2). The write command can optionally piggyback an atomic message to signal completion. This can be useful when GPU threads both want to deliver a data payload to the destination memory address, as well as incrementing a related counter (e.g., the number of the tokens received) at the receiver.

Atomics: GPU thread delegates an atomic operation to the CPU proxy thread to execute. The request contains destination offset, atomic value, and destination rank. This operation should execute atomically with concurrent operations sent by senders from multiple ranks. The atomic operations serve two logical purposes. First, they act as a remote doorbell with a memory-barrier semantics to ensure that previous writes have completed. For example, an atomic write to a flag bit following three token writes can establish that these three writes have been delivered. Second, atomics can also act as a way for the receiver to track how many tokens each expert has received in total. For example, suppose expert 5 on rank 2 receives 2 tokens from rank 5 and 5 tokens from rank 7. A counter for expert 5 must be maintained and updated by both ranks to reflect the total of 7 tokens. Different networking vendors have varying support for atomics; we describe one example in §4.1 on EFA.

Drain: Delegates a CPU proxy thread to drain the RDMA completion queue and ensure that all outstanding RDMA operations have completed. This is critical to ensure that the GPU threads can safely proceed without having their local states overwritten by unfinished requests from previous iterations of dispatch and combine. UEP optionally allows the GPU threads to pass a parameter in the Drain command to drain in-flight messages up to a certain TransferCmd index `Idx`.

Barrier: Barrier message delegates the CPU proxy thread to establish a synchronization barrier: the barrier message can support an all-peer barrier (where all participating peers need to enter the barrier), or a same-rail barrier that, under a rail-optimized topology, synchronizes only the peers mapped to the same rail (typically same GPU index across different nodes). For the former, the UEP Proxy thread creates an intra-node shared memory to enforce a hierarchical barrier—synchronization among local peers first, then across nodes. A per-node leader is established for intra-node barrier, and a cross-node leader (e.g., typically the first node) is established then for inter-node synchronization. For the latter, UEP relies on the RDMA immediate data to signal the leader rank that a barrier request is received, then the leader rank replies with the immediate data to signal the other ranks that a barrier has been successfully established.

Both Barrier and Drain are blocking on the GPU side, meaning that the GPU thread will need to check completions with the correct `TransferCmd Idx` before it can proceed with the `Check-completion(Idx)` API. While more message types can be supported, UEP supports the above four as they are adequate to cover the communication patterns for GPU-initiated EP communication.

3.2 Flexible CPU proxy to delegate communication

UEP keeps one CPU proxy per GPU, and each CPU proxy has multiple threads. While the use of CPU threads is common in collective transfers, such as in NCCL [41] and CPU-assisted IBGDA [38], UEP differs fundamentally from these approaches in three key aspects. First, the communication pattern is GPU-initiated and *token-level*, posing challenges for CPU proxy threads to quickly handle and process messages from GPUs. Second, as the message size is smaller, the number of messages needed to saturate network bandwidth is substantially higher; UEP uses more CPU threads for scalability. Third, UEP's CPU proxy is tasked with bridging the delivery semantics expected by the GPU (§2.4) and provided by the networking layer, and efficiently expressing these requirements without hurting performance is a non-trivial problem.

Multiple threads for each CPU proxy UEP uses up to 4 CPU threads per proxy. Each CPU thread is pinned to a CPU core. We note that modern GPU servers usually have hundreds of CPU cores, which are often heavily underutilized, e.g., 20%-45% CPU utilization reported by several industry companies in their GPU clusters [19, 23].

Establishing connection. With multiple threads in a CPU proxy, UEP bounds the number of connections by only allowing the i-th thread of a CPU proxy to establish connections with the i-th threads of remote CPU proxies. Communication is bidirectional: each thread is in charge of both polling the sender's completion queue for any successful outgoing write or atomic message, and polling the receiver's completion queue to handle any remote incoming requests.

Symmetric memory. The CPU proxy thread maintains the semantics of symmetric memory, as symmetric memory has been noted to be useful by prior works [35, 47, 64]. This enables the GPU thread to only notify CPU threads of the *offsets* of the transfer. CPU threads then handle the address translation, bounds checking before issuing RDMA writes, and atomic messages. Each CPU proxy registers a memory region during initialization, and exchanges the base address during handshake. Using offsets in symmetric memory

reduces the number of bits needed in control messages, compared to passing full addresses. For example, if each GPU exposes only a 2 GB transport buffer for RDMA, and the address is 16-byte aligned, a 27-bit offset is sufficient to identify any byte within the buffer, whereas passing a full virtual address would require 64 bits per transfer, taking up more bits in the TransferCmd. This also eliminates the need to use vendor-specific shared memory libraries, such as NVSHMEM [35] and rocSHMEM [56], improving portability.

Addressing delivery semantics. Heterogeneous NICs exhibit different delivery semantics: for example, some NICs may deliver RDMA writes out of order. To handle this, the CPU proxies embed a sequence number in each RDMA write via immediate data; the receiver uses the sequence number to reorder or delay processing the control messages until all prior writes have arrived. Immediate data is a 32-bit piece of data that RDMA send/write operations can piggyback in the packet header and deliver to remote CPUs over the network. Immediate data field has been standardized into the RoCEv2 packet header [1]. By having CPU proxy interprets this immediate data and enforce guarantees, the system remains correct even when the transport does not guarantee strict delivery guarantees. For comparison, in IBGDA, all transfers *completely* bypass the CPU. We delve into the details of this design next.

3.3 Expressing GPU communication requirements with CPU proxy

Similar to DeepEP [64], UEP presents two modes: low latency (LL) mode and high-throughput (HT) mode. The LL and HT kernels are not specific to one model or UEP itself; they correspond to two general expert-parallel communication modes. LL mode targets decode-style workloads with small batches, where tokens should be sent as soon as routing decisions are available. HT mode targets prefill/training-style workloads with larger batches that benefit from higher bandwidth. LL mode immediately sends the token activation initiated by the GPU via the CPU proxy, requiring no synchronization between transfers. HT mode implements message deduplication, intra-node token forwarding, as well as batching multiple tokens before sending. These optimizations can significantly improve throughput; however, they can have higher latency compared to the LL mode. High-throughput kernel employs multiple communication channels (Figure 5), a set of ring buffers per GPU that temporarily buffer tokens to send in the granularity of chunks (a configurable parameter, typically 32 tokens).

In the remainder of the subsection, we use UEP's low-latency (LL) kernel and high-throughput (HT) kernel as two illustrative examples of UEP's proxy threads enforcing delivery semantics required by GPU kernels. Note that RDMA writes are still immediately applied, though the receiver CPU proxy is notified of any delivered writes through polling the RDMA completion queue. The CPU proxy tracks metadata about these delivered writes, such as the number of writes delivered for a particular expert. Atomic is implemented via the immediate data and is not immediately applied: CPU proxy thread extracts the offset and value for the atomic itself from the 32-bit immediate data, buffers them in the control buffer (Figure 5) if needed, and selectively applies them based on the delivery semantics expected of these atomics.

Low-latency kernel requires partial completion fence. Atomic messages are used to signal token delivery (e.g., X number of writes have completed), requiring that the receiver wait until the required number of writes for a specific expert has finished. This requires *completion fence semantics*: if atomic arrives before X tokens, it should not be applied. However, it does not matter if these X tokens are delivered in order or out-of-order. This guarantee is *partial*: completions of writes to other experts do not affect updating the number of delivered tokens of this expert. Similarly, the arrival order of these X tokens does not matter; so long as these X tokens arrived before applying the atomic.

Solution: UEP lets the CPU proxy temporarily buffer the atomic message in the control buffer until the required number of tokens for a destination expert has been received. To achieve that, UEP packs the destination offset and the expert index into the 32-bit immediate data, and the receiving CPU thread will parse the immediate data, extract the expert index as well as the source rank of the connection. Each subsequent atomic message will go through a lightweight conditional check (has X number of writes to the specified expert being received?): UEP only applies the atomic update when the conditional check has passed to enforce the delivery requirements of these atomic messages.

High-throughput kernel requires partial ordering. The high-throughput kernel employs multiple ring buffers as communication channels per GPU to temporarily buffer and batch tokens to send. Batching improves throughput; however, it also means the GPU should communicate to maintain the head and tail of these ring buffers on remote ranks. Each token is written to a slot in the destination ring buffer, and by carefully controlling the head and tail values of the ring buffer, UEP ensures that no token will overwrite other yet-to-be-read tokens on the same slot of the ring buffer.

A write message is typically followed by an atomic operation to increment either the head or tail values of the ring buffer. If the write and atomic become reordered with other writes and atomics, this can lead to the receiver reading stale data from the communication channel, or the sender overwriting data written by a prior transfer. For example, consider two writes. The first write is issued to slot 4 on the receiver. The second write is issued to slot 5 on the receiver. Both writes carry an atomic to increment the head value of the receiving ring buffer to indicate to the remote kernel that a new message has been delivered. However, if the atomic for the second write arrives first before the atomic for the first write, the remote GPU kernel can read the slot 4, before the delivery of the write to slot 4, leading to reading wrong results.

Similar to LL mode, enforcing ordering only needs to be

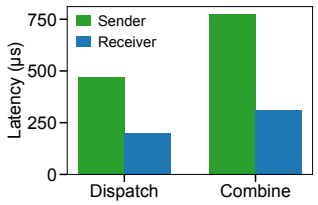

Figure 7: Sender-side vs. receiver-side on enforcing delivery semantics (on testbed NV_EFA3 detailed in Table 2). *Receiver-side* gives better performance compared to sender-side.

partial. The ordering guarantees only need to be done for each communication channel, rather than globally across all messages, which is expensive if not done in hardware.

Solution: UEP ensures that per-channel communication is locally ordered. It achieves this by enqueueing messages from the same communication channel into the same GPU-to-CPU FIFO queue. Similar to the low low-latency kernel, the receiver CPU proxy thread will extract the sequence number from the immediate data; if the received message arrives out-of-order, it will temporarily buffer these atomic messages (that are out-of-order with writes) in the control buffer. Only after the prior writes and atomics have been applied (e.g., message $1-5$ from communication channel i has been applied), the receiver thread will sequentially apply the next buffered atomic message (e.g., atomic with index 6 from communication channel i).

Where to enforce the delivery semantics. An alternative approach is for the *sender*, as opposed to the receiver, to delay sending the atomic messages only after it has received the completion queue entry for the writes sent for that token. This approach is typically used by the NIC hardware to guarantee strict ordering when adaptive routing is used in the network and packet reordering happens [13]. It has the advantage of saving hardware SRAM resources without tracking per-packet states. However, compared to tracking at the receiver, this approach makes the sender wait for one extra RTT for the atomic messages sent, as in this approach, the sender can only issue atomic messages after it polls the completion entry for the prior writes. We have observed suboptimal performance (Figure 7), as the latency penalty of waiting for token completion accumulates.

In summary, the networking layer typically provides either a stronger or weaker guarantee in hardware than what is typically required by the application, e.g., ensuring that *all* messages are strictly ordered, or guaranteeing none at all. From discussing with industry practitioners, installing various guarantees comes at a hardware cost trade-off: supporting strong guarantees at the NIC hardware typically means that the hardware NICs are more expensive to make. In comparison, CPU is flexible in customizing and enforcing various delivery semantics. The minimal requirement for UEP is reliable delivery of RDMA operations (e.g., as commonly provided by RC or SRD protocol), and a way to carry small control metadata to the receiver, such as RDMA immediate data. These requirements are typically provided by existing RDMA NICs.

4 Implementation

We implement UEP by extending DeepEP with 20.8K lines of C++ (including 2.4K lines of CUDA/ROCm C++) and 1K lines of Python, while remaining API-compatible with DeepEP. UEP significantly extends DeepEP in two ways: i) supporting heterogeneous GPUs and NICs, including NVIDIA and AMD GPUs, and NVIDIA, AWS EFA, Broadcom, and Intel NICs (other NIC vendors should be naturally supported via the portable `libibverbs`); and ii) supporting token-level and customizable communication requirements across NICs and EP modes (i.e., LL or HT), as described in §3.3. UEP is architecturally portable: porting to AMD GPUs and AWS EFA NICs is done with *only* 3 person-months, requiring relatively less effort compared to supporting such communication across every NIC and GPU pair, which typically requires dedicated teams.

Removing GPU-vendor-specific software stack. Existing GPU-driven communication stacks often rely on NVSHMEM for device-side synchronization, memory ordering, and GPU-initiated one-sided operations. However, such a software stack assumes a specific GPU vendor and depends on hardware features that may not exist on AMD GPUs or non-IB NICs. UEP instead manages symmetric memory with CPU proxy threads, and expresses NVSHMEM-related GPU-initiated communication APIs via its own CPU proxy.

Queue Pair (QP) load balancing. Each proxy thread for a particular GPU is in charge of managing a set of NICs in the same NUMA group as the GPU (e.g., there are 2×200G EFA NICs per H200 GPU on AWS). In low-latency (LL) mode, each thread creates an RDMA queue pair for a given destination rank; in high-throughput (HT) mode, each thread creates multiple QPs (corresponding to the number of communication channels, §3.3) between pairs of ranks. Depending on communication requirements, the GPU might require a set of messages to be sent out from a single QP, or it does not impose any requirements on which QPs to send, where the CPU thread round-robins among the QPs it manages.

Aggregating NICs of different bandwidths. Beyond QP load balancing, UEP aggregates bandwidth across multiple NICs per GPU: e.g., one ConnectX-7 NIC may deliver 400 Gbps, but achieving similar bandwidth with EFA NICs may require aggregating two 200 Gbps NICs per GPU. UEP relies on CPU threads to load balance across different NICs. We omit the details for brevity.

Interfaces for adding support of new NIC or GPU To add a new NIC, UEP requires the NIC to expose a standard host-side RDMA interface, ideally through libibverbs or a compatible verbs provider. This is common for most, if not all, RDMA-capable NICs. For new NICs, UEP provides a modular interface that allows CPU proxy threads to translate TransferCmd into NIC work requests, manage QPs/CQs, exchange base addresses, and handle NIC-specific limits such as maximum in-flight writes. To add support for a new

Name	# servers	Network	GPU	HBM, # SMs, NVLink	NIC	CPU	Cloud

GPU, UEP requires translating GPU-side kernels (e.g., from NVIDIA to AMD) and having the kernel call UEP transport channel APIs (e.g., supporting various TransferCmd types as in §3.1). We next present two case studies to illustrate this.

4.1 Supporting EFA

Emulating atomics with CPU proxy threads. EFA NICs currently do not provide hardware RDMA atomics (e.g., global counters). UEP implements software-based atomics: the sender issues a payload write followed by a small RDMA write carrying an immediate value encoding the new counter or flag; the CPU proxy or receiver thread updates local completion counters allocated on the *host* memory (e.g., via `cudaMallocHost()`) upon detection of the immediate data. UEP carefully ensures that the GPU observes the host-allocated counter and uses it for control decisions. This ensures the correctness of completion notification without relying on vendor-specific atomic support.

4.2 Supporting AMD

UEP generalizes the expert-parallel communication kernels so that they no longer assume NVIDIA-style warps, NVIDIA-specific PTX intrinsics, and hardware engine. In particular, UEP does the following changes:

- Migrating CUDA-specific PTX intrinsics to use ROCm alternatives, including atomics, memory fences, and timers.
- Migrating CUDA warp-based programming to support AMD wavefront, including switching `WARP_SIZE` from 32 to 64, using AMD wavefront-level synchronizations.
- Migrating NVIDIA TMA-based data copy [5] to support AMD CU-based (i.e., compute units, like NVIDIA SMs).
- UEP uses wavefront (i.e., warp in NVIDIA's term) specialization for AMD. For the HT kernel, UEP merges its `coordinator`-role wavefronts into `receiver`-role wavefronts [10], as AMD GPUs usually support fewer wavefronts than NVIDIA warps but more threads per wavefront.

Note that to support AMD GPUs with heterogeneous NICs, only GPU kernels need to be ported, rather than the CPU-side code to operate on heterogeneous NICs; UEP's approach allows us to immediately run on AMD platforms with heterogeneous NICs after AMD GPU-side changes, without having to do independent development between AMD GPU and each individual NIC. This shows that UEP enables $O(m)$ effort, instead of IBGDA's $O(m \times n)$, to support GPU-initiated token-level communication for expert parallelism.

5 Evaluation

Our evaluation aims to answer the following questions:

- How does UEP improve MoE model training? (§5.2.1, §5.2.2)
- How does UEP improve MoE model serving? (§5.2.3)
- How does UEP's performance compare to baselines on heterogeneous devices? (§5.3.1 and §5.3.2)
- How does UEP's performance compare to DeepEP on NVIDIA GPUs and NICs? (§5.3.1)
- How do different design choices (e.g., number of CPU threads) impact UEP performance? (§5.4)

5.1 Methodology

Experimental setups. A list of testbeds can be found in Table 2. We used testbeds from a variety of GPU vendors (NVIDIA and AMD) and NIC vendors (AWS, NVIDIA, Broadcom) to show that UEP is portable across platforms and benchmark UEP's performance.

Baselines.

- **NCCL [41] / RCCL [3].** We use collective communication libraries as a baseline for the EP communication stack on NVIDIA (NCCL) and AMD (RCCL) GPUs.
- **DeepEP [64].** DeepEP is a state-of-the-art, GPU-initiated RDMA communication system for expert-parallel MoE.
- **Perplexity Kernels (PPLX) [29].** We evaluate against Perplexity's custom MoE communication kernels (denoted PPLX), which are highly optimized for low-latency decode.
- **CPU-assisted IBGDA [38].** We emulate a CPU-assisted IBGDA design using a single UEP proxy thread, similar to the existing CPU-assisted IBGDA approach.
- **Mori [50].** Mori is a modular RDMA library; we include it to compare against a ROCm-native RDMA stack.
- **Theoretical Best**: Theoretical results for HT mode derived from available RDMA bandwidth.

To ensure a fair comparison, we use the same amount of GPU resources (e.g., the same number of SMs per GPU as DeepEP, and the same number of CUs as Mori). UEP is designed as a drop-in replacement for DeepEP-style applications. It has already supported various inference frameworks, such as vLLM and SGLang, and training frameworks such as MegatronLM and AMD Primus, with no application-level changes.

(a) Dispatch. **(b)** Combine.

Figure 10: EP32 comparison when varying numbers of tokens on NV_EFA3. UEP uses the minimum of HT and LL latency, while PPLX only has one mode.

5.2 Application performance

5.2.1 Training on AMD Primus/Megatron-LM

Figure 8 reports end-to-end Megatron-LM training performance in TFLOPS and tokens per second for DeepSeek-V3 [30] over 16 servers. Across all models, UEP matches or exceeds the TFLOPS (by 7-36%) and throughput achieved by RCCL (by 7-45%). These results show that UEP leads to performance benefits compared to RCCL for Megatron-LM training on AMD.

5.2.2 Training on H200/EFA with Megatron-LM

Table 3 reports end-to-end Megatron-LM training performance in TFLOPS per GPU on NV_EFA3 with 4 servers (32 H200 GPUs over EFAv3). We evaluate three configurations: *Qwen3-235B, long-seq* runs Qwen3-235B-A22B [60] with seq=49152, GBS=8, EP=16, TP=4, PP=2, CP=2; *Qwen3-235B, large-batch* uses the same model with seq=20480, GBS=128, EP=16, TP=4, PP=2, CP=2; and *DeepSeek-V3* [30] truncated to 12 layers (∼135B total, ∼5B activated; 256 experts, top-k=8, hidden=7168) with EP=32. Across all three settings, UEP exceeds the TFLOPS achieved by NCCL by 12–24%: 22% for *Qwen3-235B, long-seq*, 12% for *Qwen3-235B, large-batch*, and 24% for *DeepSeek-V3*. UEP improves Megatron-LM training throughput without modifications to the model code.

5.2.3 Inference on SGLang with EFA

We evaluate UEP in SGLang v0.5.3 with EP set to either 16 or 32 on a prefill-heavy workload (input length 4096, output length 5) using `deepseek-ai/DeepSeek-R1-0528` [18] and `Qwen/Qwen3-235B-A22B-FP8` [60]. The results are presented in Figure 9. We compare against NCCL, as DeepEP does not run on EFA; at the time of writing, PPLX had not been integrated into any open-sourced inference engine. For DeepSeek R1 at EP=16, UEP reaches an input throughput of 46K tok/s, about 5% higher than NCCL. Scaling to EP=32, UEP further improves to 74K tok/s input, a 1.6× speedup over its own EP=16 run. NCCL cannot yet run [9, 57] on EP=32 (confirmed with SGLang maintainers). For Qwen3, at EP=32, UEP reaches 62K tok/s throughput versus 44K tok/s for NCCL (about 40% higher). We also observe that CPU utilization increases modestly with UEP, from an average 8% CPU utilization to 22% utilization.

5.3 Microbenchmark

In this subsection, we compare the dispatch and combine latency on NVIDIA GPUs (§5.3.1) as well as AMD GPUs (§5.3.2). Under each GPU vendor, we compare different NIC setups, including AWS EFA, CX7 with IB, and Broadcom Thor-2 NICs. UEP is able to run across all testbeds. In each testbed, we compare UEP against the available baselines that are specifically optimized for each setup.

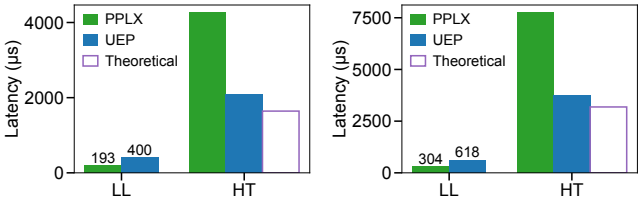
5.3.1 On NVIDIA GPUs

Comparison on AWS EFA. Figure 10 and Figure 11 show EP32 dispatch and combine latency on NV_EFAv3 (on AWS `p5en` instances) as we vary the number of tokens. As we increase the number of tokens, UEP outperforms PPLX and the gap widens: for medium and large batches, UEP consistently delivers substantially lower dispatch (2.3×) and combine latency (1.1-1.5×), demonstrating better scalability as token counts increase.

We would like to make two observations on the LL mode comparison between PPLX and UEP: First, PPLX does not support in-kernel BF16-to-FP8 conversion, assuming that the input data is already passed in as the FP8 data type. This makes com-

Table 4: Dispatch performance on NV_EFA3. w/ Conv additionally adds a small data conversion latency (from BF16 to FP8) for PPLX.

	UEP		PPLX	
	No Batch	Batch	Raw	w/ Conv.
Latency (μs)	216.61	**177.70**	232.30	266.90



(a) Dispatch. **(b)** Combine.

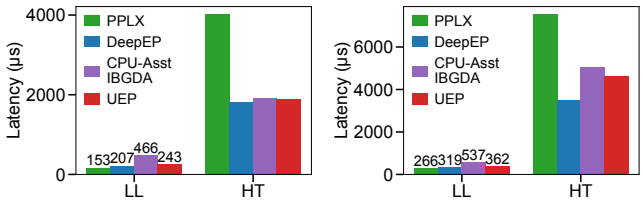
Figure 11: EP32 comparison on NV_EFA4.

parison tricky, as the original DeepEP and many large-scale MoE models use BF16 as input and BF16-to-FP8 conversion is consequently a *key* step to save communication traffic. To be favorable to PPLX, in the figures of this paper, we *ignore* the PPLX data-type conversion latency and directly compare the PPLX dispatch latency (assuming FP8 input) versus UEP dispatch latency (assuming BF16 input), where UEP does an additional step of converting BF16 to FP8 in the GPU kernel. We present a comparison in Table 4. If we add the data type conversion time to PPLX, PPLX's dispatch time rises to 266.9 μs from 232.3 μs. Second, the latest UEP additionally supports best-effort per-expert token batching in the low-latency kernel. On 2 nodes of NV_EFA3, best-effort token batching improves the UEP latency from 216.6 μs to 177.7 μs. Unfortunately, as our rented AWS VMs run out of time, we are not able to further measure these optimizations on a larger scale (EP=32).[3]

Comparison on CX7 with IB. Figure 12 compares EP32 dispatch and combine latency on CX7 with InfiniBand for both low-latency (LL, small tokens) and high-throughput (HT, large tokens) modes. In LL mode, UEP incurs slightly higher latency than DeepEP and PPLX due to the overhead of its CPU proxy on small messages. However, in HT mode, UEP achieves latency comparable to the original DeepEP (within 5% for dispatch) while outperforming PPLX for both dispatch (2.1×) and combine (1.6×), showing that UEP preserves high performance on throughput-oriented workloads.

Comparison on GH200 with NVLink-C2C. Figure 13 reports latency on a single-GPU GH200 node with NVLink-C2C between the CPU and GPU. The HT (high-throughput) mode of DeepEP requires an 8-GPU NVLink/NVSwitch topology and therefore cannot run on this platform, so we only compare LL mode. In this setting, UEP achieves lower transfer latency than the original DeepEP, demonstrating that UEP operates efficiently over a cache-coherent C2C CPU–GPU interconnect,

[3]The results in Figure 11 are without the best-effort per-token batching optimization.



(a) Dispatch. **(b)** Combine.

Figure 12: EP32 comparison on NV_IB.

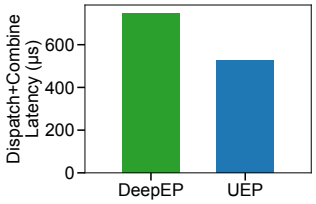


Figure 13: EP2 LL comparison on two GH200 nodes. While EP2 is a less practical setting, it shows the current trend of unified memory between GPUs and CPUs (e.g. with NVLink-C2C) enables us to obtain better performance by enabling fast CPU-GPU communication.

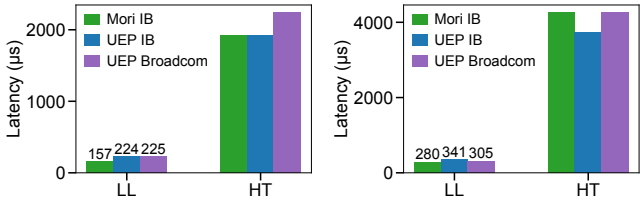

(a) Dispatch. **(b)** Combine.

Figure 14: EP32 comparison on AMD_IB and AMD_BRC.

which we believe to be a future trend. We hypothesize that this benefit comes from two reasons. First, different from DeepEP, which issues a write operation followed by an atomic operation, UEP piggybacks an atomic operation over a write operation with the remote CPU proxy applying the immediate data carried along the write operation, saving one extra message (§5.4). Second, UEP removes the NVSHMEM dependency and its associated software overheads.

5.3.2 On AMD GPUs

Figure 14 shows EP32 dispatch and combine latency on AMD GPUs when using Broadcom NICs (UEP Broadcom) and NVIDIA InfiniBand NICs (UEP IB and Mori IB). At the time of writing, Mori only officially supported NVIDIA NICs. The results demonstrate that UEP runs efficiently across heterogeneous NICs, achieving similar performance on Broadcom and IB in both LL and HT modes. On InfiniBand, UEP IB even outperforms Mori IB in the HT (high-throughput) configuration for combine, while Mori IB has a slightly lower latency than UEP IB in LL mode.

5.4 Design drill-down

Stress testing UEP FIFOs. Figure 15 benchmarks how the latency of the FIFO queue compares to network latency with increasing 7KB message load. The latency incurred along the

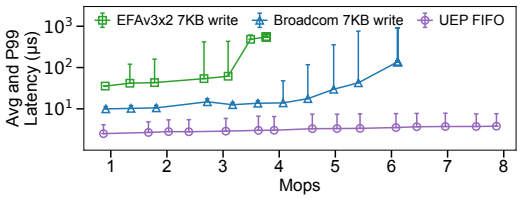

Figure 15: UEP FIFO performance. We run 8 FIFOs simultaneously on NV_EFA3 (each for one GPU) and report the first FIFO's result. Note that the y-axis is in log scale.

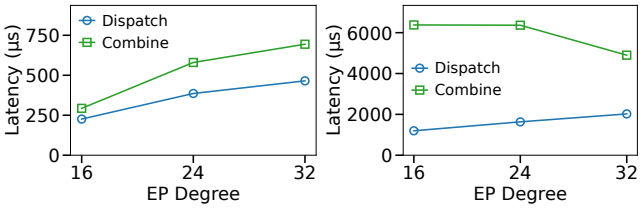
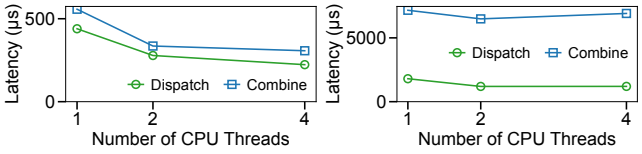


(a) LL **(b)** HT

Figure 16: Sensitivity to EP size. We measure the UEP HT and LL mode latency as we increase the EP size from 16 to 32.



(a) LL **(b)** HT

Figure 17: Sensitivity to number of CPU threads (NV_EFA3).

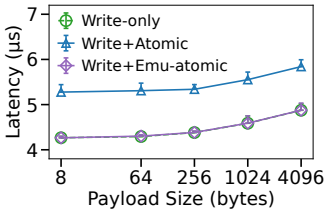


Figure 18: Comparing the latency of emulated atomics across different payload sizes.

FIFO queue is an order of magnitude smaller than the network latency. Furthermore, UEP FIFO queues are able to scale to large QPS (e.g., 8 Mops), capable of handling modern MoE workloads. Compared to the latency of typical dispatch and combine ($\sim$200 μs for LL, and $>$ 2000 μs for HT), CPU proxy (3$\sim$5 μs) introduces negligible latency overhead compared to native GPU-initiated RDMA with IBGDA. Note that this benchmark does not batch requests from GPUs to CPUs; we believe that with lightweight batching, it is feasible to handle the next-generation 800G network [7].

Varying EP degrees. Figure 16 shows that UEP's dispatch and combine latency increases modestly as we increase the EP size from 16 to 32. The trend holds in both LL and HT modes; under the HT mode, combine latency stays flat (and even dropping at EP=32). Overall, UEP scales gracefully across the 16–32 EP range we evaluated.

Varying number of proxy threads. Figure 17 shows that LL and HT kernels suffer from suboptimal performance when the number of CPU threads is 1. The performance significantly improves when we add more CPU threads (e.g., to 4). With more threads per CPU proxy, UEP is able to use more cores to drive higher-throughput communication. We note that CPU utilization is typically low, as GPU servers typically have a large number of CPU cores (Table 2); we observe that even with 4 CPU threads, the CPU utilization only increases modestly.

Latency impact of using emulated atomics. Figure 18 quantifies the latency impact of UEP's emulated atomics, compared against a plain RDMA write and a write followed by an RDMA atomic operation (e.g., in DeepEP). All three paths are issued in a chain RDMA doorbell with the data write unsignaled, so the receiver never waits between operations. Across the write payload sizes from 8 B to 4 KiB, the emulated path follows closely to the write-only baseline: the atomic update by the CPU proxy is essentially free compared to the network delay. In contrast, the write followed by an RDMA atomic costs a roughly $\sim$1 μs extra, because the atomic is an additional operation that the responder NIC must execute. UEP avoids the additional message by piggybacking the atomic update on the immediate data and letting the remote CPU proxy apply it upon polling the receiver work completion entry.

6 Discussion and Future Work

Congestion control with CPU proxy. We observe that the number of outstanding requests can have a significant impact on various NICs, affecting tail latency [46, 66]. This becomes increasingly significant as the number of destinations increases, where having one straggler can significantly slow down dispatch and combine time. Software-based flow control is challenging to implement with IBGDA, as GPU threads typically are not flexible enough for implementing network-level policies.

Instead, UEP delegates *control decisions* to the flexible CPU proxy, which could easily support request tracking and pacing. If the outstanding requests become high, the CPU proxy thread temporarily buffers the messages at the sender, so that the messages will not cause an incast at the receiver side. The CPU proxy also bears responsibility for multi-QP management: because each GPU may be connected to multiple NICs or multiple QPs, the proxy can throttle or shard the outgoing requests across NICs and QPs to avoid congestion [65], and adapt to NIC-specific characteristics (e.g., maximum outstanding write requests) without burdening the GPU kernel logic. This separation allows exploiting multiple NICs transparently and optimizing throughput while still keeping the GPU's logic simple.

Elastic EP with CPU proxy. NVSHMEM, including IBGDA, CPU-assisted IBGDA, and IBRC, does not expose error handling to GPU kernels and assumes RDMA operations always succeed. However, events such as GPU failure, scale up, and down can happen in practical scenarios, where

NVSHMEM would need to restart the existing cluster. UEP could achieve elastic EP by using the flexible CPU proxy to handle failure and scaling events, transparently masking them from the GPU kernel.

More efficient low-latency kernel. DeepEP's low-latency kernel (without token deduplication or hierarchical reduce) could be further optimized. This would particularly benefit AWS EFA NICs that cannot process small message transfers efficiently (see Figure 15). UEP currently extends DeepEP LL kernels, which we plan to further improve as future work. We deem these optimizations as orthogonal to UEP's contribution in a portable expert-parallel communication architecture by decoupling NICs and GPUs.

Intended deployment mode for UEP. UEP is primarily designed for platforms where IBGDA is unavailable or impractical, such as non-NVIDIA GPUs or NICs without the required GPU-initiated RDMA support. However, UEP can also run on IBGDA-capable platforms, where the CPU proxy can provide additional flexibility for communication management.

Failure semantics. In practice, the CPU and GPU on the same server often fate-share: CPU processes are already responsible for launching GPU kernels, and widely used systems such as NCCL also rely on host CPU threads to initiate and coordinate communication. Thus, UEP does not introduce a separate failure domain.

7 Related Work

EP communication systems mainly have two categories.

CPU-initiated. CPU-initiated communication, such as NCCL [41], RCCL [3] (for AMD GPUs), and PPLX [29] relies on the CPU to initiate communication, including constructing and posting RDMA work requests, polling completion queues, and managing QP state transitions. Nearly all MoE training and serving frameworks support NCCL/RCCL for MoE communication. However, as mentioned in §2.2, they would require either re-packing tokens or transferring small tokens, and do not support token deduplication and hierarchical reduce, both leading to low performance as the number of tokens increases. Recent efforts such as UCCL-Tran [65] and NCCLX [55] preserve NCCL/RCCL's CPU-driven design, with various performance optimizations: UCCL-Tran focuses on CPU-driven collective transport optimizations such as software packet spraying, while UEP targets expert-parallel GPU-initiated token-level communication. NCCLX introduces topology-aware collective algorithms, zero-copy, and SM-free transfers. Both are orthogonal to UEP.

GPU-initiated. GPU-initiated communication, by contrast, issues network transfers directly from the GPU, enabling fine-grained token-level operations like deduplication and hierarchical reduce that are critical to EP communication efficiency. DeepEP [64], Mooncake-EP [25], Mori-EP [50], and ROCm-DeepEP [49] (based on rocSHMEM [56]) belong to this category. Although providing high performance, they only work for either NVIDIA GPUs or AMD GPUs, and require strict ordering for the underlying NICs. NVIDIA's recent HybridEP [39] atop of DeepEP supports intra-node and multi-node NVLink scenarios with reduced SM usage, while UEP focuses on inter-node RDMA scenarios.

MSCCL++ [53] adopts the GPU-initiated approach to implement NCCL/RCCL collectives such as all-reduce and reduce-scatter, but does not support irregular EP communication. The CPU-assisted IBGDA [38] and IBRC [31] transports from NVSHMEM [35] could theoretically support non-NVIDIA GPUs via their CPU proxy designs. But they suffer from lower performance for small token activations due to single-threaded proxies and assume strict ordering for the NICs. The EFA transport [36] from NVSHMEM supports AWS EFA NICs, but suffers from poor performance [29] by using a single-threaded proxy. Compared to them, UEP supports both heterogeneous GPUs and NICs, enables fine-grained token-level operations, and provides high performance even with small tokens.

8 Conclusion

Modern MoE workloads require fast and scalable expert-parallel communication, yet existing systems that support token-level GPU-initiated communication remain tied to NVIDIA-specific GPU-initiated RDMA, limiting portability across the increasingly heterogeneous accelerators and NICs. Such an approach results in brittle systems: the communication kernel requires strict delivery semantics from the underlying networking stack, and with limited visibility into error handling, congestion control, and network management. This paper introduces UEP, a portable EP communication system that achieves DeepEP-level performance without relying on specialized GPU–NIC integrations. Our implementation across NVIDIA and AMD GPUs and multiple NIC vendors shows that UEP outperforms the best existing EP solution by 2.1×. UEP is a drop-in replacement for DeepEP-compatible applications such as SGLang and AMD Primus/Megatron-LM, improving token throughput by up to 40% on an NVIDIA+EFA platform, and DeepSeek-V3 training throughput by up to 45% on a 16-node AMD+Broadcom platform.

Acknowledgement

We sincerely thank the anonymous reviewers and our shepherd for their insightful comments. We would also like to thank Chon Lam Lao for helpful discussions. This work is in part supported by gifts from Accenture, AMD, Anyscale, Broadcom, Cisco, Google, IBM, Intel, Intesa Sanpaolo, Lambda, Lightspeed, Mibura, Microsoft, NVIDIA, Samsung SDS, and SAP. We additionally acknowledge AWS, in particular Jun Wu, Yida Wang, Brian Barrett, and Nafea Bshara, for their sponsorship and partnership in this research. Abstract

Batch inference has become a central mode of AI computation, yet existing inference engines still rely on execution models designed for interactive serving. When scaled to millions of sequences, batch workloads reveal two fundamental requirements: the ability to handle extreme inter- and intra-sequence load variation that emerges only at runtime, and the ability to sustain high utilization across large fleets of GPUs. Existing systems fail to meet these requirements, losing substantial fractions of achievable throughput.

We introduce a new architectural foundation for batch inference: the sequence coroutine compute model, which represents each sequence as a fine-grained, event-driven coroutine. This model exposes expressive primitives that allow the runtime to reorganize work dynamically, enabling larger expert-level batches, mitigating stragglers, reallocating work across devices, and maintaining utilization even on cost-effective or memory-constrained GPUs. Building on this abstraction, we implement BatchGen, a production-ready system that uses the coroutine model at cluster scale. On a 128-GPU cluster, BatchGen reduces batch completion time by up to 2.3×, and on memory-constrained accelerators it outperforms the strongest offloading baseline by up to 9.6×.

1 Introduction

Batch inference has become one of the fastest-growing and most resource-intensive modes of AI computation [28, 58]. Offline inference pipelines [14, 53], synthetic data generation [26, 40], model evaluation [2, 5, 24], test-time scaling [44, 45], and RL rollouts [36] now dominate the compute budgets of major AI deployments. Unlike interactive serving [22, 32, 56], these workloads optimize batch completion time (BCT), operate at massive sequence scales [1, 34], and often run on memory-limited accelerators.

Batch inference introduces fundamentally new system requirements. A batch engine must (1) dynamically increase expert-level batch sizes for sparse models, (2) continuously rebalance load as long-tail sequences emerge, and (3) sustain high utilization across large fleets of GPUs. Crucially, these requirements arise directly from how modern AI is being scaled. State-of-the-art models rely on extreme sparsity, especially large Mixture-of-Experts (MoE) architectures, where tokens activate only a few experts among hundreds. Even million-token global batches decompose into small per-expert batches that fall far below GPU-saturating throughput. Meanwhile, test-time scaling and heavy reasoning workloads generate persistent long-tail sequences, creating stragglers that dominate BCT and leave many GPUs idle. These structural properties – expert sparsity, modular computation, and heavy-tailed generation – define a new operating mode that demands a scheduler capable of reorganizing computation at fine granularity.

Existing systems cannot meet these requirements because they inherit a latency-first execution model from interactive serving. Systems such as vLLM [22], SGLang [56], and TensorRT-LLM [32] statically bind each sequence's computation and KV state to a fixed GPU, executing forward passes atomically to minimize per-sequence latency. This prevents pausing between neural modules, forming larger expert batches at runtime, or redistributing load as long-tail sequences appear. Disaggregated designs [57, 60] retain fixed placement assumptions and thus continue to underutilize GPUs. Even throughput-oriented systems [7, 59] inherit the same static scheduling model and cannot address the root causes of insufficient expert batching or decoding stragglers.

Our key intuition is that sequences themselves provide the right granularity for dynamic scheduling. Neural networks expose natural yield points at module boundaries, and per-sequence state is compact and migratable. This motivates a shift in design: treat sequences not as long-lived tasks pinned to devices, but as fine-grained, event-driven coroutines that can pause, resume, combine, partition, and migrate across GPUs. This architecture directly addresses the structural inefficiencies of batch inference. Specifically, this paper makes the following contributions:

(1) Sequence coroutine compute model. Each sequence is represented as a coroutine that carries all state required for correct execution. The model provides four expressive primitives, `yield`, `combine`, `partition`, and `migrate`. These operations allow the system to reorganize computation while preserving correctness. They make it possible to pause execu-

[*]Co-leading authors.

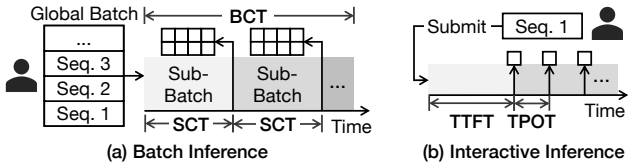

Figure 1: New system design goals for batch inference.

tion and combine sequences to form larger batches for sparse modules, partition stragglers across idle GPUs, and migrate coroutine state for effective load balancing. Existing inference architectures cannot naturally express these behaviors.

(2) Efficient sequence coroutine runtime. The runtime implements event-driven scheduling at cluster scale and is grounded in two key observations. Prefill and decode place very different demands on memory and therefore benefit from different strategies for managing coroutine state. Meanwhile, both phases can run within a unified execution framework that jointly schedules, combines, and partitions coroutines over a shared pool of GPUs. This approach maximizes utilization and avoids leaving devices idle when workloads fluctuate.

(3) BatchGen, a production-ready system that utilizes this design. BatchGen supports multi-node and multi-GPU execution, provides a compatible and expressive batch inference interface, and includes a checkpoint management service that enables rapid cold starts. These capabilities are essential for practical deployment, especially when resource availability changes over time.

(4) Extensive evaluation of the system. Across MoE models, test-time scaling workloads, and reinforcement learning rollouts, BatchGen delivers strong and consistent improvements. On a 128-GPU cluster, it increases batching efficiency for expert layers, reduces the impact of long tail decoding stragglers [16], and lowers batch completion time by up to 2.3×. It outperforms leading inference engines [22, 32, 56] even on memory-constrained accelerators.

BatchGen has been deployed on production clusters to support batch-inference applications. We have open sourced BatchGen at `https://github.com/batchgen-project/batchgen` to benefit the community. We believe the event-driven sequence coroutine architecture represents a fundamental shift for batch inference, akin to the transition from thread-per-request servers (e.g., Apache [3]) to event-driven architectures (e.g., NGINX [31]) that redefined large-scale web systems.

2 Background and Motivation

2.1 Batch Inference and Its Key Objective

Major vendors now provide dedicated batch inference services, including OpenAI Batch Inference [34], AWS Bedrock batch processing [1], and Azure batch endpoints [29]. These services follow a simple model: users submit a batch of input sequences, such as prompts for LLMs, and receive the outputs only after the entire batch has finished processing. Depending on the application, batch sizes can vary widely, from tens of sequences in test-time scaling or thousands in reinforcement learning rollouts to millions in large-scale offline inference.

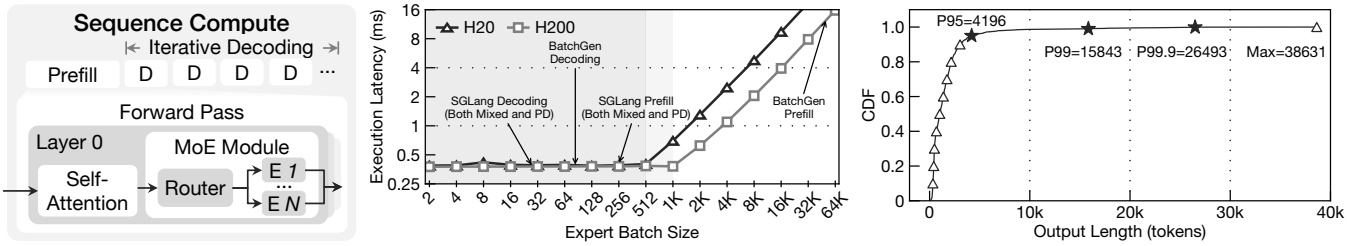
Batch inference systems focus on minimizing the completion time of the entire batch, which is fundamentally different from the responsiveness metrics emphasized in interactive inference. As shown in Figure 1, we define the *batch completion time* (BCT) as the total time from batch submission until every sequence in the batch has been processed. When an application requires partial or early results, the system divides the input into sub-batches, and returns outputs incrementally as each sub-batch finishes. In these cases, we define the *sequence completion time* (SCT) as the time from batch submission until a specific sequence's output becomes available. SCT is determined by the completion time of the sub-batch that contains the sequence. Our primary optimization goal is to minimize BCT, since the user receives the full result only when the entire batch is done. In contrast, interactive inference prioritizes user-perceived responsiveness, focusing on metrics such as time to first token (TTFT) and time per output token (TPOT).

2.2 The Missing Batch Inference System

As adoption of batch inference increases across both industry and academic workflows, the demand for an efficient batch inference engine becomes even more evident. However, there are several challenges in scaling batch workloads: (i) batches continue to grow in size, which requires inference engines to sustain very high levels of concurrency. (ii) the computation required for each sequence can vary widely, which leads to substantial imbalance across GPUs and directly affects batch completion time. (iii) modern models introduce additional variation even within a single sequence because different neural network modules can have very different computational costs, further increasing the imbalance.

These limitations are not confined to a few specialized workloads. Instead, they appear consistently across batch inference settings. Below, we explain why high concurrency and load imbalance naturally arise from the way modern AI models and applications scale.

Insight 1: Intra-sequence imbalance is inherent to sparsity-driven model scaling. State-of-the-art AI models increasingly rely on sparse architectures, most notably Mixture-of-Experts (MoE), as the primary mechanism for scaling model capacity. Shown in Figure 2a, modern models such as DeepSeek-R1 [11], Kimi-K2 [21], GPT-5 [35], Gemini 3 Pro [38], and Grok [47] all deploy MoE models with hundreds of experts. The MoE layers contain the majority of



(a) MoE sequence compute. (b) Insufficient batch size for experts. (c) CDF of output lengths for DeepSeek-R1.

Figure 2: Challenges in MoE batch inference.

the model parameters and contribute a large portion of the compute required for each token.

Since each token activates only a small subset of experts, different tokens within the same sequence follow different execution paths. Some experts are selected far more often than others, and these variations accumulate as model capacity grows. As a result, intra-sequence imbalance is not a product of specific implementations but an intrinsic consequence of sparsity-driven scaling.

The intra-sequence imbalance causes today's state-of-the-art inference engines, even when they are configured in disaggregated mode (prefill-decoding separation), to suffer from underutilizing the GPUs by around 50% even though the input batch has sufficiently massive sequences (shown by Figure 2b). SGLang mixed means that prefill and decoding phases are deployed on the same servers, while SGLang PD uses prefill-decoding disaggregation, with the two phases deployed on separate servers.

Insight 2: Test-time scaling amplifies long-tail generation, causing inter-sequence imbalance. Batch inference workloads exhibit a persistent long-tail effect, where a small fraction of sequences dominate the overall computation. This phenomenon is especially critical in scenarios where batch completion time dominates the pipeline time, such as RL rollouts and deep-thinking pipelines.

Figure 2c illustrates this effect for DeepSeek-R1 on a production dataset trace. The imbalance in decoding lengths is severe: the P99 output length is 3.78× longer than P95, and the maximum length reaches 9.2× that of P95. These stragglers determine batch completion time, leaving most GPUs idle while waiting for a few long-running sequences.

The long tail issues create two key scalability challenges. (1) First, because decoding is sequential, a few extremely long sequences determine the batch completion time, acting as stragglers. (2) Second, GPUs processing shorter sequences finish early and remain idle, amplifying load imbalance between GPUs. In production workloads we consistently observe that this imbalance causes existing engines [22, 32, 56], and their disaggregated variants to lose roughly 10% to 70% of achievable GPU performance. This demonstrates that inter-sequence imbalance is not a rare occurrence but an inherent property of large batch inference workloads.

Takeaway. Together, these requirements and insights reveal the need for a new class of systems: **batch-native inference engines** that can sustain high utilization across large fleets of parallel GPUs while processing massive numbers of concurrent sequences, despite inter- and intra-sequence load variation that is only revealed at runtime.

3 BatchGen Design Intuitions

We begin by examining the design philosophy underlying existing inference engines.

Today's latency-driven scheduling model is a fundamental mismatch for batch inference. State-of-the-art systems such as SGLang [56] and vLLM [22] – regardless of whether they operate in continuous batching mode, chunked prefill, or a disaggregated configuration – are architected around a single objective: *complete each sequence as quickly as possible*. To meet this objective, they *bind* each sequence's computation and state (e.g., KV-cache) to a fixed device and execute it without interruption.

This binding philosophy appears at two levels. *Within* a forward pass, execution is atomic: once a batch enters the model, all sequences traverse every layer together before any scheduling decision can be made. There is no mechanism to pause between modules–e.g., to accumulate more sequences after attention before executing MoE. *Across* forward passes, sequences remain attached to the same device; moving a sequence's state elsewhere is treated as an exceptional, expensive operation to avoid. As a result, each sequence is permanently bound to its assigned GPU and cannot be moved or rescheduled. Once a sequence joins a batch, it stays with that batch until its own completion.

This design is well suited for interactive serving, where minimizing per-sequence latency dominates all other concerns. However, in batch inference, the rigidity becomes a core limitation-both in the *scheduling plans* the system can express and in the *granularity* at which it can intervene. The engine cannot pause a sequence mid-layer to form a more efficient expert batch, cannot adapt the plan as imbalance de-

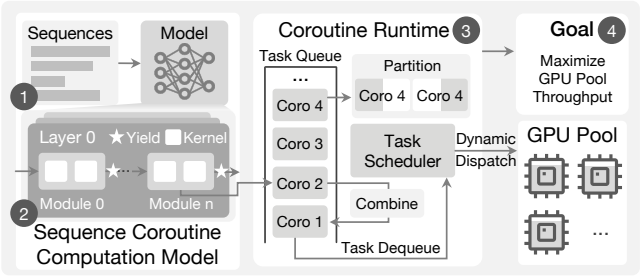


Figure 3: Event-driven Sequence Coroutine Architecture.

velops, and cannot redistribute work when some sequences finish far earlier than others.

Requirements for new batch-native inference scheduling model. In this paper, we revisit batch inference from first principles. In existing systems, a sequence is assigned to specific devices, and this assignment remains fixed because re-binding is viewed as adding unnecessary latency. Even in continuous batching [22, 50, 56], where micro-batches may be reorganized, the *sequence itself* remains implicitly tied to a particular device and cannot freely move or be decomposed.

This observation leads us to a novel system design opportunity: Can we model sequence computation as fine-grained coroutines and dynamically schedule them in a throughput-oriented, event-driven architecture?

We make four key insights, illustrated in Figure 3, that show why such a system design is practical and effective for today's batch inference workloads:

❶ **Sequences provide a natural granularity for coroutine-based scaling.** In batch inference, both compute and memory load scale with the number of sequences, and each sequence has an independent execution lifetime. This makes sequences a natural unit for coroutine computation.

❷ **Neural network modules offer natural yield points.** Sequence computation performs forward passes through modular components (e.g., attention, MoE layers) in prefill and decode. Module boundaries naturally serve as coroutine yield points for event-driven scheduling.

❸ **Sequence state can be dynamically combined, partitioned, and migrated.** The state associated with each sequence (e.g., hidden states in prefill, KV cache in decode) is tensor-structured and self-contained, allowing flexible pausing, combining, partitioning, and migration without affecting correctness.

❹ **Batch inference optimizes batch completion time, hiding the dynamic scheduling latency of sequences.** The extra overhead of coroutine scheduling may be undesirable for interactive workloads, but in batch settings, where end-to-end batch completion time is the primary metric, this overhead is amortized and outweighed by improved throughput from high-concurrency coroutine execution.

To the best of our knowledge, no existing system follows our proposed architectural model. Interactive inference engines such as SGLang [56] and vLLM [22] bind each sequence to a fixed GPU for its entire lifetime. Disaggregated inference systems, including DistServe [57], Splitwise [37], and Mooncake [39], relax this constraint by assigning each inference phase, such as prefill or decode, to a specific GPU, but the phases still remain statically placed. MegaScale-Infer [60] further disaggregates decode into attention and expert modules, but continues to rely on fixed placement of these components. Kernel oriented systems such as NanoFlow [59] improve execution efficiency, but do not address their underlying scheduling and placement limitations.

	Interactive Inference	Disaggregated Inference	Sequence Coroutine (Ours)
Scheduling plan	Static	Static	**Adaptive**
Scheduling granularity	Coarse-grained, fixed	Coarse-grained, fixed	**Fine-grained, flexible**
Operational cost	Medium	High	**Low**
Throughput	Medium	Medium	**High**

Table 1: Scheduling characteristics of three inference system architectures.

Architectural advantages. We name our new system architecture the *event-driven sequence coroutine architecture*. Table 1 summarizes its potential effectiveness. By exploiting sequence-level coroutines and providing system mechanisms for their yield and combination, we can significantly increase batch sizes on sparse operations (*e.g.* each expert in MoE) at runtime and thereby achieve significantly higher GPU utilization than interactive engines (shown in Figure 2b).

Meanwhile, when long-tail generation or load imbalance is detected, low-cost event-driven scheduling can yield, migrate, partition, and recombine sequence coroutines to avoid stragglers and maintain balanced loads.

Because GPUs are managed as a shared resource pool rather than being pre-allocated to specific sequences, sequence coroutines can be dynamically dispatched to any available GPU, making the system easy to deploy across batch jobs with widely varying input–output length distributions.

Finally, sequence coroutines execute under an event-driven model in which GPUs always have useful events to process, while the scheduler keeps most coroutine state in host memory. This substantially reduces peak GPU memory usage and lowers the operational cost of batch inference.

A powerful analogy is the transition from thread-per-connection servers (e.g., Apache HTTP Server [3]) to event-driven architectures (e.g., NGINX [31], SEDA [46]). Apache performs well under modest load but degrades under highly variable, large-scale traffic; NGINX treats requests as coroutines and uses event-driven scheduling to sustain scalability. Batch inference demands the same paradigm shift.

4 The Sequence Coroutine Model

4.1 The Sequence Coroutine Abstraction

We abstract sequence coroutines as follows: a representation of a neural network model's per-sequence execution that can be paused, migrated, combined, partitioned, and resumed without losing correctness.

Establishing this abstraction requires answering three key questions: (i) How to model the sequence's computation process and intermediate state? (ii) How to enable sequence coroutine execution in a neural network that is typically built using modular abstractions? (iii) How to execute concurrent sequence coroutines on a limited number of compute units?

Modeling sequence computation and state. The sequence computation (defined in Figure 2a) requires states that fully determine the current and future computations. We define the data structure as shown in Figure 4a, using language models as an example for the values in each field. Each sequence can be uniquely identified, with the amount of computation to be scheduled (*i.e.* `max_out`, `max_in`). The coroutine state stores the KV-cache, while the output consists of the hidden states passed between module forward calls, enabling the coroutine to resume execution correctly at the next scheduling point. Sequence computation exposes primitives (*i.e.* `yield`, `combine`, `partition`, `migrate`) to enable coroutine scheduling on sequence computation, and callbacks for customized operations on sequence states.

Creating coroutines through module wrappers. We provide an abstraction layer that preserves the modular semantics of existing model definitions (*e.g.* `torch.nn.Module`), while inserting scheduling points at runtime (Figure 4b). During model initialization, BatchGen applies wrappers on selected modules, allowing coroutine steps to be generated automatically. The wrapper allows any custom scheduling policy to be implemented using coroutine primitives. By default, the coroutine yields the sequence compute on exit.

Concurrent sequence coroutine execution. Concurrency is managed by a coroutine scheduler for coordination over the GPU pool (Figure 4c). Once modules are wrapped, a sequence computation naturally forms a *coroutine execution flow* that defines the successor relationships between computation stages. When a coroutine yields, it enqueues its successor, while the scheduler selects one or more inactive sequence coroutines from the global queue to dispatch onto available compute units. A many-to-one mapping corresponds to `combine`, a one-to-many mapping corresponds to `partition`, and a one-to-one mapping corresponds to a simple resume.

4.2 Sequence Coroutine Mechanisms

When designing mechanisms for sequence coroutines, we have three requirements: (i) they must provide yield primitive that preserves correctness for stateful neural network execution; (ii) they must enable coroutine combination to inflate expert-level batch sizes in MoE computation; and (iii) they must support coroutine partitioning to mitigate stragglers in long-tail prefill and decoding stages.

Sequence coroutine yield mechanism. A `YIELD` in sequence compute behaves analogously to the await primitive in pro-

gramming languages such as Python: yield suspends a sequence coroutine, checkpointing its state produced and releasing GPUs, such that control can safely return to the scheduler. Figure 5 Ⓐ illustrates this process: sequence S_1 yields after a module computation and becomes inactive, allowing the scheduler to resume inactive S_2 on the same GPU.

Sequence coroutine combination mechanism. Standard coroutine semantics require an explicit `resume` primitive to continue suspended execution. In our model, resume semantics are part of `COMBINE`: since the purpose of combining sequences is to form a batch for computation, resumption occurs implicitly. This design eliminates a separate primitive while preserving expressiveness.

Analogous to data-stream operators in Spark [51], `COMBINE` merges multiple yielded sequences into a single batch for efficient GPU execution. Figure 5 Ⓑ illustrates this process: intermediate states (in the form of tensors) are concatenated from S_1 and S_2, doubling the batch size for the sparse module and increasing compute density on a single GPU.

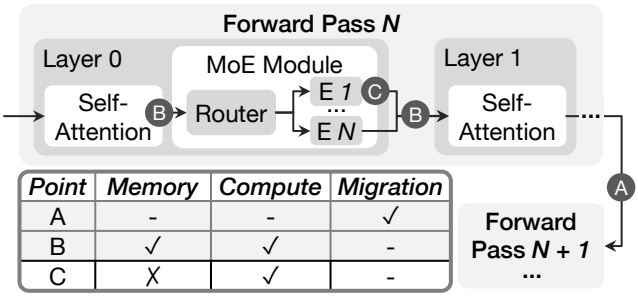
Sequence coroutine partitioning mechanism. `PARTITION` distributes a single long-running sequence across multiple GPUs using tensor parallelism to accelerate completion. Each GPU executes the same program over its assigned portion of the data. Figure 5 Ⓒ illustrates this on a single sequence: the scheduler finds another idle GPU to form a parallelism group for the module. The GPU group can be local to a node or distributed, depending on the scheduler's decision.

Sequence coroutine migration mechanism. `MIGRATE` transfers a sequence's state (*e.g.* KV-cache and metadata) to a different physical device for load balancing. The call is asynchronous while still ensuring consistency. The physical location of the sequence is left to the scheduler for book-keeping. Figure 5 Ⓓ illustrates this for moving to another GPU. This also applies to sequences in Host and other media as well.

4.3 How to Use Sequence Coroutine?

In this subsection, we use an MoE model to illustrate how to use the sequence coroutine abstraction for batch inference.

Two types of yield points. *Intra-forward* yield points occur within a single forward pass. When a downstream module reaches good device utilization only at a different batch size than the module preceding it, sequences yield after the upstream module so that the runtime can accumulate and `COMBINE` them into a batch downstream. For instance, attention saturates the GPU at a modest batch size while the sparsely activated MoE requires a much larger one. This applies to any sequence of modules with heterogeneous batch-size demand. Because the decisive factor is the model's compute characteristics, intra-forward yield points are selected once, statically, per model (§5.4). *Inter-forward* yield points occur across forward passes and are driven by runtime conditions rather than model structure. A sequence yields either



Point	Memory	Compute	Migration
A	-	-	✓
B	✓	✓	-
C	✗	✓	-

Figure 6: Yield point selection.

to achieve better utilization for batch progression (*e.g.* switch from decode to prefill to refill sequence) or under resource pressure (*e.g.* evict sequence under growing decode length that exceeds GPU memory). The yielded sequence can be combined again later with other active sequences running on GPU. Because these conditions depend on runtime state, inter-forward yield points are decided dynamically (§5.3).

Key development question: the choice of yield points. A central question arises when adopting sequence coroutines: given a model with multiple modules-and thus many candidate yield points-where should developers place yield points to maximize throughput?

For MoE architectures, we observe three practical and reusable yield-point options (shown in Figure 6): Ⓐ treating the attention + MoE layers as a single coroutine unit, Ⓑ splitting the attention and MoE layers into two coroutine units, and Ⓒ treating each expert in an MoE layer as an independent coroutine unit.

These options reflect throughput-memory trade-offs: Ⓐ a combined attention-MoE coroutine minimizes intermediate states for sequence computation but limits expert-level batching and sequence concurrency; Ⓑ a split design allows the system to dynamically increase expert-level batch sizes without overwhelming memory usage; and Ⓒ a per-expert coroutine maximizes sequence computation concurrency but has prohibitive memory costs when initiating millions of coroutines.

According to these insights, we design the coroutine schedule to be hierarchical. For MoE batching, we adopt option Ⓑ, inflating the batch size at MoE layers to achieve substantial throughput gains while keeping memory usage controlled at attention layers. To mitigate long-tailed decoding, we additionally employ option Ⓐ. This enables lightweight migration and allows parallelism configurations to be adjusted dynamically through state checkpointing already made during yield.

The coroutine callbacks allow users to inject custom logic to handle sequence local state without modifying the runtime. These callbacks can be used to implement techniques such as dynamic quantization of KV-cache on a per-sequence basis [13], which can respond to runtime memory pressure or accuracy requirements.

Algorithm 1: Scheduling model forward pass

12 **if** ONLONGTAIL*(nodes, gpus)* **then**
13 wait until all $s \in \mathcal{S}_{\text{node}}$ **YIELD** on target GPUs;
14 **PARTITION** remaining sequences to target GPUs;

5 System Design and Implementation

5.1 Sequence Coroutine Scheduling Algorithm

We design a sequence coroutine scheduler to sustain high compute efficiency across prefill and decoding. The core challenges stem from sparsely activated MoE layers, which require large batches, and from unpredictable long-tailed decoding. Our scheduler uses coroutine primitives to accumulate batches, adapt memory usage, and reduce long-tail inefficiency through continuous batching and dynamic parallelism.

Providing sufficient batch size for sparse module. Our scheduling algorithm aims to provide a sufficient batch size for MoE model by `COMBINE`-ing yielded sequences from attention. The design is motivated by a key insight: *a module-level roofline model enables static planning for batch accumulation*. Given the system's capacity for both active (GPU-resident) and inactive (host-resident) sequences, we can select the largest feasible module batch size that remains within memory constraints.

We design the coroutine scheduling in alignment with Figure 4b for attention, MoE, and model forward pass as in Algorithm 1, where the shaded area represents the code inside module wrapper that creates a coroutine. For attention, the batch is split into sub-batches of size B_{attn}; each sub-batch executes attention, buffers its hidden states, optionally offloads KV-cache, and then yields. For MoE, all sub-batch hidden states are combined into a large batch of size B_{moe}.

Mitigating long-tailed and unbalanced decoding. Long-tailed decoding can only be managed at runtime, as output lengths are unknown in advance. We address this challenge through two mechanisms: *Dynamic sequence management* maintains high GPU utilization by continuously refilling the batch with prefilled sequences. When sequences complete or are evicted, the scheduler invokes `COMBINE` to merge waiting sequences into the active batch, preventing GPUs from idling. We detail this in §5.3. *Straggler acceleration and load balancing* handle the final phase of batch completion. When only a few long-running sequences remain, `PARTITION` redistributes their computation across idle GPUs—using tensor parallelism for single stragglers or data parallelism for multiple. Throughout execution, `MIGRATE` rebalances sequences across nodes to prevent skew from uneven completion rates.

We illustrate the scheduling loop in Algorithm 2. Nodes begin with prefilled sequences stored in host memory (line 1). The main loop (lines 2–6) repeatedly selects batches, executes forward passes, and invokes dynamic sequence management. The ONREFILLNODE callback (lines 7–11) triggers prefill when GPUs become underutilized. The ONLONGTAIL callback (lines 12–14) detects stragglers and applies `PARTITION`, which requires yielding active sequences to reconfigure GPU memory for the new parallelism strategy with its impact demonstrated in §6.3.

We design two callbacks, ONREFILLNODE and ONLONGTAIL, to manage long-tail behavior. ONREFILLNODE supplies additional inactive sequences to the decoding phase so that idle or underutilized GPUs remain fully occupied (lines 7-11). When long-tail sequences persist and no inactive sequences remain to refill the batch, the scheduler invokes ONLONGTAIL (lines 12-14). This callback waits for all active sequences on the target GPUs to yield, ensuring their states are safely checkpointed before reconfiguring model parallelism and redistributing the remaining work.

5.2 System Memory Model

We design the system memory layout to support coroutine scheduling with minimal overhead. The key challenges arise from the different memory demands of prefill and decoding, the sensitivity of batch combination size to peak memory usage, and the need to shift efficiently between phases while preserving accumulated state.

Our memory layout addresses these issues by unifying host and device memory management, paged KV-cache management, and providing phase-agnostic GPU buffers that can be reconfigured without disrupting coroutine execution. The residence of the KV cache and model weights, i.e., whether each is offloaded to host memory, is a throughput-driven decision resolved by the coroutine scheduling plan (§5.4), depending on whether the host-device transfer cost is outweighed by the throughput gain from larger-batch execution.

Figure 7 illustrates BatchGen's memory layout and execution flow for both prefill and decode phases, rooted in the following principles.

Host memory should serve as a unified store. On each node, the host memory holds shared model parameters and KV-cache for all sequences scheduled to the node (in ❶). This provides two benefits: (i) *a single source of truth* for all model states, avoiding redundant per-GPU copies, and (ii) *local coroutine store* for checkpointing KV-cache on `YIELD` and restoring it on `COMBINE` without distributed synchronization. Parameter movement is unidirectional: host memory serves as the source for GPU prefetching, not a destination for offloading.

Supporting local phase switching with fine-grained GPU buffers. BatchGen partitions GPU parameter memory into two regions (in ❷ and ❸). (i) *Resident parameters* store parameters that remain in the GPU throughout the current phase, which is typically small (*e.g.*, LayerNorm). During decoding, it may include all attention parameters when memory permits. (ii) *Parameter and KV buffer* is a transient staging area for prefetching and offloading. The buffer slot ownership is released after the module completes execution. As prefill and decoding share the same design, we reconfigure the size of these components during the phase swap.

Increasing peak memory budget for prefill. Prefill-phase attention exhibits high peak memory demand due to FlashAttention's $O(N)$ memory complexity, where N is the sequence length. In contrast, decode-phase attention requires only $O(1)$ memory per sequence, as each iteration processes a single token against the existing KV-cache. We design the prefill phase to offload more aggressively by asynchronously offloading the microbatch KV-cache from each layer's attention to host and reclaiming its GPU buffer immediately. The prefill phase has enough computation to hide the offloading cost. At any instant the GPU therefore holds at most two layers' worth of KV-cache, making prefill memory less demanding from both batch size and sequence length. This results in minimizing

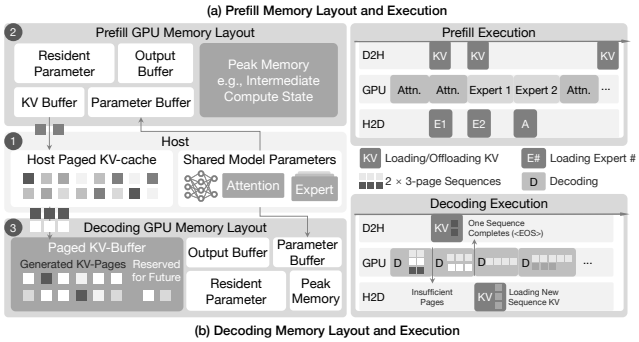

Figure 7: Memory layout and execution flow for prefill (top) and decode (bottom) phases. Host memory serves as checkpoint storage for parameters and KV-cache, while GPU memory is partitioned into persistent and transient regions.

buffer size in prefill (in ❷). The example for the ring parameter buffer and single KV buffer is shown in Figure 7a, with the running and prefetching expert using the ring buffer and KV-cache offloading (asynchronously after attention) using the single buffer.

Increasing sequence concurrency for decoding. Each GPU maintains a paged KV-cache manager (in ❸) that allocates and tracks KV pages at a fine granularity. During decoding, BatchGen employs a two-page buffer strategy: each sequence reserves only two KV pages for subsequent decoding iterations, with additional pages allocated on demand as the sequence grows. This lazy allocation maximizes the number of active sequences. Offloading during decoding considers a trade-off between parameters and KV-cache transfer cost and the throughput gain from larger batch size. Decode has low arithmetic intensity thus offers little computation to hide host-to-device transfers. We demonstrate a case for benefits under tight memory budgets (§6.5). When GPU memory becomes insufficient, we evict sequences until two pages can be allocated for all active sequences. Detailed design will be covered in §5.3.

5.3 Dynamic Sequence Management

The dynamic sequence management design is unique to batch inference: to maximize throughput, we must maintain large batch sizes or high parallelism throughout both prefill and decoding phases.

BatchGen checks memory state and adjusts the active batch every P tokens (i.e., after decoding one KV page of tokens). At each page boundary, the scheduler executes four phases: (i) *Sync*: wait for pending asynchronous KV append operations to complete—these operations continuously propagate newly generated KV entries from GPU to host memory, maintaining host as the single source of truth; (ii) *Eviction*: `YIELD` completed sequences, releasing their GPU and host KV pages;

(iii) *Extension*: for sequences approaching their allocated page limit, either extend allocation if GPU pages are available, or `YIELD` them to host (marking as suspended) to free pages for other sequences; (iv) *Refill*: `COMBINE` new sequences from the prefilled or suspended pool, launching async KV restoration that overlaps with the next page's forward passes.

These operations provide the following properties:

Ensuring decoding batch size is sufficient. BatchGen uses *adaptive sequence selection*. When GPU memory is insufficient for all active sequences, BatchGen must decide which sequences to `YIELD`. The scheduler prioritizes yielding sequences with the most progress (highest decoded length), as they have more KV-cache already checkpointed to host and are closer to completion. This strategy maximizes the number of sequences that can make forward progress.

Ensuring load-balance on refill. Long-tail generation creates imbalance across GPUs as sequences complete at different times. When a GPU finishes sequences, BatchGen uses `MIGRATE` to redistribute suspended sequences from other nodes, keeping all GPUs utilized. Refill candidates are selected in FIFO order to preserve fairness. When all nodes lack sufficient suspended sequences, BatchGen temporarily switches to prefill mode to generate new sequences. Note that `MIGRATE` requires the coroutine task queue to be blocked to (i) avoid races between active execution and memory transfer, and (ii) synchronize on the global count of inactive sequences. This blocking is low-cost since migration overlaps with sequence computation on other GPUs.

Ensuring single sequence straggler is parallelized. When straggler sequences remain, batching benefits diminish and most GPUs become idle. BatchGen allows configuring a threshold on global batch size to trigger `PARTITION`: for multiple stragglers, sequences are distributed across GPUs using data parallelism; for a single straggler, computation is partitioned across GPUs using tensor parallelism. The KV-cache distribution depends on the attention architecture: for MLA, the compressed latent KV-cache is replicated across GPUs; for MHA/GQA, the KV-cache is split across attention heads.

5.4 Optimization of Scheduling Plans

The runtime also follows a static plan that fixes batch sizes, buffer allocations, and yield points. Manual tuning is infeasible given the combinatorial space of model scales and hardware configurations, so BatchGen derives this plan automatically through lightweight profiling and simulation.

Module-level performance modeling. Modern LLMs are structurally homogeneous, allowing BatchGen to profile a single representative layer rather than the entire model. It measures attention, MoE, and collective communication kernels over multiple batch sizes and fits the results to roofline-style models that predict runtime as a function of batch size and memory allocation.

Category	Operation	Cost
Intra-forward `YIELD`	Hidden state checkpoint	$<5\,\mu$s
	KV-cache offload	overlapped
Inter-forward `YIELD`	CUDA event sync	$<1\,\mu$s
	Metadata update	$<10\,\mu$s
`COMBINE`	Without offloading	0 (GPU resident)
	With offloading	$\sim$0.2 ms per seq. per layer
`PARTITION`	Parallelism reconfig	$\sim$5–10 s (when triggered)
`MIGRATE`	KV-cache transfer	Opportunistic, overlapped
Scheduling	Intra-forward	0 (static plan)
	Cross-node sync	5–10 ms / 64 tokens

Table 2: Coroutine primitive overhead for DeepSeek-R1 on 8×H20 with 10K context length and batch size 512.

Execution DAG construction. BatchGen models a single layer's forward pass as a directed acyclic graph (DAG) to simulate execution under different configurations. Each node in the DAG represents either a computation (attention, MoE, `YIELD` checkpointing) or a data transfer (parameter prefetch, KV-cache offload/restore for `COMBINE`). Edges encode dependencies: a module cannot execute until its parameters are loaded; `COMBINE` cannot proceed until KV-cache restoration completes (if needed). Node costs are assigned from the profiled execution times and memory requirements at each candidate batch size. The critical path through this DAG—the longest dependency chain—determines the layer's execution time, capturing how computation and data movement overlap.

Configuration search. Given a DAG, finding the critical path requires a single topological traversal using dynamic programming, with complexity $O(V+E)$ where V and E are the number of nodes and edges. Since a layer's DAG contains fewer than 100 nodes, this computation is negligible. BatchGen enumerates candidate configurations (B_{attn}, B_{moe}, and buffer sizes), constructs the corresponding DAG for each, and selects the configuration with the shortest critical path.

5.5 Coroutine Overhead Analysis

A natural question is whether coroutine-based scheduling introduces noticeable overhead. Table 2 summarizes the cost of all coroutine primitives.

Frequently invoked primitives have negligible overhead. Coroutine boundaries occur once per module. Hidden-state checkpointing writes only $\sim$7 MB for 512 sequences (7168-dim), completing in under 5 μs at HBM bandwidth, compared to $\sim$3 ms for the module's computation. KV-cache offloading is issued asynchronously and fully overlaps with MoE execution. Between forward passes, `YIELD` performs a CUDA event sync ($<1\,\mu$s) and updates sequence metadata on the CPU ($<10\,\mu$s for 512 sequences).

`COMBINE` overhead depends on whether KV-cache offloading is active. Without offloading, combined sequences are

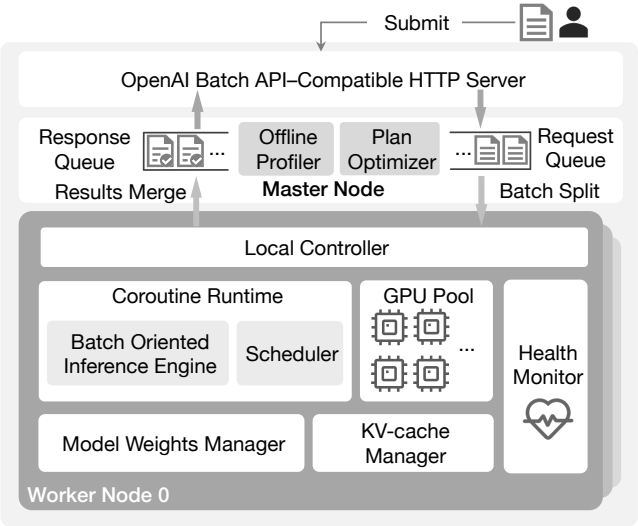

Figure 8: BatchGen system architecture with master-worker organization, API endpoints, and inference engine.

already GPU-resident, incurring zero cost. With offloading, `COMBINE` must restore KV-cache from host memory; for a 10K-token sequence this takes ∼0.2 ms per layer over PCIe 5.0. This cost arises only when refilling batches and is amortized by the larger batches that offloading enables.

Primitives with millisecond-level overhead are negligible to overall computation time. `MIGRATE` is invoked opportunistically to balance the number of inactive sequences across nodes. The number of migrations over a batch stays small relative to the total sequence count and the migration cost can be smaller than prefill. When `MIGRATE` is scheduled in advance, the KV-cache transfer is fully overlapped with ongoing computation on other sequences, adding zero latency to the critical path. For instance, on a standard H100 HGX node with 400 Gb/s (∼50 GB/s) InfiniBand link, prefilling a 2K-token DeepSeek-R1 sequence costs ∼112 ms even at the GPU's peak throughput (BF16 MLA attention at 989 TFLOP/s plus FP8 MoE GEMMs at 1979 TFLOP/s), whereas migrating the sequence's entire 144 MB MLA KV-cache over that link takes only ∼2.9 ms, which is less than 3% of the prefill compute it overlaps with. Although `PARTITION` takes seconds, it is triggered only when long-tail sequences are detected (typically once per batch near completion) and enables idle GPUs to accelerate remaining stragglers. Meanwhile, batch completion time is more than 10 minutes. Dynamic scheduling occurs only at page boundaries (every 64 tokens), requiring 5–10 ms for cross-node synchronization—approximately 0.1–0.2% of the compute time for 64 decode iterations.

5.6 Implementation Details

We implement BatchGen in 13K LoC of C++ and 49K LoC of Python. The C++ layer implements the host-side KV-cache system and the asynchronous host–device copy engine, while the Python layer implements the coroutine scheduler and the PyTorch-based forward-pass skeleton for each model. Beyond third-party kernels (e.g., FlashAttention [8], DeepGEMM [10]), BatchGen develops and maintains its own library of kernels for batch inference, adapted to BatchGen's KV-cache and input/output buffer layout.

Figure 8 shows the BatchGen system architecture for deployment at scale with the control plane implemented on an industrially customized Ray [30]. Key features include:

OpenAI-compatible batch API. BatchGen exposes an HTTP endpoint compatible with the OpenAI Batch Inference API [34]. A master node per model-parallel group accepts batch submissions, partitions sequences across workers via the coroutine scheduler, and returns results preserving input order. This enables BatchGen to serve as a drop-in replacement for existing batch inference pipelines.

Batch-oriented inference engine. The inference engine integrates high-performance compute and communication kernels (e.g., DeepEP [9]) and includes additional kernel fusions tailored for model types. It supports phase-specific parallelism strategies: (i) *DP prefill with offloading*, where prefill is compute-bound and parameter/KV transfers are fully hidden, enabling scalable data parallelism; and (ii) *DP+EP decoding*, which combines data-parallel attention with expert-parallel MoE to maximize bandwidth utilization during generation.

Cold-start optimization. Batch inference often runs on spot instances where cold-start latency impacts usable compute time. BatchGen includes a *model weights manager* with: (i) *Huge pages*: Allocating GPU-accessible host memory incurs page faults proportional to pool size. BatchGen uses 2 MB huge pages, reducing initialization time from minutes to seconds for TB-scale pools. (ii) *Fast checkpoint loading*: BatchGen adopts the memory-mapped checkpoint format from ServerlessLLM [15], enabling rapid weight loading that fits within typical spot instance lifetimes.

Failure detection and recovery. At scale, GPU and node failures are inevitable. BatchGen implements *health monitoring* where per-node responses carry all GPU statuses. For recovery, `MIGRATE` can either transfer KV-cache state or trigger recomputation. Since migrating hundreds of gigabytes may be slower than regenerating, BatchGen uses its performance model to estimate both costs and selects the faster path.

6 Evaluation

Testbed. We evaluate BatchGen on a production-grade multi-GPU cluster representative of real LLM deployment environments. The testbed includes NVIDIA H20 and H200 servers scaled from 8 to 128 GPUs. Each node offers high-bandwidth intra-node connectivity via NVLink and PCIe 5.0, with 2 TB of host memory, and nodes are interconnected through a

Model	Framework	H20 (8 GPUs)		H20 (16 GPUs)		H200 (8 GPUs)

200 Gb/s RDMA-enabled InfiniBand fabric, matching common datacenter configurations for large-scale model serving.

Baselines. Our primary baselines are SGLang (v0.5.5.post3) [56] and vLLM (v0.11.2) [22], which are widely recognized as SOTA open-source systems. We evaluate SGLang-Optimized, which applies exhaustive tuning for maximum throughput: we configure 16 DP-attention ranks (a throughput-friendly parallelism strategy), tune the memory allocation fraction to the threshold before OOM, and selectively restrict CUDA graph capture to necessary batch sizes to reduce GPU memory consumption and allow larger runtime batches.

For memory-constrained scenarios (§ 6.5), we compare against systems with offloading optimizations: DeepSpeed [12], FlexGen† [41], and MoE-Lightning† [7]. For disaggregated inference (§6.4), we evaluate prefill-decode (PD) disaggregation using SGLang's implementation. We exclude attention-expert disaggregation [60] due to the lack of open-source implementations.

Models. Our evaluation spans four SOTA MoE models, including Mixtral-8×7B (47B parameters) and Mixtral-8×22B (141B parameters) [18], DeepSeek-R1 (671B parameters) [11], and Kimi-K2 (1T parameters) [21].

6.1 Application 1: Offline Inference

We evaluate BatchGen using LongBench [4]. We evaluate on two common production patterns: (i) *prefill-heavy* (8K input, 2K output tokens): reflects summarization and information extraction tasks, and (ii) *decoding-heavy* (2K input, 8K output tokens): captures reasoning-intensive workloads such as chain-of-thought question answering. Table 3 reports batch completion time for 6K sequences.

BatchGen achieves larger speedup on weaker GPUs. On 16×H20 and 8×H200 clusters, BatchGen delivers 1.25–1.66× speedup over SGLang-Optimized across all configurations. The improvement is consistently larger on H20 than on H200. H200's higher compute throughput shrinks the relative cost of prefill, where BatchGen's batch accumulation provides the most benefits. On H20, prefill dominates end-to-end time, and BatchGen's ability to form large expert batches yields proportionally greater gains.

BatchGen enables larger models and far larger batches under tight memory budgets. On 8×H20 GPUs (768 GB total HBM), baseline behavior diverges by model. DeepSeek-R1's parameters (approximately 642 GB in FP8) fit in HBM, but baselines must partition remaining capacity between KV-cache and working memory, limiting batch sizes to 8–16 sequences. SGLang-Optimized cannot improve over default SGLang in this regime—exhaustive tuning yields no additional headroom when memory is saturated. BatchGen achieves 1.31–1.85× speedup by offloading KV-cache to host memory, enabling batch sizes of 1800+ sequences. For Kimi-K2 (1T parameters), no baseline completes execution: the model exceeds HBM capacity entirely. BatchGen is the only system that runs Kimi-K2 on this hardware configuration.

The offloading regime exhibits a counterintuitive effect: BatchGen delivers nearly identical throughput on DeepSeek-R1 and Kimi-K2, even though Kimi-K2 is about 1.5× larger. With offloading, performance becomes PCIe-bandwidth-bound rather than compute-bound. Because both models have similar per-token KV-cache sizes and PCIe bandwidth is fixed, their achievable batch sizes-and thus throughput-converge. This trade-off remains advantageous: offloading enables much larger expert batches, keeping MoE layers in the memory-bound regime where compute scales sublinearly with batch size, while greater sequence-level parallelism amortizes transfer costs.

Comparison with TensorRT-LLM. We additionally compare against TensorRT-LLM [32], which represents state-of-the-art kernel optimization but requires non-trivial deployment effort. On 16×H20 GPUs with the 8K-2K workload, BatchGen outperforms TensorRT-LLM by 10%, demonstrating that coroutine-based scheduling provides benefits orthogonal to kernel-level optimizations.

6.2 Application 2: Test-Time Scaling

Unlike offline batch inference, test-time scaling places SLO constraints on batch completion time to maintain acceptable user experience, requiring systems to choose batch sizes that finish before the deadline. We use Recursive Self-Aggregation (RSA) [43] as a representative workload. After the first round, each subsequent round combines K prior answers as the prefill input, producing a prefill-to-decode ratio of K:1. We evaluate this setting on DeepSeek-R1 using 16×H20 GPUs with a fixed 8K decoding length per round.

BatchGen enables efficient SLO–throughput tradeoffs. Table 4 reports the number of sequences served under 30-minute and 60-minute SLO targets. BatchGen processes 1.25–1.57× more sequences under the 30-minute SLO and 1.66–

Model	Framework	T=4, N=8, K=4		T=2, N=16, K=4		T=3, N=8, K=2	
		30min	60min	30min	60min	30min	60min
DeepSeek-R1	vLLM	10.9	23.1	10.7	20.1	7.3	15.0
	SGLang-Opt	12.8	25.9	13.4	24.7	34.0	69.2
	BatchGen	**16**	**43**	**21**	**42**	**53**	**121**
	Speedup	*1.25×*	*1.66×*	*1.57×*	*1.70×*	*1.56×*	*1.75×*

Table 4: Number of sequences served under SLO constraints for RSA test-time scaling on DeepSeek-R1 with 16×H20 GPUs. RSA uses T rounds, N candidates per round, selects K candidates for the next round, and fixes decoding length at 8K. Higher is better. Speedup is relative to SGLang-Optimized.

1.75× more under the 60-minute SLO compared to SGLang-Optimized. The larger gains under relaxed SLOs reflect BatchGen's ability to form larger batches when deadlines permit, improving expert-level compute density. Prefill-heavy configurations (higher K) show greater improvements because compute-bound prefill enables effective overlap of parameter and KV-cache transfers at no additional cost.

BatchGen maintains advantages even under constrained batch sizes. Under tighter SLOs, BatchGen cannot always operate at its theoretically optimal batch configuration. For instance, in the (T=4, N=8, K=4) 30-minute scenario, meeting the completion deadline requires reducing the MoE batch size below the compute-saturating threshold. This sub-optimal configuration explains why BatchGen's speedup at 30 minutes (1.25×) is lower than at 60 minutes (1.66×)—the SLO constraint limits batching flexibility. Nevertheless, BatchGen still outperforms all baselines, demonstrating that its coroutine-based scheduling provides benefits even when batch sizes are externally constrained. This makes BatchGen suitable for online services with relaxed (minute-to-hour scale) SLOs where some latency–throughput tradeoff is acceptable.

6.3 Application 3: RL Training Acceleration

Reinforcement learning from human feedback (RLHF) [36] is a standard stage in LLM training, and its rollout phase often dominates total training time. Unlike offline inference, RL rollout fixes the batch size (typically 256–1024) [17], removing the primary lever used in batch inference: enlarging batches to improve expert utilization.

A major bottleneck in rollout is straggler sequences. Long-tailed generation lengths create synchronization barriers in synchronous training, forcing all workers to wait for the slowest trajectories. As the batch drains, GPU utilization collapses: once only a few sequences remain, most devices idle.

BatchGen mitigates stragglers via its coroutine callbacks. The OnLongTail callback triggers when the number of active sequences falls below a threshold, allowing the runtime to apply `PARTITION` and redistribute remaining work across idle GPUs, switching from data to tensor parallelism for single long-tail sequences. The same mechanism supports alternatives such as FP8 decoding or speculative decoding without changing the core runtime.

Workload	Framework	H20 GPUs		
		32	64	128
12K-4K	vLLM	866.0	437.2	218.9
	SGLang-Opt	239.2	120.8	61.1
	BatchGen	**139.7**	**66.3**	**33.5**
	BatchGen *	**110.7**	**52.6**	**26.3**
6.5K-2.8K	vLLM	236.9	120.5	61.1
	SGLang-Opt	139.9	71.2	36.0
	BatchGen	**63.9**	**30.4**	**15.5**
	BatchGen *	**59.4**	**28.3**	**14.6**

Table 5: End-to-end time (minutes) for processing 10K requests on DeepSeek-R1. BatchGen * uses SGLang kernels with the BatchGen coroutine runtime.

We evaluate on VeRL [6] with DeepSeek-R1 on 16×H20 GPUs. In a typical setting, each RL iteration uses 256 prompts with one response per prompt, for 256 rollout sequences in total, evenly distributed across the 16 GPUs at 16 active sequences per GPU initially. Generation lengths are heavily long-tailed, so the batch drains unevenly: OnLongTail triggers once the global active batch falls to ≤ 8 sequences whose generation length exceeds 40K tokens. In our traces these final sequences account for 30–80% of rollout time, yet leave at most 0.5 active sequences per GPU on average, exposing substantial idle capacity. BatchGen reclaims this capacity by applying `PARTITION` with FP8 decoding to the stragglers, reducing per-iteration rollout time by 5–10%, with the gain increasing as the final generation length grows, consistent with [16]. Since rollout accounts for 60–80% of training time, these savings translate directly into shorter end-to-end training.

6.4 Scaling to Large Deployments

We evaluate BatchGen at production scale with up to 128 GPUs using two trace-derived workloads: a prefill-heavy setting (12K input, 4K output tokens) and a balanced setting (6.5K input, 2.8K output). To disentangle runtime gains from kernel improvements, we also report results for BatchGen *, which replaces BatchGen's kernels with SGLang's while preserving the coroutine scheduler.

Table 5 shows end-to-end time for 10K requests. Because the evaluated SGLang and vLLM versions exhibit stability issues when scaling DeepSeek-R1 beyond two nodes (16 GPUs), we extend them to 32-128 GPUs by running multiple independent 16-GPU data-parallel groups and aggregating throughput. BatchGen achieves 1.71-1.82× speedup on the 12K-4K workload and 2.2-2.3× on the 6.5K-2.8K workload relative to SGLang-Optimized.

P:D Ratio	1:7	2:6	3:5	4:4	5:3	6:2	7:1
PD Disagg. (min)	137.9	67.4	49.0	38.6	40.1	55.6	112.0
BatchGen (min)				**17.5**			
Speedup	*7.9×*	*3.9×*	*2.8×*	*2.2×*	*2.3×*	*3.2×*	*6.4×*

Table 6: Comparison with PD disaggregation on 128×H20 GPUs (10K requests, 8K-2K workload). Each ratio unit is 16 GPUs. BatchGen requires no ratio tuning.

The performance gains from scaling stem from increased batch sizes: more GPUs provide additional memory capacity to accumulate larger batches before MoE execution, improving expert utilization. However, scaling exhibits sub-linear speedup due to communication overhead in MoE layers—the all-to-all collective for expert routing grows with GPU count. In our implementation, gains plateau beyond 64 GPUs; for the 128-GPU configuration, we deploy two 64-GPU instances and partition the input batch across them.

Scaling beyond single-instance limits. For a fixed model and parallelism strategy, there is a GPU count beyond which adding devices reduces per-GPU efficiency, as MoE all-to-all communication grows while computation per GPU stays constant. BatchGen treats this saturation point as the natural size of a single instance. Larger deployments are formed by replicating multiple independent instances, with an upper-level scheduler partitioning inputs and aggregating outputs. This hierarchical design preserves per-instance efficiency while scaling throughput linearly with instance count.

We compare against prefill-decode (PD) disaggregation [57] on SGLang at 128 GPUs. Each P or D unit consists of 16 GPUs, yielding seven P:D ratios. Table 6 shows that PD disaggregation performance varies by 3.6× across configurations (38.6 to 137.9 minutes), requiring exhaustive profiling to identify the optimal ratio. BatchGen outperforms even the best PD configuration (4:4) by 2.2× without manual tuning.

Production deployment. BatchGen is deployed as the batch-inference engine on an industry partner's production cluster. It runs as independent BatchGen instances launched and managed by an industry-customized Ray [30] orchestrator. Each instance exposes an OpenAI-compatible API, and the scheduler intentionally over-subscribes it, dispatching far more requests than its concurrent capacity. Over-subscription serves two purposes. First, it keeps a large pool of sequences resident on each instance, giving the BatchGen runtime freedom to form batches by `COMBINE`-ing sequences selected from the pool rather than in arrival order (§4.2), which maximizes expert-level batching. Second, it keeps the instance continuously saturated: as sequences complete, the runtime immediately backfills from the resident pool, so concurrency stays high and the GPUs never drain. Completed requests are streamed to an instance-local directory that the scheduler polls periodically to collect results and dispatch new work.

→Models	Mixtral-8×7B		Mixtral-8×22B		DeepSeek-R1-671B	
→Datasets	GSM8K	ChatBot	GSM8K	ChatBot	GSM8K	ChatBot
vLLM	20.4h	N/A	375.0h	N/A	N/A	N/A

BatchGen‡	**1.7h**	**10.0h**	**5.1h**	**30.8h**	**41.3h**	**328.5h**

Table 7: Time to complete GSM8K (8.5K samples) and ChatBotArena (36K samples) on a single A5000 GPU (24 GB). N/A indicates the system either runs out of memory or would take longer than 1000 hours to complete. Best results in **bold**, second best <u>underlined</u>.

6.5 Working with Limited Memory

We evaluate BatchGen's offloading capability on commodity hardware by running large-scale MoE inference on a single NVIDIA A5000 GPU (24 GB) with a 28-core AMD 7453 CPU and 1 TB of host memory. This setup highlights BatchGen's ability to execute models far beyond GPU capacity.

As shown in Table 7, we report end-to-end processing time on GSM8K (512→256) and ChatBotArena (256→512). FlexGen only supports dense models and MoE-Lightning is not open-sourced, so we reproduce their offloading strategies based on the original papers and integrate them into our runtime†. For the single-GPU case, BatchGen additionally offloads attention computation to the CPU to relieve GPU memory pressure; this optimization is disabled in multi-GPU settings where CPU bandwidth is insignificant relative to total GPU resources‡.

BatchGen achieves significantly higher efficiency under limited resources. Under constrained hardware settings where most baselines cannot complete the dataset within a reasonable time, BatchGen achieves up to a 9.6× speedup. As model size increases, baseline systems fail entirely, while BatchGen continues to finish the workload. FlexGen and MoE-Lightning suffer from extremely small per-expert batch sizes–40-1000× smaller than what is required to fully utilize the GPU–because they retain full MoE layers on device, capping the memory available for batching. In contrast, BatchGen accumulates large batches via coroutine *yields* and fully offloads experts, enabling per-expert batch sizes that reach the compute-bound regime. vLLM remains bottlenecked by on-demand parameter fetching, whereas BatchGen closes this gap by fully overlapping parameter transfers with computation in the coroutine runtime and its buffer.

7 Limitations and Future Work

Batch-size regime and best-effort operation. For a given model, its compute characteristics determine an optimal batch size at the `COMBINE` point that saturates the device. In practice, however, this saturation point cannot always be reached: even

when enough candidate requests are available to batch, the system's memory capacity may be insufficient to hold them, in which case BatchGen forms the largest batch memory permits and operates below saturation on a best-effort basis. Figure 2b illustrates this regime: saturating the compute of every expert requires 16384 tokens to reach the MoE gate. This target is comparatively easy to meet during prefill, where a single sequence of length 16384 suffices, but during decoding it corresponds to a global batch of 16384 concurrent requests—rarely attainable given the long-context requests typical of production. Decoding therefore runs in the best-effort regime. In our limited-memory evaluation (§6.5), a batch size of 6000 still yields gains, bounded by host memory.

Generalization and future work. The coroutine abstraction is general: it applies to any generation workload whose stages have distinct compute characteristics and memory requirements. Our current implementation targets transformer MoE models, a widely deployed architecture that benefits directly from intra-model yielding at attention–MoE boundaries. Extending BatchGen to other models and tasks is future work. Within a single model, vision-language models are a natural candidate: image encoding is substantially more compute-heavy than the language stages, so a yield point after the encoder could let the runtime rebatch the lighter stages. The abstraction also extends across models: where a generation pipeline connects multiple models with distinct computation characteristics—as in omni-modal systems that couple a language model with separate speech or vision models [48,49]—each model can be treated as a coroutine task, applying yield and `COMBINE` at model boundaries to batch each at its own optimal granularity.

8 Related Work

Throughput-optimized offloading systems. Current offloading systems have not targeted sparse modules and long-tailed decoding. FlexGen [41] is designed for dense modules, thus treating MoE layer as a single dense layer for offloading. DeepSpeed [12] and MoE-Lightning [7] are agnostic to expert batching, with a global batch size on the whole model decided. PowerInfer [42] and Fiddler [20] partition computation between the GPU and CPU, with light weighted attention and expert compute running on CPU, aiming for small batch size where compute is not intensive.

Continuous batching for high throughput. Continuous batching (used in vLLM [22], Orca [50], and Llama.cpp [33]) was introduced to address long-tail related TTFT concerns in interactive inference. These frameworks insert small prefill batches into the decoding phase. vLLM [22], Orca [50], and Llama.cpp [33] follow this strategy directly. NEO [19] interleaves prefill and decoding across GPU and CPU resources, while systems such as BlendServe [54] and other micro-batching approaches [27] share the GPU in the temporal domain. The effective average batch size over the entire execution becomes even smaller, limiting throughput.

Batching in training systems. Training fixes batch sizes to ensure gradient stability and convergence, while inference can vary batch sizes freely. In addition, the training systems are optimized for prefill and gradient updates [55], and decoding speed is not a factor. The MoE training line of work [23,25,52] is orthogonal to BatchGen, although BatchGen is compatible with the fixed batch size in RL post-training of LLMs [36].

9 Conclusion

This paper introduces the event-driven sequence coroutine architecture, a new computation model for large-scale batch inference. By enabling fine-grained yielding, combining, partitioning, and migration of sequence computation, BatchGen overcomes structural bottlenecks in sparse models and long-tail decoding, delivering substantial improvements in batch completion time across various applications. Beyond immediate throughput gains, our results suggest broader implications: extending coroutine abstractions to multimodal workflows, and co-designing the coroutine with the underlying high-performance GPU kernels. We believe this architecture opens a rich systems research agenda for the next generation of AI engine design.

Abstract

Fast-evolving machine learning (ML) workloads have increasing requirements for networking. However, host network transport on RDMA NICs is hard to evolve, causing problems for ML workloads. For example, single-path RDMA traffic is prone to flow collisions that severely degrade collective communication performance. We present UCCL-Tran, an extensible software transport layer to evolve GPU networking. UCCL-Tran decouples the data path and control path of existing RDMA NICs and efficiently runs the control-path transport on host CPUs. This software extensibility brings in transport innovations that cannot be achieved in hardware for ML workloads, e.g., a multipath transport to resolve flow collisions. ML collectives atop UCCL-Tran achieve up to 4.5× higher performance compared to existing RDMA NICs.

1 Introduction

Machine learning (ML) workloads and their requirements for networking are evolving rapidly. Less than ten years ago, deep neural networks only had millions of parameters, and were trained atop hundreds of CPUs/GPUs with parameter servers or allreduce collective communication [62]. After five years, large language models (LLMs) began to surge with billions of parameters, and were trained atop thousands of more powerful GPUs with multi-level parallelism and diverse collectives like allreduce, allgather, and reduce-scatter [13, 40]. In the recent two years, large-scale LLM serving has become the norm; prefill-decode disaggregation [109], as an efficient serving technique, requires fast peer-to-peer communication. This year, serving Mixture-of-Experts (MoE) models like DeepSeek-V3 [66] became very popular, featuring challenging all-to-all communication among hundreds of GPUs.

However, networking techniques especially the host network transport on RDMA NICs are hard to adapt and evolve to better suit the needs of ML workloads. Essentially, hardware changes are time-consuming and take much longer time than software changes. This can lead to a mismatch between the application needs and existing hardware optimizations, which often translates into poor performance. For example, Meta has reported that DCQCN [111]—a popular congestion control (CC) algorithm in datacenters supported by RDMA NICs—does not work well for LLM training workloads with low flow entropy and high traffic burstiness [34]. As a result, Meta decided to disable the CC support in NICs and instead implement traffic scheduling at the application layer. Similarly, DeepSeek disabled the CC when running large-scale all-to-all for serving MoE models [29]. However, running a large-scale RDMA network without CC is brittle, as it can lead to deadlocks, head-of-line blocking, and pervasive congestion [12, 35, 41, 45, 73, 111].

In another example, Alibaba has observed severe performance degradation for collective communication during LLM training. This was due to the high level of flow collisions, which in turn was caused by the RDMA NICs supporting only single-flow/path per connection [87]. To avoid this problem, Alibaba has redesigned the network topology for LLM training using a rail-optimized dual-plane architecture. However, such a redesign is costly to build and maintain. As we will show in §3.2, a software-only solution implementing multipath at the application level would have avoided such topology changes.

In §2.2, we discuss four more examples where ML workloads require adapting RDMA hardware support, including network incast in MoE serving, semi-reliable gradient transmission, efficient loss recovery, and avoiding vendor lock-in. Furthermore, the existing hardware-baked host network transport layer makes it difficult to productize new research proposals [16, 59, 85, 102] to improve the performance of ML workloads in real-world scenarios.

These examples point to *network extensibility* as one of the key challenges in datacenter networks. In this paper, we focus on addressing this challenge in the context of RDMA-enabled hosts, by proposing and implementing a software-only extensible transport layer called UCCL-Tran (abbreviated as uTran). This software-only approach makes it much easier to

[*]Equal contribution.
[‖]This work does not relate to the position at Amazon.

efficiently support new ML workloads, e.g., CC algorithms that can better support ML traffic than existing DCQCN, and multipathing to mitigate flow collisions. To implement this approach, we need to address two challenges: (1) How to decouple the data and control paths for existing RDMA NICs? The data path handles network data transfers for the GPU, while the control path manages transport control decisions like CC, packet reliability, and multipath load balancing (LB). Only if the control path is decoupled from the data path can we implement it on the CPU. (2) How can we achieve hardware-level performance with the control path running on the CPU? This is challenging given the high inter-server bandwidth, e.g., 3.2 Tbps [4, 71].

To address the first challenge, UCCL-Tran repurposes the features of existing RDMA NICs to achieve efficient data and control path separation. In particular, UCCL-Tran leverages RDMA Unreliable Connection (UC) to bypass hardware-baked CC and packet reliability logic, and uses RDMA immediate data to pass transport control states between sender and receiver CPUs. For some NICs that do not support UC, such as AWS EFA [92], UCCL-Tran leverages the scatter-gather feature over RDMA Unreliable Datagram (UD) to achieve separation.

To address the second challenge, UCCL-Tran leverages an array of techniques tailored to the unique characteristics of ML workloads. On the one hand, UCCL-Tran leverages GPUDirect [28] to alleviate CPU overhead. On the other hand, UCCL-Tran employs control coalescing to make transport control decisions for every 32KB data chunk rather than every packet; this works well as many transport decisions such as CC do not require per-packet reaction, but just per-RTT to avoid overreaction [39, 64]. As a result, UCCL-Tran can handle 400 Gbps unidirectional traffic with a single CPU core, and achieve the same message latency as hardware-based transport. UCCL-Tran leverages 256 RDMA QPs (Queue Pairs) per connection to perform multipathing, without worrying about the high QP context swapping overhead highlighted in previous work [104]; this is because ML workloads feature bulk data transfer with mostly MTU-sized large packets, which effectively amortizes the swapping overhead. UCCL-Tran's software transport is practical and economical in modern GPU servers, which usually have hundreds of powerful CPU cores; in fact, these CPU cores are often heavily underutilized. For example, several companies report cluster-wide CPU utilization of 20%-45% in their GPU clusters [44, 52]. From our private conversation with the model training team of a major GPU vendor, their CPU utilization is averagely 14.5% out of 128 cores, when using Megatron-LM [82] for model training.

UCCL-Tran provides an expressive yet easy-to-use interface. To demonstrate the versatility of this interface and the power of UCCL-Tran's extensibility, we use three case studies. First, we implement a multipath transport protocol that mitigates flow collisions by leveraging packet spraying, i.e., randomly sending packets from a single connection across different paths [31]. Compared to existing RDMA transport on hardware, ML collectives using our transport achieve up to 4.5× higher throughput on NVIDIA ConnectX-7 NICs, and up to 1.9× higher on Broadcom Thor-2 NICs with rail-optimized topology, which improves end-to-end LLM training throughput by 7.5%. Second, we implement a receiver-driven protocol EQDS [85] to handle network incast in MoE-like workloads, achieving 4.9× better message tail latency over InfiniBand built-in transport. Third, we implement selective retransmission [70] for efficient transport loss recovery, and show its superiority over RDMA hardware transport under packet loss. These case studies highlight that UCCL-Tran can effectively enable innovations in the transport protocols that are hard to implement in today's network stack without expensive and time-consuming changes. UCCL-Tran is open-sourced at https://github.com/uccl-project/uccl.

2 Background and Motivation

2.1 RDMA and Collectives

GPU networking is extremely heterogeneous. At the high level, GPU collective communication libraries like NVIDIA NCCL [83] and AMD RCCL [7] use RDMA and kernel TCP (non-RDMA) for inter-server networking, with RDMA preferred since it is faster and more efficient. RDMA provides various communication primitives called Queue Pairs (QPs) including Reliable Connection (RC), Unreliable Connection (UC), and Unreliable Datagram (UD):

- RC provides one-to-one message semantics (up to 1GB per operation), with NIC hardware handling packet reliability and CC. Some vendors like NVIDIA allow disabling CC.
- UC also provides one-to-one message semantics but without NIC hardware logic for packet reliability or CC.
- UD provides one-to-many datagram semantics, i.e., under one MTU per operation, without packet reliability or CC.

Intuitively, one can think of RDMA QPs as TCP/UDP sockets: RC is like a TCP socket that provides one-to-one message abstraction with reliability; UD is like a UDP socket that provides one-to-many datagram semantics without reliability; UC is one-to-one without reliability. Some cloud providers build their own RDMA NICs and QPs. For example, AWS EFA NICs replace RC with SRD (Scalable Reliable Datagram) [93] that implements datagram semantics, multipathing, packet reliability, and CC.

To use RDMA NICs, the CPU issues *verb* operations such as two-sided send/recv and one-sided read/write that transfer data over QPs. Internally, the verb builds a Work Queue Entry (WQE) and performs MMIO-write into the RDMA NIC registers. Upon completion, and depending on whether the verb is two-sided, the RDMA NIC generates a Completion Queue Entry (CQE) for the software to consume. Note that UD supports only two-sided verbs, UC supports all verbs except RDMA read, while RC supports all verbs. RDMA traf-

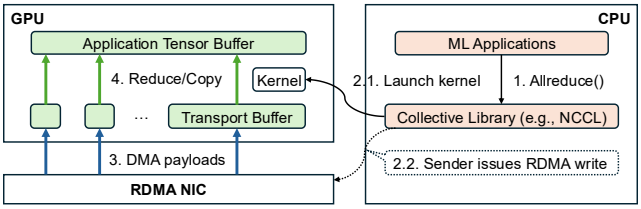

Figure 1: Collective communication over RDMA (receiver side). The receiver directly receives data into the GPU memory (e.g., GPUDirect [28]); the sender side works similarly except that it will additionally issue an RDMA write in step 2.

fic could go through different network fabrics such as RoCE (RDMA over Converged Ethernet) and InfiniBand.

Figure 1 shows an overview of how collective communication uses RDMA. Once the ML application calls a collective like allreduce, the collective library launches a *reduction kernel* on each participant GPU to handle data reduction/copy. Next, the sender CPU issues multiple RDMA writes over RC QPs to transfer data chunk by chunk. The receiver CPU polls completion flags in its memory, which the sender sets upon write completions. The library manages a set of *transport buffers* on the GPU memory to buffer the RDMA data, and relies on the GPU kernel to copy data between the transport buffers and application tensor buffers. The GPU kernel also performs reductions (e.g., sum, max) on the transport buffers (from multiple sender GPUs) into the tensor buffers.

2.2 Motivation on Extensibility

Host network transport on RDMA NICs is hard to evolve compared to software applications. This creates problems for fast-evolving ML workloads. We have shown two such examples in §1; below, we give four additional examples to motivate the need for transport layer extensibility.

Receiver-driven CC for incast. Recent MoE serving workloads are prone to network incast problems. In DeepSeek's online deployment of their 671B V3 model [66], each of the 320 GPUs holds a single expert module, where hidden states are exchanged between expert modules across GPUs, i.e., Expert Parallelism (EP). As the request pattern and load change over time, some experts become much hotter than others, receiving more network traffic from other experts leading to network incast issues. DeepSeek reports the hottest expert could receive 10× more load than the average one. Expert load balancing algorithms such as EPLB [30] try to balance the load by dynamically replicating experts. However, this happens at a much slower pace (e.g., 10 minutes [29]) to avoid the high cost of moving experts, thus unable to handle transient incast. Such transient network incast can be better handled by receiver-driven CC [43, 85], which controls last-hop congestion—unfortunately, there is no receiver-driven CC on commercial RDMA NICs.

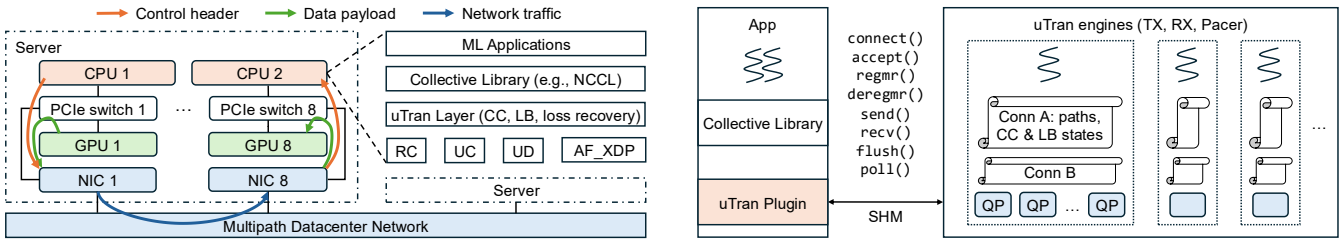
Application-transport codesigns. Codesigning applications and transport behaviors could bring huge performance benefits. For example, recent work MLT [102] customizes loss recovery behaviors for ML training to allow semi-reliable transmission based on the gradient importance from applications. Despite achieving great performance improvement, it is not feasible to integrate MLT into existing RDMA NICs even for the latest NVIDIA ConnectX-7 [79], due to a lack of enough programmability.

Inefficient loss recovery. RDMA NICs are known to perform poorly under packet loss, especially for old-generation NICs [63, 73, 97, 104]. This is caused by the inefficient go-back-N retransmission logic hardcoded on these NICs due to limited on-chip SRAM constraints. As a result, RDMA deployment normally requires Priority Flow Control (PFC) to achieve a lossless network fabric. However, PFC may lead to deadlocks, head-of-line blocking, and victim flows [45, 73], and its likelihood is higher as the GPU networking bandwidth keeps increasing (for the reason, we kindly refer to page 4 in [45]). If we could extend the transport layer of GPU networking with more efficient selective retransmission, we could better handle packet loss and rely less on PFC [73].

Heterogeneous NICs. Datacenters usually consist of multiple generations and vendors of RDMA NICs due to continuous expansion, cost optimization, and to avoid vendor lock-in. While NVIDIA, Broadcom, AMD, and more vendors all have 400 Gbps RDMA NICs for ML [9, 18, 79], they come with subtly different control path logic such as packet reliability and CC. In practice, this heterogeneity reduces achievable bandwidth by 2-33× when communicating between NICs from different generations/vendors, as reported by Alibaba [63]. Prior work Flor [63] has shown that extensibly aligning these NICs' control path logic in software could avoid such issues.

2.3 Prior Work on Extensibility

Leveraging SmartNICs. Several recent efforts aim to make RDMA transport programmable by offloading it to the SmartNIC RISC cores, but they have constraints in extensibility and performance. Google Falcon SmartNICs [38, 39] only support programming rate update actions for latency-based Swift CC [58] and path selection decisions with limited paths [88]; similar constraints also apply to firmware updates on hardware RDMA NICs. AMD Pensando SmartNICs [9] support using P4 language [17] to program their transport layer, but P4 has limited programmability, e.g., hard to implement efficient loss recovery; it is also unclear if they could support receiver-driven CC. FPGA-based SmartNICs provide higher performance but have limited extensibility due to hardware resource constraints [104]. AWS EFA SmartNICs [92] implement a proprietary multipath reliable transport SRD [93] with out-of-order packet delivery using NIC ARM cores, to address network congestion in HPC and ML workloads. The SRD protocol is implemented using EFA-specific firmware and supports live upgrade with good extensibility. However, we empirically find that the EFA SmartNICs on AWS `p4d.24xlarge` GPU VMs perform poorly for connection-intensive all-to-all



(a) UCCL-Tran architecture.

(b) UCCL-Tran threading model.

Figure 2: Overview of UCCL-Tran extensible transport for GPU networking. We assume a common intra-server topology for GPU servers [23] where individual PCIe switches directly connect a few GPUs, NICs, and CPU, providing high-bandwidth data transfer among them.

collectives (see §6.1). We attribute this to the limited processing power and cache capacity of SmartNIC ARM cores due to power constraints, as also demonstrated by prior research on publicly available SmartNICs [67, 86, 90].

Note that the above all-to-all measurement uses the AWS EFA NICs on the `p4d.24xlarge` instances, and thus it may not apply to their new-generation EFA NICs on `p5/p5en/p6` instances. Specifically, the ever-changing EFA firmware and upgraded EFA hardware may lead to different performance results for connection-intensive all-to-all collectives. In general, if these SmartNICs get upgraded with higher processing power and cache capacity to better handle all-to-all, we view it as an echo to UCCL-Tran's high-level methodology of software extensibility for GPU networking.

Leveraging CPUs. A line of work has leveraged host CPUs to make better control decisions in GPU networking. ZeroNIC [97] modifies the NIC hardware to run the control path of RDMA transport on CPUs, while leaving the data path on the NIC following GPUDirect. In contrast, UCCL-Tran aims to be more practical without modifying existing hardware; UCCL-Tran by design supports efficient multipathing, compared to ZeroNIC's single path transport. Flor [63] leverages RDMA UC to bypass the control path of the RDMA hardware and implements flexible software control on CPUs. Flor targets CPU-based storage applications with 100 Gbps traffic per server, while UCCL-Tran targets more network-intensive ML applications that have 3.2+ Tbps traffic per server [4, 71] and develops multipathing to avoid flow collisions. To this end, UCCL-Tran adopts several different designs such as multi-QP and connection splitting (see §3.2 and §3.3).

Other efforts design transport protocols to address specific network challenges. Ultra Ethernet Consortium (UEC) [22] standardizes several multipath transport protocols with packet spraying to address flow collisions for ML workloads: a sender-driven one based on STrack [59] and SMaRTT-REPS [16], and a receiver-driven one based on EQDS [85]. Prior to UEC, MP-RDMA [68] and MPTCP [77] designed multipath protocols for CPU workloads to improve robustness under network failures. Overall, these protocols leverage various congestion signals such as Explicit Congestion Notification (ECN) [1], RTT [72], and packet trimming status [21, 43, 85] to make multipath CC and LB decisions.

3 UCCL-Tran Design

Figure 2a shows the high-level architecture of UCCL-Tran. UCCL-Tran layer sits between the collective library such as NCCL and the low-level communication primitives exposed by NIC hardware, e.g., RC, UC, and UD for RDMA NICs and AF_XDP [98] (a user-space fast packet IO) for non-RDMA NICs. ML applications use collective APIs such as `allreduce` and point-to-point APIs such as `SendRecv` exposed by the collective library without directly interacting with the UCCL-Tran layer. Both the collective library and the UCCL-Tran layer are compiled into individual shared libraries, i.e., `libnccl.so` and `libnccl-net.so` for NCCL, providing a drop-in replacement for ML applications without code modification or recompilation. UCCL-Tran leverages the network plugin system of existing collective libraries [6, 24] to avoid changing the library code in most cases, with exceptions for UCCL-Tran over UD that requires a slight code modification (detailed in §3.1). For brevity, the remaining paper targets RDMA NICs such as NVIDIA ConnectX NICs and AWS EFA NICs [92]; we will explicitly mention when targeting non-RDMA NICs.

Figure 2b shows the threading model of the UCCL-Tran layer. The UCCL-Tran plugin interacts with a group of UCCL-Tran engine threads via shared memory to create connections, register/deregister GPU memory regions with the RDMA NICs, and send/recv/flush/poll network messages. Each engine thread runs TX, RX, and pacing functionalities of UCCL-Tran multipath reliable transport for multiple UCCL-Tran connections. As described in §3.1, UCCL-Tran engines instruct the RDMA NIC to receive network data, split control headers and application data payloads, and directly DMA them into the CPU and GPU memory separately. The whole process bypasses the packet reliability and CC logic on RDMA NIC hardware as much as possible by using proper RDMA primitives. After getting control headers in CPU, UCCL-Tran engines make transport decisions such as CC, LB, and handling packet loss and reordering. Since these decisions are executed by a normal user-space process on the CPU, instead of on RDMA NIC hardware, they can be easily extended by

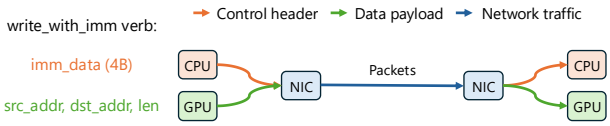


Figure 3: Leveraging RDMA `write_with_imm` to separate control header and data payload for UC/RC.

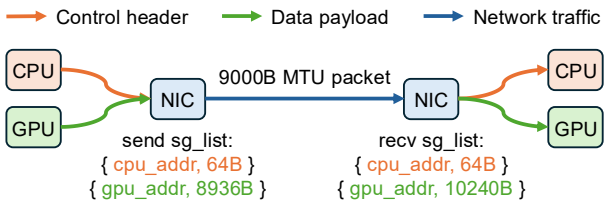

Figure 4: Leveraging RDMA send/recv scatter-gather to separate control header and data payload for UD.

collective library or ML application developers.

In UCCL-Tran, all connections between a specific pair of NICs share the same set of QPs (e.g., 256), including the case of multiple GPUs sharing one NIC. This design fully harnesses the underlying multipath datacenter network while not burning too many QPs (§3.2). UCCL-Tran further integrates a bag of techniques to run software transport as efficiently as possible, e.g., control coalescing, connection splitting, chained posting, and more (§3.3). UCCL-Tran also supports extending transport for non-RDMA NICs through the AF_XDP user-space packet IO, bypassing conventional kernel TCP stacks. We now describe them in the rest of this section.

3.1 Separating Control Path and Data Path

The overall goal of separating the control path and the data path is to enable running extensible transport on the CPU, while efficiently transferring data to/from GPUs in a GPUDirect manner. This goal has three specific aspects: (1) We should involve as little control logic as possible in the data path to let the CPU make more transport decisions, like CC and packet reliability. (2) We must achieve GPUDirect for the data path efficiency [36, 97]. (3) We should support heterogeneous RDMA NICs. For example, NVIDIA NICs support UC, while Broadcom and AWS EFA do not.

UC as the preferred QP. UCCL-Tran chooses UC as the preferred QP whenever available on the RDMA NIC, similar to Flor [63], because it supports efficient segmentation and reassembly offloading to the NIC (in contrast to UD), while bypassing hardware-baked CC, loss recovery, and out-of-order packet handling (in contrast to RC). As shown in Figure 3, UCCL-Tran uses the efficient RDMA verb of write with immediate to transfer data chunks over UC; this verb operates in a two-sided mode, so that both sender and receiver CPUs can react to the data transfers. For the data path, the sender CPU specifies the addresses of source and destination data chunks when issuing the verb, and then the sender NIC will automatically segment the source data chunk into MTU-sized packets with packet headers prepended and send them out. When receiving these packets, the receiver NIC will remove the packet headers and reassemble payloads into the *contiguous* memory region specified by the sender CPU.

For the control path, write with immediate allows carrying a 32-bit `imm_data` from the sender CPU to the receiver CPU, serving as the control header for UCCL-Tran transport. Figure 3 shows an example. UC guarantees that any successfully arrived chunk will generate a CQE with the `imm_data` embedded, which is then consumed by the receiver CPU. Within the 32-bit budget, UCCL-Tran allocates 8 bits for connection ID and 7 bits for message ID, supporting 256 connections for each pair of NICs on a UCCL-Tran engine and 128 in-flight messages for each connection, which is sufficient for collective communication. UCCL-Tran then allocates 8 bits to the chunk sequence number (CSN) to identify the position of a chunk in the message being transferred. Another 1 bit is allocated for marking the last chunk of a message. The remaining 8 bits are reserved for more advanced CC such as receiver-driven ones (see §4.2).

RC with CC disabled. In practice, UC is not always supported across different RDMA NIC vendors [63], e.g., Broadcom [18]. In these cases, UCCL-Tran will opt to RC with CC configured to be disabled, and then leverage RDMA write with immediate in a similar way as UC. On the one hand, RC prevents UCCL-Tran from customizing the packet reliability mechanism baked in NIC hardware; on the other hand, it allows faster ACKs and more precise RTT estimation in hardware.

UD as the last resort. Some RDMA NICs do not allow disabling CC for their RC QPs, e.g., AWS EFA NICs (to be precise, EFA NICs do not have RC but only SRD). To support them, UCCL-Tran leverages UD at the cost of higher CPU usage compared to UC and RC. On the one hand, UD totally bypasses any hardware control logic on RDMA NICs, well-aligned with our goal. On the other hand, UD only supports sending/receiving MTU-sized data (i.e., no segmentation or reassembly offloading); so UCCL-Tran needs to consume more CPU cycles to do segmentation and reassembly.

Challenge of separation. One key challenge for UCCL-Tran over UD is that UD does not support RDMA write with immediate (but only the `send/recv` verbs), so that UCCL-Tran over UD cannot designate the immediate data as the transport control header. Then *how can UCCL-Tran separate control header and data payload using UD (i.e., placing them to CPU and GPU separately)*? UCCL-Tran must guarantee that the control header and data payload are *fate-sharing* in terms of loss status and arrival order, so that UCCL-Tran can make valid transport decisions based on the control header. One strawman solution would be transferring the control header and data payload together as a single packet into the destination GPU memory, and then the CPU reading the control header from the GPU memory. But this incurs additional

performance overhead.

UCCL-Tran's approach is to leverage the scatter-gather feature to let the NIC hardware automatically merge the control header and data payload during RDMA send, and split these two during RDMA recv; Figure 4 shows an example. On the sender side, the CPU issues an RDMA send verb with a two-entry `sg_list` that specifies the control header address+length on the CPU, and the data payload address+length on the GPU. The RDMA NIC will then read the header and payload from the CPU and GPU respectively, and merge them into a single network packet to send out, as long as the total length does not exceed the MTU size. On the receiver side, the CPU pre-posts a recv verb with a two-entry `sg_list` that specifies the receiving address+length for the header and payload, respectively. Note that the header length must be a fixed value that the sender and receiver agree on, e.g., 64B in this example; the payload length specified in the recv verb need not exactly match the send verb, but should be no smaller. Later, when the packet arrives at the receiver NIC, the NIC will automatically split the header and payload across CPU and GPU, following the boundary of the fixed header length. UCCL-Tran's approach always keeps the control header fate-sharing with the data payload, and avoids the CPU reading any extra header from the GPU.

Challenge of reassembly. UCCL-Tran over UD still faces another challenge of *how to correctly and efficiently reassemble packets on the receiver GPU*. Recall that UD does not support reassembly offloading to the NIC, and only allows sending/receiving a single packet in one verb (§2.1). We note that sender-side segmentation is relatively easy, as the CPU could partition the transport sending buffer into individual data payloads (based on MTU size), and specify their addresses in send verbs. However, for the receiver-side reassembly, even if the CPU pre-posts recv verbs that specify in-order individual data payload addresses drawn from the transport receiving buffer, the packets will land into the buffer in an out-of-order manner due to packet loss or reordering over the multipath network. This reassembly challenge is unique to UD, as UC/RC allows the sender to directly specify the receiver-side GPU buffer addresses in the write with immediate verb.

Addressing this challenge requires some form of *scattered memcpy* GPU kernel that copies out-of-order data payloads to the transport receiving buffer (following the right order given by the receiver CPU). But the question is where to launch and run such a kernel. To avoid extra kernel launching overhead, UCCL-Tran chooses to fuse such scattered memcpy operations into the existing reduction kernel in collective libraries (§2.1). Our fused kernel will first do scattered memcpy to copy out-of-order data payloads into the transport buffers, then do the original reduction work from the transport buffers to the application tensor buffers. The only overhead of this approach is the extra GPU memory bandwidth consumption, but this is bounded by the network bandwidth. Given the high GPU memory bandwidth (e.g., 1.6-2.0 TB/s in A100), such extra bandwidth consumption is negligible.

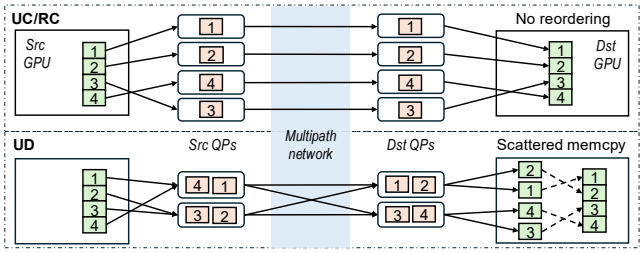

Figure 5: Multipathing and handling packet reordering in UCCL-Tran.

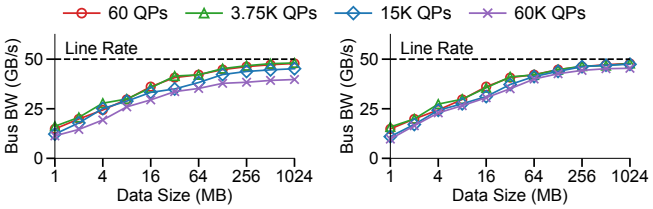
For non-RDMA NICs, UCCL-Tran builds a reliable transport atop UDP with the AF_XDP technique, an efficient kernel socket that lets the NIC directly DMA network packets to user-space memory regions. We choose AF_XDP as it achieves similar high performance as DPDK [110], but is kernel-native and does not require special NIC drivers, thus easy to deploy [100]. Similar to how collective libraries such as NCCL use kernel TCP for non-RDMA NICs, UCCL-Tran over AF_XDP does packet reassembly on the CPU, followed by a `cudaMemcpy()` to transfer the received message to the GPU.

3.2 Harnessing Multipath

One of the key motivations for GPU network extensibility is to harness the multipath capacity of modern datacenter networks (§2.2). UCCL-Tran achieves this by using multiple UC, RC, or UD QPs, as shown in Figure 5. Basically, network traffic from different QPs will likely go through different network paths, as both RoCE and Infiniband usually use ECMP (Equal-Cost Multi-Path) for multipath routing with source and destination QP numbers as the hash inputs [34, 81]. For UC and RC, UCCL-Tran by default uses 256 QPs, which provides maximum 256 different network paths as used by recent transport research [16, 59]. For UD, UCCL-Tran uses a much smaller number of QPs by combining different source and destination QPs. For example, 16 source UD QPs and 16 destination UD QPs will provide maximum 16×16=256 different network paths, because for connection-less UD, each source QP can send packets to any destination QP. UCCL-Tran also supports a configurable number of QPs for different collectives, e.g., a smaller number might work well for all-to-all with relatively high entropy [34]. To avoid burning too many QPs, especially when the collective library creates multiple connections between the same pair of NICs (e.g., because of multiple GPUs sharing one NIC), UCCL-Tran lets all these connections *share the same set of QPs*.

We note that making this multi-QP design choice is not trivial, especially as a line of prior work has highlighted the severe QP scalability issues on RDMA NICs [20, 53, 54, 57, 61, 75, 104]. For example, SRNIC [104] reports ∼23% bandwidth drop when scaling RC QPs from 256 to 512, and 46% drop



(a) For RC QPs. **(b)** For UC QPs.

Figure 6: UCCL-Tran all-to-all network bandwidth on CX_IB testbed (16 400G NICs, see §6 for details) with different numbers of QPs per NIC. 60 QPs per NIC correspond to the typical NCCL QP scaling factor of 4 (i.e., 4 QPs per connection) in production [34, 59]. 60K QPs per NIC essentially model the QP swapping overhead for UCCL-Tran all-to-all across 241 GPUs using 256 paths per connection (i.e., 61440/256=240, plus 1 to include itself) or 961 GPUs using 64 paths. This has covered the largest-scale collective as far as we know, i.e., 256 GPUs by Meta [34] and 320 GPUs by DeepSeek-V3 [66].

when scaling to 16k. This bandwidth drop is caused by the *QP swapping overhead*: the NIC can only hold/cache limited QP contexts on its SRAM, and must spill/swap the excessive rest to the host DRAM over PCIe, incurring frequent QP swapping. Surprisingly, we do not observe such a severe performance drop for collective communication—Figure 6 shows only ∼17% drop when scaling RC QPs from 60 to 60k, and a negligible drop for UC (that has a smaller QP context size than RC).

There are two reasons behind this counter-intuitive phenomenon. First, ML workloads feature large messages, and thus collectives mostly transfer MTU-sized packets; such large transfers effectively amortize the QP swapping overhead. Second, with GPUDirect, GPU data transfers only go through the PCIe switch, but not the PCIe root complex that is connected to the CPU [56]; therefore, there is no PCIe contention between GPU-NIC traffic and CPU-NIC traffic (that is incurred when NIC swaps QP contexts and CPU posts verbs). In contrast, prior work focuses on *small-message CPU workloads* such as in-memory Key-Value stores that only transfer dozens of bytes at once for each QP, thus bottlenecked by the QP swapping overhead and PCIe traffic contention. Later in §3.3, we show that UCCL-Tran optimizes transport efficiency by transferring data in a larger chunk granularity (e.g., 32KB), further reducing the QP swapping overhead.

For non-RDMA NIC multipathing, UCCL-Tran specifies different UDP ports in packets before sending them out in AF_XDP. This adds no overhead compared to single-path transport.

Handling out-of-order packets. Many factors could cause out-of-order packet delivery, including multipathing, packet loss, and the unpredictable multi-QP scheduler in RDMA hardware [104]. Existing RDMA NICs perform poorly when handling out-of-order packets, as they cannot maintain large reordering buffers and states due to limited on-chip SRAM constraints [73, 104]. In contrast, UCCL-Tran is able to handle out-of-order packets efficiently thanks to its software flexibility and separation of data and control paths. Basically, UCCL-Tran follows typical TCP designs with `seq` and `ack` numbers to guide packet reordering, fast retransmission (upon duplicate ACKs), and timeout retransmission. UCCL-Tran sets a larger duplicate ACK threshold for fast retransmission, instead of the default three in TCP, to accommodate more frequent packet reordering caused by multipathing. Different from TCP, UCCL-Tran maintains its packet reordering buffers in the GPU memory and lets the NIC directly DMA network data there. Figure 5 depicts this process with examples. For UC/RC, the reordering buffers are individual data chunks, and the sender CPU specifies in-order chunk addresses when posting verbs. For UD, the reordering buffers are individual packet payloads, and the GPU reduction kernel reorders packets when copying them into the transport buffers (§3.1).

3.3 Towards Efficient Software Transport

So far, we have discussed how UCCL-Tran decouples the control path and data path to make flexible transport decisions on the CPU, and how UCCL-Tran achieves multipathing. The next question is *how to efficiently implement a software multipath transport to support the high bandwidth in GPU networking*. This is challenging as a single GPU server could have 8×400 Gbps RDMA NICs, totaling 3.2 Tbps bandwidth bidirectionally [46]; the next generation RDMA NIC will achieve 800 Gbps [27], rendering 6.4 Tbps bandwidth. As a reference, Google's software transport Snap [69] can handle 80 Gbps traffic on a CPU core (though they do not use RDMA NICs). Our goal is to use 1 CPU core to handle 400G *unidirectional* traffic (i.e., 2 cores for 400G bidirectional traffic; excluding possible pacer cores for receiver-driven CC). To this end, we leverage the following techniques:

Run-to-completion execution. Each UCCL-Tran engine thread runs RX, TX, pacing, timeout detection, and retransmission functionalities for a set of connections in an efficient run-to-completion manner [14, 51]. UCCL-Tran employs Deficit Round Robin (DRR) [94] scheduling to fairly multiplex one engine thread among multiple functionalities and connections.

Connection splitting. To handle 400+ Gbps traffic per NIC more efficiently, UCCL-Tran pivots away from the Flor [63] design of a single CPU core for one connection, but leverages multiple cores for one connection with connection splitting. Basically, UCCL-Tran equally partitions the 256 QPs among all engine threads responsible for a specific NIC; each engine thread gets its own connection states for CC and LB, forming a sub-connection. Within each sub-connection, UCCL-Tran uses RDMA SRQ and SCQ (Shared Recv/Completion Queues) to reduce the overhead when polling multiple recv and completion queues. The application threads atop the UCCL-Tran plugin are responsible for choosing the least-loaded engine (e.g., the engine with the least unconsumed messages) when dispatching messages via SHM. In this way,

UCCL-Tran could scale transport processing of a single connection to multiple cores, and handle transient load imbalance among CPUs at runtime. It also reduces TX packet bursts by avoiding sending all messages at once from a single core.

Control coalescing. There is an inherent tradeoff between the control decision granularity and software transport efficiency. One could run CC, LB, and reliability logic for each packet to achieve precise control of the transport behaviors, at the cost of consuming more CPU cores. Alternatively, one could relax the control granularity by coalescing several same-path packets and making control decisions together, thus with lower CPU consumption. For UC/RC, this also means an RDMA write could directly transmit several packets as a single data chunk, leveraging NIC-offloaded segmentation and reassembly. UCCL-Tran employs this control coalescing design with 32KB chunk size as default, striking a balanced tradeoff. Under this chunk size, UCCL-Tran can saturate 400 Gbps unidirectional bandwidth with 1 CPU core (§6.4.3), while not severely disrupting transport behaviors/performance (see our packet-level simulation in §C.5.1). Nevertheless, UCCL-Tran could also adaptively adjust chunk size based on the congestion level, e.g., switching to a small chunk size to make more precise control when congestion window (`cwnd`) drops below a threshold or severe packet loss happens.

Chained posting. UD does not support NIC offloading for segmentation and reassembly, thus it incurs more MMIO writes than UC/RC when issuing send/recv verbs (e.g., for individual packets). To reduce such overhead, UCCL-Tran leverages the chained posting feature of RDMA NICs to issue one MMIO write for posting up to 32 send/recv verbs. Concretely, the WQEs of these 32 verbs are chained together through the `next` pointer in previous WQEs, and get posted to the RDMA NIC in one MMIO write.

3.4 Congestion Signals

Relatively restricted congestion signal is a common limitation for software-based reliable transport atop RDMA NICs, including UCCL-Tran and Flor [63]. This is because existing RDMA NICs consume packet headers that contain congestion signals like ECN marks [1] and packet trimming status [21, 43, 85], and deliver only the packet payload to the software. Fortunately, the software can still use the RTT congestion signal by leveraging hardware TX/RX timestamping supported by many RDMA NICs, and rely on packet loss as the last-resort congestion signal. Therefore, our current UCCL-Tran implementation uses per-path RTT and packet loss to detect congestion and choose paths. In fact, latency-based CC and LB are being widely used in Google's datacenters [58, 88].

Signal fidelity. Running CC and LB in software using RTT also raises signal fidelity concerns. Overall, there are three factors affecting the fidelity: ① accurate RTT estimation at the sender, ② CC decision delay at either the sender or receiver, i.e., the software delay from receiving the congestion signal (e.g., ACK-derived timestamps) to updating the congestion window/rate, and ③ ACK turnaround delay at the receiver, i.e., delay between receiving data chunks and sending back ACK. For ①, UCCL-Tran leverages the NIC hardware timestamps and excludes ACK turnaround delay from the RTT (similar to Swift [58]). For ② and ③, theoretically, these delays impact how fast the sender can react to network condition changes, thus impacting the decision precision; however, in practice, even hardware-based transport handles CC events in a per-RTT granularity (e.g., tens of microseconds) rather than per-ACK to avoid overreaction [64]. For example, Google Falcon hardware transport runs CC to update rate once per RTT [39]. Thus, the few microseconds of decision delay introduced by the software is negligible. Nevertheless, UCCL-Tran still employs several techniques to reduce the two delays: similar to Flor [63], UCCL-Tran uses a dedicated high-priority QP for ACK (using in-network priority such as DSCP) and always first polls its completion queue; UCCL-Tran further allocates the ACK polling a higher processing budget during DRR scheduling. We quantify these delays in §6.5.3.

3.5 NIC Capabilities

UCCL-Tran supports a wide range of RDMA NICs and non-RDMA NICs. For RDMA NICs, UCCL-Tran relies on their segmentation and reassembly offloading capabilities to achieve high CPU efficiency. This capability is widely supported through the RC and UC QPs in commodity NICs. For non-RDMA NICs, UCCL-Tran relies on fast user-space packet IO to efficiently drive the underlying NICs through UDP. This capability is also usually enabled in commodity NICs via DPDK or AF_XDP. For both NICs, UCCL-Tran further relies on the ECMP feature of the underlying network switches to achieve multi-pathing: for RDMA, UCCL-Tran uses different RC/UC QPs; for non-RDMA, UCCL-Tran chooses different UDP ports.

UCCL-Tran leverages timestamping to derive the RTT congestion signal used for congestion control and multi-path load balancing. The signal fidelity can be further strengthened with hardware timestamping that is supported by NVIDIA RDMA NICs. UCCL-Tran can also benefit from NIC vendors exposing more congestion signals, such as ECN and packet trimming status.

4 Extensibility Case Studies

UCCL-Tran provides expressive interfaces to implement and extend multipath transport. Due to space limitations, we elaborate on them in Appendix A. Collective library and application developers could also directly extend UCCL-Tran transport code, e.g., with the new loss recovery scheme in MLT [102], and deploy it quickly in a normal user-space process. We now demonstrate how UCCL-Tran extensibility enables new transport designs that work best for different ML workloads.

4.1 Multipath Transport with Packet Spraying

Recent transport research [16, 59] and UEC advocate packet spraying with hundreds of paths as an effective way to address flow collisions in ML workloads. It is naturally challenging for hardware NICs to implement packet spraying because of excessive per-path states, such as path RTTs. Instead, UCCL-Tran can easily support packet spraying by maintaining per-path RTT in software. UCCL-Tran's software transport uses Power-of-Two sampling [74] to select a path with the lowest RTT, then runs CC to decide how many packets and what rate to transmit. UCCL-Tran implements two CC algorithms: one is CUBIC [42] used in Linux kernel TCP as the default CC, and another is Swift [58], an RTT-based CC used by Google. UCCL-Tran supports both per-path CC states (e.g., per-path `cwnd`) and global CC states controlling all paths; both achieve similar collective performance in our testbeds. UCCL-Tran by default uses global CC during evaluation.

4.2 Receiver-Driven CC

Receiver-driven transports, such as EQDS [85], NDP [43], and Homa [76], proactively control packet sending rate at the receiver by allocating credits to senders. These transports have proven to resolve the last-hop congestion for network incast effectively, which could happen in MoE serving (§2.2). However, to the best of our knowledge, there are no off-the-shelf NICs that support receiver-driven transports. One reason is that they are vastly different from popular sender-driven ones, and implementing them would require NIC hardware modification. Instead, UCCL-Tran's extensibility enables developers to quickly implement and tune receiver-driven transports in software. We choose to implement EQDS [85] in UCCL-Tran as an example, the state-of-the-art receiver-driven transport adopted by UEC [22]. Our EQDS implementation closely follows the EQDS paper [85] with a dedicated pacer thread per NIC on the receiver to issue credit packets for senders. For more details, we refer to Appendix B.

4.3 Efficient Loss Recovery

UCCL-Tran allows customizing the transport loss recovery logic to support more advanced mechanisms other than the go-back-N retransmission baked into many RDMA NICs. Go-back-N directly drops out-of-order packets to avoid buffering them on expensive on-chip SRAM, but this gives poor performance when packet loss happens [53, 104, 111]. Instead, we implement a more efficient selective retransmission [70] in UCCL-Tran, by maintaining reordering buffers in the GPU memory (§3.2). Our implementation follows the standard selective retransmission mechanism in TCP, and uses a `std::map` to track an arbitrary number of out-of-order packets. With more efficient loss recovery in UCCL-Tran, ML workloads could possibly run in lossy datacenter networks without PFC (§2.2).

We note that the latest generation of NVIDIA RDMA NICs [79] has implemented a limited form of selective retransmission based on NACK with a small fixed tracking window (to keep low SRAM usage). UCCL-Tran's selective retransmission based on SACK+bitmap is better than these NACK-based one, which has been proven to lead to slow, imprecise recovery and high tail latency [96].

5 Implementation

We implement UCCL-Tran in 28.4K lines of C++ as a network plugin to NCCL/RCCL, the standard collective library for NVIDIA/AMD GPUs. Our current implementation supports NVIDIA RDMA NICs via RC and UC, Broadcom RDMA NICs via RC, AWS EFA NICs via UD/SRD, and AWS ENA non-RDMA NICs via AF_XDP. UCCL-Tran leverages the standard `libibverbs` for RDMA NICs and kernel built-in AF_XDP for non-RDMA NICs; therefore, it should naturally support other vendors' NICs. To enable scattered memcpy when using UD for AWS EFA NICs, we add or modify ∼170 LoC to the NCCL codebase, including a scattered memcpy GPU kernel and C++ code that passes packet pointers to the kernel via CPU-GPU shared memory (created by `cudaHostAlloc()`). We added two new interfaces to the NCCL network plugin system: `irecv_scattered` that receives data in a list of scattered packets, and `irecv_free_ptrs` that frees the scattered packet buffers after scattered memcpy. UCCL-Tran also supports running NCCL with multiple processes.

There are some implementation details worthy of note. For NVIDIA NICs, to calculate network RTT based on NIC hardware TX/RX timestamps and CPU ACK timestamps, we implement a NIC-CPU clock synchronization scheme following Swift [58]. We use a synchronization time interval of 100μs. For AWS EFA NICs that do not support hardware timestamps yet, we calculate RTT based on software timestamps minus estimated packet queueing delay at the host. We estimate the queueing delay by dividing the size of queued packets by the NIC bandwidth. For AWS EFA NICs, we find that allocating UD QPs with consecutive QP numbers for a connection yields much better performance than not. We suspect this is because the EFA NICs do round-robin assignments when mapping a QP (and its associated packets) to a ARM core; consecutive allocations help map the QPs of a connection to different ARM cores, avoiding load imbalance.

6 Evaluation

In this section, we aim to answer the following questions:

- What is the collective performance of UCCL-Tran software multipath transport compared to hardware-based ones (§6.1)?
- Can UCCL-Tran improve ML application performance (§6.2)?
- Can UCCL-Tran extensibility benefit certain workloads (§6.3)?
- What is the scalability of UCCL-Tran (§6.4)?

Name	# of Servers	Network	Topology	MTU	NIC	GPU	CPU
CX_ETH	6	Ethernet	Cross racks, fat-tree	4KB	NVIDIA ConnectX-7 400G ×8	NVIDIA H100-80G ×8	160 cores
AMD	4	Ethernet	Cross racks, rail-optimized	4KB	Broadcom Thor-2 400G ×8	AMD MI300X-192G ×8	128 cores
EFA	4	Ethernet	Cross racks, fat-tree	9KB	AWS EFA 100G ×4	NVIDIA A100-40G ×8	96 cores
CX_IB	2	InfiniBand	Same rack	4KB	NVIDIA ConnectX-7 400G ×8	NVIDIA H100-80G ×8	128 cores

Table 1: Evaluation testbeds. CX_ETH, AMD, and EFA are rented from TensorWave, IBM Cloud, and AWS (`p4d.24xlarge`), respectively.

• How do different designs impact UCCL-Tran (§6.5)?

Testbed. Table 1 describes our evaluation testbeds. The first three testbeds across racks evaluate how UCCL-Tran handles network congestion and flow collisions. They also demonstrate the genericity of UCCL-Tran, i.e., applying to AMD GPUs and Broadcom/EFA NICs. The CX_IB testbed under the same rack stress-tests the UCCL-Tran software implementation, as it has no network congestion or flow collisions. For some tests, we try to simulate a larger testbed by disabling NCCL NVLink and SHM communication. This forces GPUs within a server to communicate through the network, and each GPU essentially behaves like a virtual server, e.g., CX_IB becomes 16 virtual GPU servers each with 400G network bandwidth.

Experiment setup. For collective performance evaluation, we use NCCL v2.23.4 [26] and NCCL-tests `9d26b84` [25], the latest versions when we start integrating UCCL-Tran into NCCL, and focus on the representative allreduce and all-to-all collectives. NCCL-tests vary the collective message size and measure the achieved bus bandwidth. We focus on message sizes from 1MB to 1GB, commonly used in real ML workloads [87, 103, 105]. For AMD GPUs, we use RCCL `532f54c` [48] and RCCL-test `5b27b96` [47].

Comparison baselines. On CX_ETH and CX_IB, we compare UCCL-Tran to the NCCL built-in RDMA support that uses RC on ConnectX-7/CX-7. UCCL-Tran uses 256 UC/RC QPs for each NIC pair, while the NCCL built-in uses QP scaling with 4 RC QPs per connection [34, 59]. UCCL-Tran uses CUBIC CC on CX_IB unless specified, which performs better than Swift in the lossless InfiniBand. Since InfiniBand has no packet loss for CUBIC to reduce `cwnd`, to avoid severe network congestion, we enforce a maximum `cwnd` value in UCCL-Tran CUBIC CC to limit the maximum inflight bytes, similar to TCP flow control. Similar setups apply to the AMD testbed.

On EFA, we compare UCCL-Tran to the official AWS NCCL-EFA plugin v1.13.2 [3] that uses the multipath SRD [93]. UCCL-Tran uses 10×26=260 UD QPs to serve all connections, which yields the best performance empirically, while the NCCL-EFA plugin uses the best parameters recommended by AWS. UCCL-Tran uses CUBIC CC on EFA by default, as EFA NICs do not support hardware timestamping that is critical to Swift CC. In all testbeds, UCCL-Tran uses per-path RTT for multipath LB (§4.1).

As the cost of extensible software transport, NCCL atop UCCL-Tran uses more CPU cores than vanilla NCCL. By default, the vanilla NCCL uses 2 cores per GPU, while UCCL-Tran uses 2 more cores per NIC to run the engine threads, with 1 additional core per NIC for receiver-driven CC due to the pacer.

Figure 8: RCCL-tests results on AMD.

6.1 Collective Performance

On CX_ETH. Figure 7 compares the performance of UCCL-Tran vs. ConnextX-7 on the CX_ETH testbed. For NCCL over CX-7, we use multiple QPs for each connection between two GPUs by adjusting `NCCL_IB_QPS_PER_CONNECTION`. However, it still suffers from significant performance drops under larger message sizes and lower peak performance. This is because flow collisions in the fat-tree topology cause severe network congestion, which in turn leads to exponential backoffs in the CX-7 CC mechanism. Instead, UCCL-Tran is able to scale up performance stably with message size increasing, by making smarter LB and CC decisions in software. Overall, UCCL-Tran outperforms CX-7 by up to 2.32/1.60/1.24× (corresponding to 4/8/16 QPs) and 1.79/3.82/4.54× for allreduce and all-to-all, respectively.

On AMD. Figure 8 compares the performance on the AMD testbed. This testbed has a rail-optimized topology that helps reduce network congestion when used together with the PXN technique [78]. Under this topology, UCCL-Tran achieves comparable performance as Thor-2 for allreduce, and outperforms Thor-2 by up to 1.68/1.61/1.78× (corresponding

Figure 11: Application performance evaluation.

to 4/8/16 QPs) for all-to-all, by better controlling network congestion.

On EFA. Figure 9 compares the collective performance of UCCL-Tran and SRD on the EFA testbed. UCCL-Tran CUBIC and EQDS achieve similar performance with significant improvement over SRD (except for ≥256MB allreduce): for allreduce, UCCL-Tran outperforms SRD by up to 1.27×; for all-to-all, the speedup is up to 3.27×. UCCL-Tran outperforms SRD because beefy CPU cores are faster in making transport decisions than wimpy ARM cores on `p4d.24xlarge` EFA NICs (that run SRD), especially when handling connection-intensive all-to-all. Surprisingly, simple CUBIC CC performs very well. This is mainly because UCCL-Tran leverages hundreds of network paths and avoids congested ones before sending packets; so most of the time, CC does not get involved. The small performance gap after 256MB is caused by the extra control header added by UCCL-Tran, while SRD directly reuses the UDP header for control (UCCL-Tran cannot reuse as it is not exposed to CPUs).

UCCL-Tran could also directly leverage the SRD protocol of EFA NICs to send/recv individual datagram packets. UCCL-Tran over SRD does connection management and multipath load balancing in CPU, and packet reassembly in GPU (§3.1), overcoming the limited processing power and cache capacity of SmartNICs on `p4d.24xlarge`. As a result, it achieves similar high performance to UCCL-Tran CUBIC and EQDS.

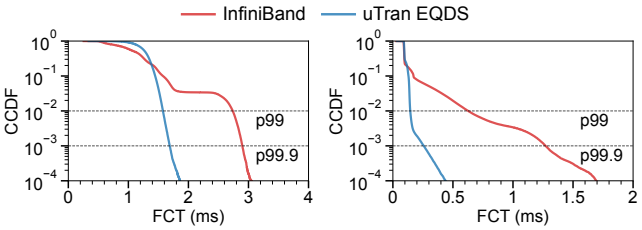
On CX_IB. Figure 10 compares the allreduce and all-to-all performance of UCCL-Tran vs. ConnextX-7 on the CX_IB testbed. UCCL-Tran UC/RC performs almost the same as ConnectX-7 with various data sizes, except that UCCL-Tran UC performs slightly worse (i.e., less than 4%) than ConnextX-7 and UCCL-Tran RC for allreduce after 128MB. For allreduce, this exception is because of the extra overhead of handling packet reliability in UC; for all-to-all, ConnextX-7 and UCCL-Tran RC do not perform better than UCCL-Tran UC, because all-to-all is connection-intensive, causing more QP swapping for RC. These experiments confirm that UCCL-Tran can make highly efficient control decisions in software, reaching the performance of ASIC-based RDMA NICs (i.e., NVIDIA ConnectX-7) for ML collectives.

Due to space limitations, we show the results of more collectives in Appendix C.1, on EFA with NVLink+SHM enabled in Appendix C.2 (up to 2.14× faster), and on non-RDMA NICs in Appendix C.3 (up to 4.1× faster).

6.2 Application Performance

UCCL-Tran is motivated by the practical needs of both LLM training and serving workloads. We run two applications to evaluate how UCCL-Tran improves ML workload performance. One is an end-to-end training of the DeepSeek-V2-Lite model [65] with 16B parameters and 64 routed experts on the AMD testbed using expert parallelism. We use the AMD Primus [8] training framework and its Megatron-LM backend. We also scale the model up and down to 128 and 32 routed experts to evaluate more training scenarios. Another is a DeepSeek-V3-like MoE serving application. Due to the testbed constraint (e.g., hundreds of GPUs required for meaningful DeepSeek-V3 serving with expert parallelism [66, 99]), we use a realistic DeepSeek-V3 trace including GPU compute time and network message sizes (i.e., hidden state sizes) from [106], and emulate the computation and communication behaviors with PyTorch and NCCL on EFA (NVLink+SHM disabled).

Figure 11a shows the results for DeepSeek-V2-Lite training. UCCL-Tran improves the end-to-end training speedup of up to 7.5%, without any line of code change to the training framework. Figure 11b shows the results for DeepSeek-V3 serving. UCCL-Tran reduces the per-request prefilling and decoding latency by 1.13× and 1.42× respectively. These experiments demonstrate that UCCL-Tran is able to bring significant benefits to real-world ML applications.



(a) Incast traffic. **(b)** Permutation traffic.

Figure 12: Complementary CDF of FCT (Flow Completion Time) on CX_IB when co-locating 15-to-1 incast and permutation traffic.

6.3 UCCL-Tran Extensibility

6.3.1 Handling network incast

In a shared RDMA network, network incast can lead to victim flows due to PFC propagation [45, 73, 104]. Such network incast can be caused by the Expert Parallelism in MoE serving (§2.2) and gather/reduce collectives in multi-level parallelism of LLM training [13, 40]. This experiment tries to create a scenario where network incast co-exists with other collective traffic, and evaluates how UCCL-Tran performs compared to the RDMA hardware transport on CX_IB. We co-locate 15-to-1 incast traffic and 16-NIC permutation traffic [16, 19, 59, 89], where each NIC streams data to another and no NIC receives more than one stream, representing typical collectives. For both types of traffic, each NIC sends 1MB messages with at most four in flight. We compare the receiver-driven EQDS in UCCL-Tran vs. the sender-driven InfiniBand CC in ConnectX-7.

Figure 12a and 12b show the FCT distributions for incast traffic and permutation traffic, respectively. Compared to InfiniBand, UCCL-Tran EQDS reduces P99/P99.9 latency by 1.73×/1.72× for incast traffic and 4.50×/4.88× for permutation traffic. This is because the InfiniBand CC only reduces the sending rate when severe congestion and queue build-up have occurred on the incast switch port; but this is too late, as the Credit-Based Flow Control [49] (PFC equivalent in InfiniBand) has already paused all upstream ports and heavily disturbed victim flows (i.e., permutation traffic). Conversely, UCCL-Tran EQDS proactively controls the rate of all senders on the receiver side, which reduces queue build-up and avoids upstream ports entering the pausing state.

6.3.2 Handling packet loss

We then evaluate how UCCL-Tran selective retransmission handles packet loss, compared to hardware-based loss recovery. Furthermore, UCCL-Tran coalesces transport decisions like loss recovery at chunk granularity for high software efficiency; therefore, we also test whether this design choice would cause poor loss recovery performance. To this end, we instrument different packet loss rates in software when running NCCL collectives over UCCL-Tran UC. Our packet loss instrumentation has considered the chunking nature in UCCL-Tran, where any packet loss will cause the whole chunk loss. Unfortunately, we cannot instrument packet loss for our CX_IB NICs as that would require reconfiguring the NIC or switch behaviors, both of which we do not have access to. Instead, we cite comparable numbers from prior literature Flor [63].

We pick two GPUs from the AMD testbed, each using one NIC for communication. The client NIC establishes a connection with the server NIC and keeps 16 inflight messages. Similar to Flor [63], we use a single QP for the connection, and disable congestion control to avoid sending rate backoff. We vary the message size (32KB∼1MB) and measure the goodput under different packet drop ratios. Figure 13 shows the results. UCCL-Tran has only ∼1% performance drop under 1/16384, 1/4096 drop ratio, compared to the reported 26%∼42% drop of RDMA hardware transport in Flor [63, Figure 7]. Even under a high drop ratio of 1/1024 and 1/256, UCCL-Tran only experiences a performance drop of 6%∼30%, compared to the reported 59%∼76% drop in RDMA hardware transport.

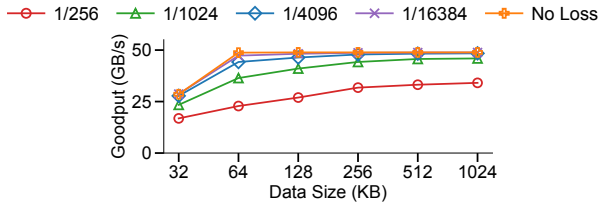


Figure 13: Goodput of UCCL-Tran under different packet drop ratios. UCCL-Tran implements selective retransmission with a dynamic RTO threshold (around several RTTs).

	Training w/ NCCL	w/ NCCL + uTran
# CPU cores / # 400G NICs	2.3	4.3

Table 2: CPU core consumption relative to the number of active 400G NICs during DeepSeek-V2-Lite training (§6.2).

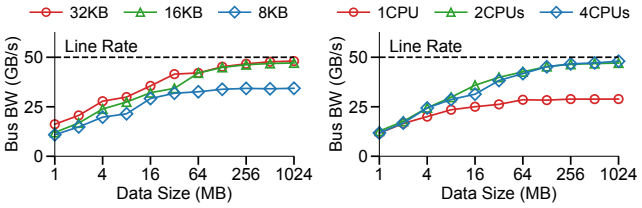
6.4 UCCL-Tran Scalability

6.4.1 CPU core consumption

In addition to the training-framework CPU usage, which is averagely 14.5% out of 128 cores in practice (§1, UCCL-Tran additionally uses 16 CPU cores (2 per GPU). Table 2 summarizes the CPU core consumption relative to the number of active GPUs. As the GPU price and CPU core count keep increasing (e.g., 192 CPU cores in AWS Hopper GPU VMs [5]), we believe trading 16 additional CPU cores for a 7.5% GPU efficiency boost is becoming increasingly worthwhile.

6.4.2 Varying chunk size

Figure 14a shows the all-to-all performance on the CX_IB testbed when varying chunk sizes. Our results reveal that saturating the line rate requires a somewhat medium chunk



(a) Varying chunk size. **(b)** Varying CPU cores.

Figure 14: UCCL-Tran all-to-all on CX_IB with different chunk sizes and number of CPU cores per NIC (NVLink+SHM disabled).

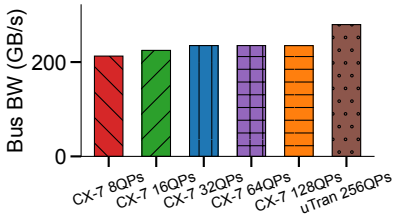


Figure 15: The highest allreduce bandwidth with different number of QPs and transports on CX_ETH. When preparing this figure during camera ready, we are no longer able to access any testbed due to the long period between the original evaluation and camera-ready, and the high expenses of RDMA-connected GPU testbeds. We are only able to retrieve the CX-7 results with up to 128 QPs from our previous logs, but we believe the trends do not change when CX-7 scales to 256 QPs (due to RC's overhead in RDMA NICs).

size, i.e., ≥16KB or 4 MTU-sized chunks. This experiment demonstrates the performance benefits of control coalescing for UCCL-Tran software transport.

6.4.3 Varying number of CPU cores

Figure 14b shows the all-to-all performance when varying the number of UCCL-Tran engines/CPU cores per NIC. For ASIC-based NICs with segmentation and reassembly offloading, even though one CPU core can only saturate bidirectional 29GB/s, two CPU cores are enough to saturate the full 50GB/s line rate. The slight performance drop for 16MB when switching from "2CPUs" to "4CPUs" should be caused by runtime variability. This experiment confirms the high efficiency of UCCL-Tran software transport, i.e., 1 CPU core saturating 400G unidirectional traffic (2 CPU cores for 400G bidirectional).

We show more scalability studies in Appendix C.4 when varying numbers of CPU cores, GPUs, and paths on EFA.

6.5 Design Drill-Down

6.5.1 Performance improvement attribution

Figure 15 shows the highest allreduce bandwidth when varying the number of QPs in different transports. There are two takeaways: 1) the performance of the raw CX-7 transport saturates at 32 QPs, and increasing QPs beyond even incurs a slight performance penalty (due to RC's high overhead), 2)

Max Bus BW (GB/s)	Allreduce	All-to-All
w/o conn split (ZeroNIC [97], Flor [63])	45.7	39.9
w/ conn split (UCCL-Tran)	48.9	48.5

Table 3: Impact of connection splitting on CX_IB.

Delay (μs)	Allreduce Light	All-to-All Light	Allreduce Heavy	All-to-All Heavy
CC decision P50	1.7	1.7	2.1	2.9
CC decision P99	3.6	3.4	7.0	10.8
ACK turnaround P50	2.0	3.0	4.0	7.0
ACK turnaround P99	3.0	10.0	10.0	36.0

Table 4: CC decision delay and ACK turnaround delay on CX_IB. "Light" uses 1KB-64KB messages, while "Heavy" uses 1GB.

CX-7 with 128 QPs still falls behind UCCL-Tran performance by a large margin. Therefore, we think simply scaling QPs to 256 is not the leading factor of performance improvement, but the dynamic path selection (i.e., power-of-two sampling based on per-path RTT) is the key to better performance. We note that such advanced dynamic path selection can hardly be done on traditional NICs due to the large per-path states they need to maintain.

6.5.2 Connection splitting

We now evaluate how connection splitting impacts collective performance in UCCL-Tran. Without connection splitting, each UCCL-Tran connection is mapped to a single engine out of the two UCCL-Tran engines per NIC; with splitting, each UCCL-Tran connection dispatches and load balances its messages among the two UCCL-Tran engines. Table 3 shows that UCCL-Tran without connection splitting (e.g., ZeroNIC [97], Flor [63]) only achieves 45.7 and 39.9 GB/s max busbw for allreduce and all-to-all, while UCCL-Tran with splitting achieves 48.9 and 48.5 GB/s respectively, saturating the line rate. This is because connection splitting enables multiple CPU cores to process inflight messages in a load-balanced manner. We anticipate connecting splitting will become more critical as the NIC scales to 800 Gbps [27].

6.5.3 Congestion signal fidelity in software

UCCL-Tran makes a fundamental shift of moving transport from hardware to software. This experiment evaluates how much software transport sacrifices in terms of congestion signal fidelity. We look at the two important metrics as mentioned in §3.4: CC decision delay and ACK turnaround delay. Table 4 shows the results. At light loads, the two delays are limited to at most 10μs in both P50 and P99; at high loads, they grow up to 36μs for P99. Both are on par with typical datacenter RTTs of 10-40 μs [37]. Therefore, this experiment confirms that UCCL-Tran software transport has high enough CC fidelity to make precise per-RTT transport decisions [39,64]. In

addition, we emphasize that while software RTT introduces some noise, the bulk data nature of ML traffic makes it more tolerant to this than latency-sensitive RPC workloads.

We show more design drill-downs in Appendix C.5, including the impact of chunk size, LB policy, kernel fusion (for scattered memcpy), and PCIe overhead analyses.

7 Discussion

HW-SW interface. UCCL-Tran works around many challenges to support extensible transport with efficient multipathing on existing RDMA NICs, at the cost of QP swapping overhead (though not high for ML collectives), control coalescing, and more. UCCL-Tran performance and control granularity would get further boosted if there were a better HW-SW interface in RDMA NICs.

We would like to highlight a few points based on our development experience: (1) UC abstraction is powerful with segmentation and reassembly offloading, but using many UC QPs for multipathing incurs some degree of QP swapping overhead; instead, it should evolve into a multipath UC abstraction that allows the software to specify different flow entropies for different verbs over a single QP, just like how UCCL-Tran specifies different UDP ports for AF_XDP. (2) NIC HW should expose more congestion signals to SW, such as ECN marks and packet trimming information; these signals can be embedded into CQEs just like hardware timestamps.

Software jitters. UCCL-Tran runs network transport on the host CPU, and may suffer from software jitters. We argue that such jitters could be avoided or reduced to a minimal level for ML workloads. For example, storage traffic nowadays could directly go from GPU to storage devices via GPUDirect Storaage, so no intensive CPU involvement. ML cluster scheduler already schedules dedicated cores for NCCL CPU proxy, which works well. We just need to reserves extra cores for UCCL-Tran. Futhermore, we can disable interrupts for certain cores that run NCCL CPU proxy and UCCL-Tran transport.

GPU-initiated communication like DeepEP [29] leverages NVIDIA IBGDA [84] to issue RDMA verbs directly from GPUs to the RDMA NICs. Although seemingly conflicted with UCCL-Tran's CPU-initiated designs, GPU-initiated communication could still be made compatible with UCCL-Tran. The key is to leverage the IBGDA CPU-assisted mode [80], where the GPU forwards RDMA requests to a CPU proxy that issues RDMA verbs; with this, we could implement UCCL-Tran's extensible transport layer inside the CPU proxy. The trade-off is on performance: NVIDIA has reported that this CPU-assisted IBGDA would sacrifice 10% performance compared to the traditional IBGDA [80]. We intend to leave the integration and performance enhancement of CPU-assisted IBGDA + UCCL-Tran as future work.

Observability. During the private conversation with GPU cluster managers, we found that network observability is critical. For example, once observing which path has congestion and when retransmission happens, the cluster manager can drain traffic away from the hotspot to improve the completion time of synchronous ML training. UCCL-Tran's software approach provides a better observability vantage point compared to the hardware-baked RDMA transport. UCCL-Tran users could directly instrument the transport layer and quickly recompile in software to, e.g., log per-path congestion level and retransmission events.

8 Other Related Work

Recent work SCR [107] implements receiver-driven CC and multipathing on the DPA (DataPath Accelerator, essentially 16 RISC-V cores) of NVIDIA BlueField-3 SmartNICs. It would have similar performance issues as AWS EFA NICs. Moreover, DPA programmability is limited to what the NIC hardware supports, e.g., only rate-based control, while packet reliability and retransmission are still baked into the hardware. Because of this, SCR needs to alter the original receiver-driven CC to let credits represent available bandwidth rather than bytes. For multipathing, SCR only demonstrates two paths; given the limited L1/L2 cache in DPA [107], it is not clear if SCR could scale to hundreds of paths [16, 59, 85]. The recent MRC [10] protocol builds a multipath RC protocol into programmable NICs such as NVIDIA ConnectX-8 and Broadcom Thor Ultra. We note it is released one year after UCCL-Tran and might suffer from similar issues as SCR.

Google GPUDirect-TCPX [2] integrates GPUDirect into the kernel TCP stack by leveraging the Header-Data Split feature in certain non-RDMA NICs. Instead, UCCL-Tran targets both RDMA and non-RDMA NICs, and further supports efficient multipathing. C4 [32] does coarse-grained flow-level traffic planning and path selection in LLM training, without programmability for low-level RDMA transport components such as CC and loss recovery. MSCCL [11] supports customizing collective communication algorithms and could work together with UCCL-Tran. Lastly, UCCL-Tran is inspired by a line of work that targets extensibility for CPU applications, e.g., Google 1RMA [95], eRPC [53], RoGUE [60], and IO-TCP [55] for extensible RDMA transport, and SPIN [15], Exokernel [33], and VINO [91] for extensible OS.

9 Conclusion

UCCL-Tran is an extensible and efficient software transport layer for GPU networking. It achieves network extensibility by separating the control path and data path for existing RDMA NICs and running the transport control path in software. Meanwhile, it achieves hardware-level performance by leveraging techniques like control coalescing and connection splitting. We hope UCCL-Tran opens the door to the productization of new research proposals on network transports for ML workloads. UCCL-Tran is open-sourced at https://github.com/uccl-project/uccl.

A Interface to Extensibility

By executing control decisions in software, UCCL-Tran allows flexibly extending its transport implementation for different scenarios. To ease the development of new multipath transport such as new CC or LB policies among different paths, UCCL-Tran exposes a set of expressive interfaces to collective library or ML application developers, as shown in Listing 1.

- `onChunkSize` is called when UCCL-Tran chunks a message for transmission, and it returns the permitted chunk size for now. CC could enforce window control here. After it returns, UCCL-Tran will build a `chunk_desc` for the chunk.
- `onPacingChunk` determines if a chunk needs to queue in the timing wheel for rate pacing, and returns true if so.
- `onSelectPath` is called when a chunk is ready for transmission. `conn_state` contains rich information for selecting path, e.g., RTT scoreboard for each path. It returns the selected `path_id` (i.e., QP ID) for transmission.
- `onTxRtxChunk` is called when the reliable transport wants to retransmit a chunk, and it returns true if this chunk is permitted to retransmit. CC could enforce window control for the retransmitted chunk here.
- `onRxChunk` is called when receiving a data chunk.
- `onRxRtxChunk` is called when receiving a retransmitted chunk. CC could react to the retransmission chunk here.
- `onRxACK` is called when receiving an ACK. CC could react to the ACK here.
- `onRxCredit` is called when receiving a credit. Receiver-driven CC could react to the credit here.

```
1 func onChunkSize(conn_state, remaining_bytes) ->
      chunk_sz;
2 func onPacingChunk(conn_state, chunk_desc) ->
      pacing_or_not;
3 func onSelectPath(conn_state, chunk_desc) -> path_id;
4 func onTxRtxChunk(conn_state, chunk_desc) -> rtx_or_not;
5 func onRxChunk(conn_state, ctrl_hdr);
6 func onRxRtxChunk(conn_state, ctrl_hdr);
7 func onRxACK(conn_state, sack_hdr);
8 func onRxCredit(conn_state, credit_hdr):
```

Listing 1: UCCL-Tran interface to extending multipath transport.

B EQDS Implementation Under UCCL-Tran

Figure 16 shows the overall implementation. For each NIC, UCCL-Tran creates a dedicated pacer thread that operates at a constant rate (derived from the NIC bandwidth) to select candidate senders, allocate credits, and send credits following the EQDS algorithm. Each pacer thread uses a credit UD QP for sending credit packets, and each TX&RX thread also has its own credit QP for receiving credit packets from remote pacers. The pacer thread maintains three lists, i.e., rtx (retransmission), active, and idle sender list, with priorities from high to low. After the TX&RX threads receive data chunks, they will notify the pacer thread via an efficient atomic write in the SHM. Then the pacer will update the sender list: senders who encounter packet loss will be put into the rtx list; senders who have satisfied their requirements will be put into the idle list; otherwise, they will be put into the active list. One note is that as packet tramming is not available in our RDMA NICs and switches, UCCL-Tran uses timeout + RTS (Request-To-Send)

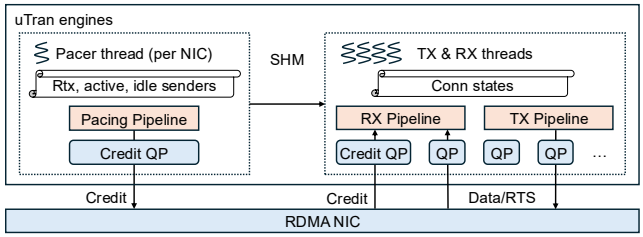

Figure 16: Implementing receiver-driven CC under UCCL-Tran.

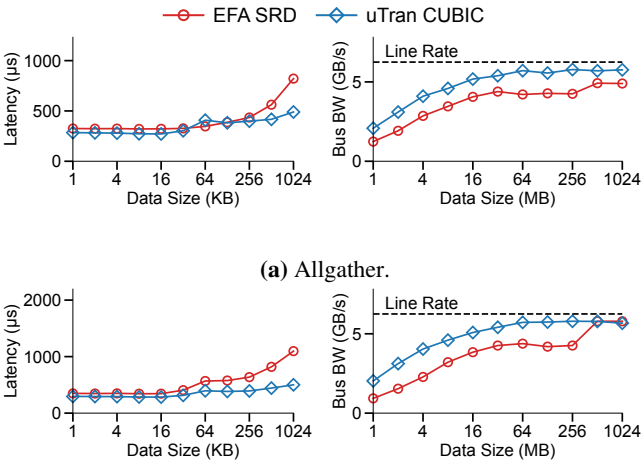


(a) Allgather.

(b) Reduce-Scatter.

Figure 17: NCCL-tests results on EFA (NVLink+SHM disabled to simulate a larger testbed).

as a replacement, as suggested by the EQDS paper.

C More Evaluation Results

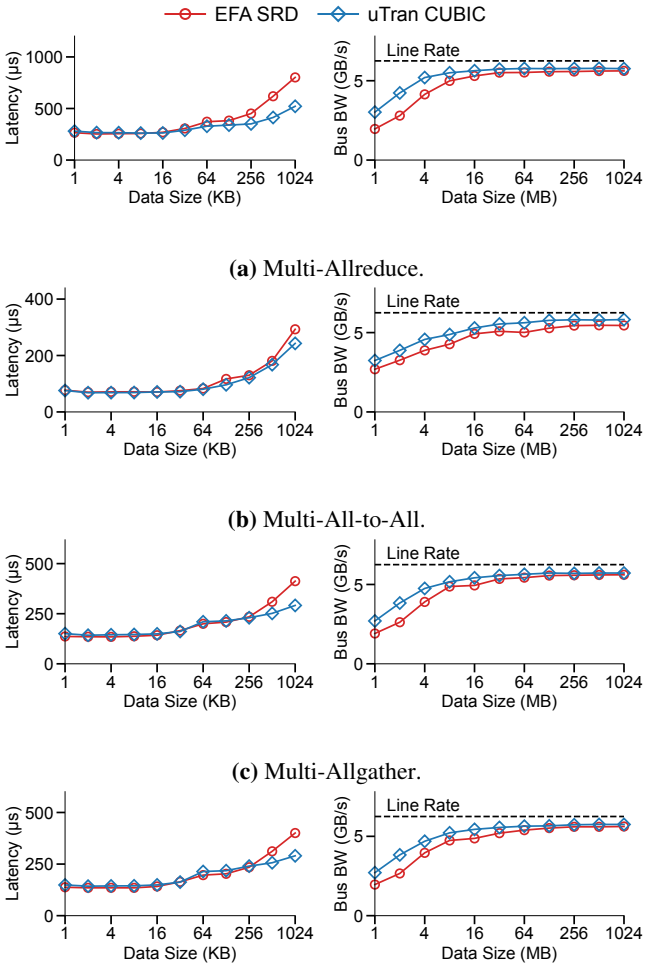
C.1 More collectives in ML workloads

C.1.1 Allgather and reduce-scatter

These two are representative collectives used in PyTorch FSDP (Fully Sharded Data Parallelism) [108], exhibiting low network congestion [34]. Figure 17a and Figure 17b compare the allgather and reduce-scatter performance of UCCL-Tran and SRD on the EFA testbed. UCCL-Tran outperforms SRD by up to 1.68× for allgather and up to 2.18× for reduce-scatter.

C.1.2 Multi-collectives

In multi-collectives, GPUs with the same local rank in each server form a collective group, and multiple groups conduct collectives in parallel. For example, multi-allreduce is used in ML workloads with intra-server Tensor Parallelism (TP) + inter-server Data Parallelism (DP). We evaluate multi-collective performance by setting the environment variable `NCCL_TESTS_SPLIT_MASK=0x7` in NCCL-tests. Figure 18a, 18b, 18c and 18d compare the multi-allreduce, multi-all-to-all, multi-allgather and multi-reduce-scatter performance of UCCL-Tran and SRD on the EFA testbed. UCCL-Tran outperforms SRD by up to 1.54×, 1.22×, 1.46×, and 1.44× for multi-allreduce, multi-all-to-all, multi-allgather and multi-reduce-scatter, respectively.



(a) Multi-Allreduce.

(b) Multi-All-to-All.

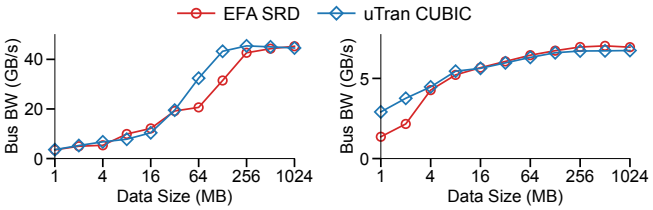
(c) Multi-Allgather.

(d) Multi-Reduce-Scatter.

Figure 18: Multi-collective results on EFA (NVLink+SHM disabled).

C.2 EFA with NVLink+SHM enabled

Figure 19 shows the collective performance comparison on the EFA testbed when NVLink and SHM are enabled (meaning a smaller testbed). Even though a major amount of data traffic goes through the high-bandwidth NVLink, UCCL-Tran still achieves much higher or comparable collective performance than SRD, i.e., up to 1.57× for allreduce and 2.14× for all-to-all.



(a) Allreduce. **(b)** All-to-All.

Figure 19: NCCL-tests results on EFA (NVLink+SHM enabled).

C.3 UCCL-Tran AF_XDP performance

Figure 20 compares the collective performance of UCCL-Tran AF_XDP vs. NCCL kernel TCP with and without proximity placement group (PPG). This experiment is done on AWS with two 50 Gbps VMs connected through AWS ENA NICs that do not support RDMA. We configure NCCL to use multiple TCP connections that achieve the best performance. With PPG that gives low network RTTs between VMs, UCCL-Tran achieves up to 4.1×/2.3× higher performance than NCCL for small/large message ranges; without PPG, UCCL-Tran achieves up to 2.7×/2.1× higher performance. This huge gain is because UCCL-Tran implements an efficient multipath transport atop the fast user-space packet IO technique AF_XDP, thus saving significant user-kernel context switching overhead and heavy-weight networking stack traversing in kernel TCP. For data sizes exceeding 16MB, both AF_XDP and TCP experience bottlenecks due to no GPUDirect support.

C.4 UCCL-Tran Scalability

C.4.1 Varying number of CPU cores on EFA

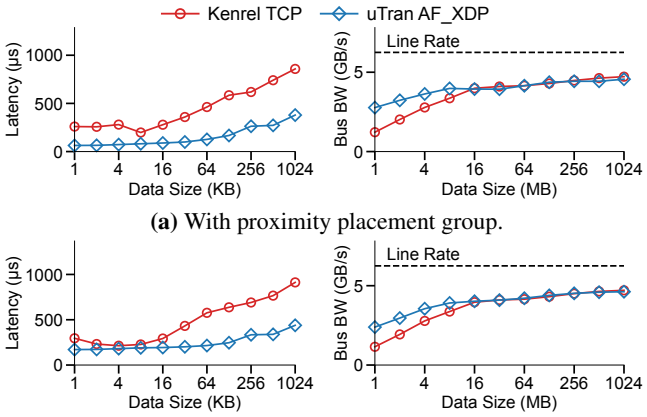
Figure 21 shows how the number of CPU cores per NIC impacts UCCL-Tran performance on EFA. As mentioned in §6.4.3, 2 cores are sufficient to saturate the EFA line rate, even for the connection-intensive all-to-all collective. Overall, thanks to chained posting, UCCL-Tran over UD is able to use 1 core to handle 100 Gbps unidirectional traffic on EFA NICs.

C.4.2 Varying number of GPUs on EFA

Figure 22 shows how UCCL-Tran scales with the number of GPUs on EFA. As expected, with less GPUs, UCCL-Tran achieves lower latency and higher bus bandwidth. But eventually, UCCL-Tran is able to approach line rate with ≥64MB data size. UCCL-Tran leverages the connection-less UD on EFA NICs, thus not suffering from QP scalability issues.

C.4.3 Varying number of paths on EFA

Figure 23 varies the number of paths on the EFA testbed (which crosses racks with multiple network paths). The high-level take here is that multipathing helps mitigate network congestion caused by, e.g., flow collisions. We expect multipath transport to shine more on a larger testbed with more network paths.



(a) With proximity placement group.

(b) Without proximity placement group.

Figure 20: Allreduce performance on non-RDMA NICs using two AWS `g4dn.8xlarge` VMs each with a 50 Gbps AWS ENA NIC.

(a) Allreduce.

(b) All-to-All.

Figure 22: UCCL-Tran collectives on EFA with different numbers of GPUs (NVLink+SHM disabled).

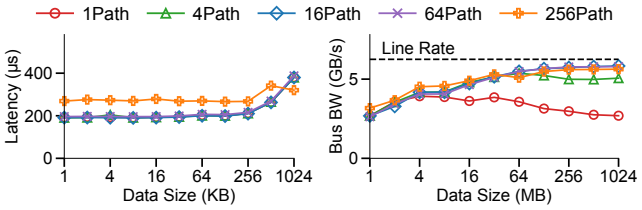

Figure 23: UCCL-Tran all-to-all on EFA with different numbers of paths (NVLink + SHM disabled).

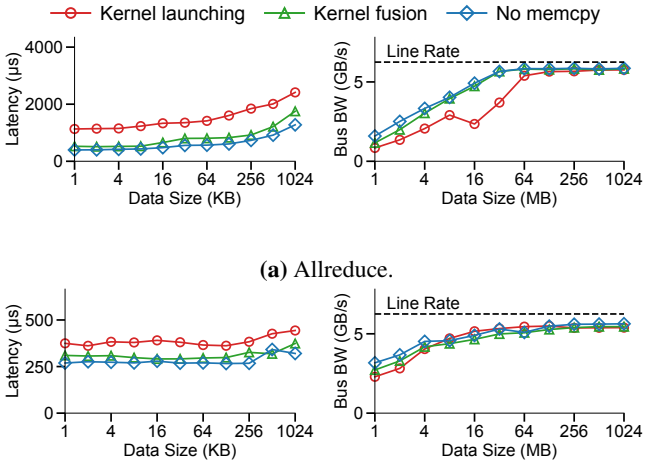
Permulation traffic completion time (ms)	Sender-driven	Receiver-driven
4KB + ECN (UEC default)	1.45	1.43
32KB + ECN	1.62 (+11.7%)	1.47 (+2.8%)
32KB + RTT	1.71 (+17.9%)	1.47 (+2.8%)
32KB + RTT + ConnSplit	1.70 (+17.2%)	1.47 (+2.8%)
16KB + RTT + ConnSplit	1.51 (+4.1%)	1.42 (-0.7%)

Table 5: Impact of chunk size and LB policy. "ConnSplit" means connection splitting, which first selects the least loaded engine and then selects the least loaded path from that engine's paths/QPs using Power-of-Two sampling (§4.1).



(a) Allreduce.

(b) All-to-All.

Figure 24: NCCL-tests results on EFA (NVLink+SHM disabled).

C.5 Design Drill-Down

C.5.1 Impact of chunk size and LB policy

This experiment aims to study the impact of chunk size and LB policy on the performance of a broad range of ML transports (not just the ones implemented in UCCL-Tran). To this end, we use UEC's packet-level network simulator `htsim` [22,101] with UEC-standard multipath transport implementation. We further modify the transport implementation in `htsim` to vary chunk size and LB policy, e.g., based on ECN or RTT, connection splitting or not. We vary the chunk size by changing the MTU size in the simulator without modifying any transport simulation code. We vary the LB policy by maintaining per-path ECN/RTT and modifying the code where the transport sender selects the path for each packet. Similar to prior work [16,19,59,89], we focus on the permutation traffic pattern to stress-test the transport, where each NIC streams traffic to another and no one receives more than one stream. We simulate 1024 400G NICs under a fully-provisioned three-tier fattree, and each NIC uses 256 paths to stream 64MB traffic with an ideal completion time of 1.28ms.

Table 5 shows the permutation traffic completion time under different designs. Overall, using 32KB chunk size and switching to RTT degrade transport performance by 17.9% for sender-driven transport and only 2.8% for receiver-driven, while connection splitting does not degrade. With a 16KB chunk size, the performance degradation of sender-driven transport becomes only 4.1%. Receiver-driven performs better because EQDS leverages in-switch packet trimming to quickly detect network congestion and react [43,85]. Overall, this experiment shows that control coalescing indeed causes transport performance degradation, but the degradation is moderate in most cases; meanwhile, connection splitting has a negligible impact on transport performance.

C.5.2 Impact of kernel fusion.

This experiment aims to quantify the overhead of scattered memcpy and justify UCCL-Tran's design choice of employing kernel fusion over kernel launching (§3.1). In the kernel launching approach, UCCL-Tran launches a dedicated copy thread (in CPU) for each UCCL-Tran engine at boot time; after receiving all packets of a transport buffer, the engine notifies its associated copy thread via a shared-memory queue; then the copy thread launches a GPU kernel to perform scattered memcpy asynchronously (this kernel is different from the reduction kernel). We further optimize the kernel launching overhead with adaptive batching [14]. Note that we cannot run the GPU kernel persistently, as this would cause deadlock with the commonly-used `cudaDeviceSynchronize()`. We also emulate the performance with no scattered memcpy by skipping packet reassembly entirely and disabling data correctness checks in NCCL-tests.

Figure 24 shows the collective performance. Scattered memcpy introduces minor performance overhead compared to no memcpy (less than 8% and 5% for allreduce and all-to-all, respectively). Kernel launching performs worse than kernel fusion for both small message latency and large message bandwidth. The suboptimal performance of Kernel launching is because of the high kernel launching overhead, especially for small messages.

C.5.3 PCIe overhead

This experiment aims to study the PCIe overhead introduced by UCCL-Tran's multipath design. We measure the PCIe

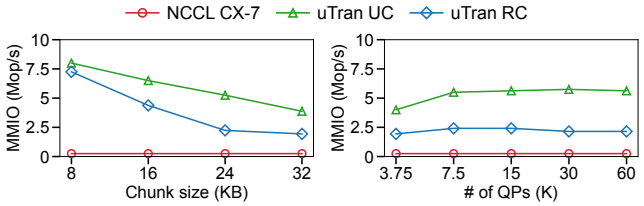


Figure 25: Number of MMIO events for each NIC under various chunk sizes and numbers of QPs on CX_IB.

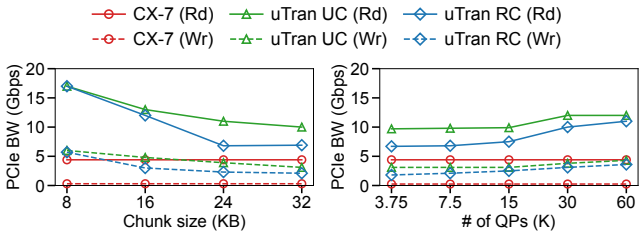

Figure 26: Extra PCIe traffic for each NIC under various chunk sizes and numbers of QPs on CX_IB. Rd: PCIe device reads from CPU; Wr: PCIe device writes to CPU.

overhead on our CX_IB testbed, while the AWS virtualization layer prevents us from accessing low-level PCIe metrics. We rerun the all-to-all experiments in §6.1 and quantify MMIO events and CPU-NIC PCIe traffic using `pcm-pcie` [50]. Figure 25 and 26 show the results. As expected, UCCL-Tran incurs higher MMIO activity and PCIe bandwidth consumption than the vanilla NCCL atop CX-7. UCCL-Tran incurs more MMIO events because it posts more verbs: UCCL-Tran transfers a small 32KB chunk per verb, while the vanilla NCCL atop CX-7 transfers a transport-buffer-sized message (e.g., default 128KB) per verb. The extra PCIe traffic of UCCL-Tran primarily comes from NIC swapping QPs (i.e., fetching uncached QP contexts from CPU memory) as UCCL-Tran uses 256 UC/RC QPs for multipath. UCCL-Tran UC consumes slightly more bandwidth than RC because it implements reliability and selective retransmission in software on the CPU.

We conclude that the number of MMIO events and extra PCIe traffic increase significantly with smaller chunk sizes, but the number of QPs does not nearly affect them. UCCL-Tran makes a reasonable trade-off between the control decision granularity and performance based on this observation and uses a 32KB chunk size as default (§3.3). We note that the extra PCIe bandwidth overhead is minor compared to the PCIe link capacity. For example, the capacity of PCIe 5.0 $\times$ 16 on CX_IB is 512 Gbps in each direction, and the overhead of UCCL-Tran (32KB, 60k QPs) accounts for less than 2.5% (12/512=2.3%).

Hardware Lifecycle-Aware Power Planning in Commercial Hyperscale Datacenters (Operational Systems)

Abstract

Modern commercial datacenters operate with heterogeneous hardware, deploying new servers to meet the growing compute demands while retaining older servers due to budgetary and environmental constraints. Datacenter planners can use daily performance and power profiling data to continually refine power budgets for legacy hardware. By contrast, power planning for new hardware must begin as early as the pre-silicon stage of server development when such data is not yet available. This paper presents our practical experience in power planning for Meta's datacenters over the past decade, emphasizing heterogeneous hardware, and shares strategies for future power planning and management.

To plan power more efficiently, we begin with a comprehensive power characterization study for hyperscale workloads in Meta's datacenters, using live production traffic data spanning millions of servers across multiple hardware generations. Building on characterization insights, we present a *hardware lifecycle*-aware rack power budgeting methodology accounting for both the hardware and workload heterogeneity. This methodology has been deployed at scale in Meta's datacenters for over a decade, enabling an average power oversubscription of approximately 20% across the fleet.

Though effective, *the current power planning approach requires production-level power telemetry, which is typically unavailable during the early stages of hardware development.* To address this challenge, we develop *PowerSight*, a machine learning-based model to predict system power without relying on power sensor data. We demonstrate practical use cases of *PowerSight* for improving power planning in future system deployments. To the best of our knowledge, this is the first comprehensive study to formally introduce the concept of *hardware lifecycles* in commercial datacenters, along with tailored power budgeting strategies for each phase.

1 Introduction

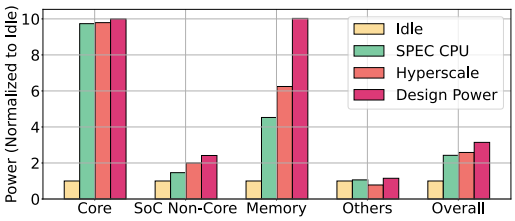
As the demand for digital services continues to rise, the power consumption of the datacenters to support them is growing rapidly [10, 44, 50, 51, 65]. To meet the growing demands, Meta – like other major datacenter operators such as Google [30, 56], Microsoft [25, 51], and Alibaba [73, 74] – continues to grow its server fleet by adding new hardware, while maintaining older systems to balance both budgetary and environmental constraints [24, 52, 68].

This mix of old and new hardware creates *heterogeneity*, making it necessary to account for *hardware lifecycles* when conducting power planning. A hardware lifecycle (§ 2) is the complete sequence of stages that a rack program goes through, from initial planning and acquisition, through deployment and operation in mass production, to eventual decommissioning and disposal. For older servers in mass production, a wealth of historical power and performance data is available across the fleet, enabling power planning methodologies based on past observations [23, 27, 34, 52, 64, 65, 77]. In contrast, when a new hardware generation is introduced, large-scale power sensor data typically becomes available only after mass production begins. However, the initial phase of rack installation demands power planning decisions before comprehensive data is available.

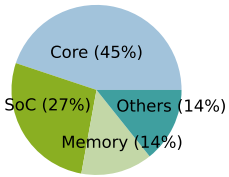
To address the challenges, we develop the *hardware lifecycle-aware power budgeting* methodology by answering the following questions:

- What are the power characteristics of heterogeneous datacenter hardware and workloads? What are the power trends across generations of hardware?
- How can power planning be adapted across hardware lifecycle stages at scale using these power insights?
- What are alternative power planning methods for early lifecycle phases when power sensors are unavailable?

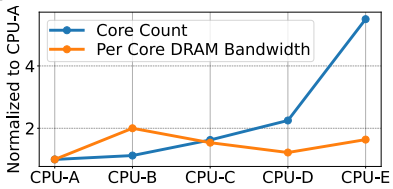
Effective power planning for hyperscale datacenters – such as Meta's, which deploy microservices across globally distributed infrastructure – requires in-depth workload characterization throughout the hardware lifecycle for power planning. To this end, we present a comprehensive analysis of system power based on live production traffic collected across



(a) Hyperscale vs. *SPEC CPU*.



(b) Power breakdown.



(c) Server trend across time.

Figure 1: (a) Core power approaches its design power, while memory power stays well below, especially for *SPEC CPU*. (b) System power breakdown of a hyperscale web service; core power is less than half of the total. (c) Server core counts have increased over CPU generations, whereas memory bandwidth per core has not kept pace.

multiple system types (Compute, Storage, AI) within Meta's datacenters at the beginning of our study.

Hyperscale workloads exhibit behaviors that differ significantly from those of standard benchmarks [22,33,61,62]. Figure 1a shows component-wise power contributions for an idle system, a *SPEC CPU2017* workload (geometric mean of int rate), and a representative hyperscale web service. Both workloads achieve peak CPU utilization, while hyperscale workloads place substantially greater power demands on the memory subsystem and other non-core components than *SPEC CPU2017* workloads. Furthermore, focusing solely on processor core power is insufficient, as it accounts for less than 50% of the system power (Figure 1b). Additionally, as illustrated by Figure 1c, server compute and memory capabilities differ across generations in Meta's datacenters.

Building on insights from our characterization study, we have enabled the infrastructure to collect component-level performance counters and power sensor data across all machines in our fleet. This fleet-wide telemetry supports power planning that accounts for the heterogeneity of both workloads and hardware throughout the hardware lifecycle, capturing a critical reality: *not all services or machines reach peak power simultaneously.* Leveraging this heterogeneity, we have developed a power oversubscription methodology that has been deployed across Meta's datacenters for over a decade. By aligning power budgeting with each stage of the hardware deployment lifecycle, this approach has enabled Meta to provision approximately 20% more racks in its global datacenter fleet without increasing the overall power footprint. *Notably, this work is the first to introduce the concept of hardware lifecycles in heterogeneous datacenter environments, along with phase-specific power budgeting strategies – an area not explored in prior datacenter power studies [27,34,52,59,64,77].*

Finally, *in the early stages of the hardware lifecycle, power planning must proceed without the production-level telemetry available in later phases*. To address this challenge, we introduce *PowerSight*, a machine learning (ML)-based model that predicts system power consumption using performance counters[1], which are available throughout all phases of the hardware lifecycle. *PowerSight* is a holistic power model capable of predicting the power consumption of compute, storage, and AI servers, as co-locating different types of servers within the same datacenter is essential to minimize cross-region communication overhead, which is particularly important for services such as AI training [15]. We also present case studies on how *PowerSight* facilitates power planning during the initial phases of the hardware lifecycle in datacenters.

In summary, our key contributions include:

- We conduct a comprehensive power characterization study using live production data at Meta, covering thousands of services deployed on multiple generations of compute, storage, and AI servers.
- We present the power oversubscription methodology that has been deployed in Meta's datacenters for over a decade, which allows us to safely oversubscribe power by ∼20% on average in compute, storage, and AI racks.
- We introduce *PowerSight*, an ML-based model for early-stage datacenter power planning. *PowerSight* can be easily deployed at scale using existing datacenter infrastructure. We also plan to publicly release artifacts to benefit the broader community in the future.

2 Background

Our study begins by introducing the foundational concepts of power distribution in Meta's datacenters.

Definition of hardware lifecycles: Commercial datacenters typically use a mix of old and new machines to handle a massive number of workloads [25,30,51,52,56,68,73,74]. As service load increases over time, datacenters add new machines to increase capacity, but often keep older machines in operation due to cost and environmental concerns [4,24,72]. Introducing a new hardware generation into production is a multi-phase process, which we refer to as the *hardware lifecycles* (Table 1). The process begins with the *pre-engineering validation test (pre-EVT)* phase, which focuses on platform

[1]Though prior works have explored using ML-based power models for power prediction [12,17,19,37,47,82], we are the first to demonstrate the real use cases of ML models for power planning in datacenters. The primary goal of this paper is to present a power planning system across hardware lifecycles that could be deployed at scale.

Table 1: Hardware lifecycle of a server. It takes 18+ months before hardware moves into the mass production (MP) stage. Power sensors are usually equipped in the DVT/PVT stage.

Stage	Timeline	Goal	Usage
Pre-EVT	2-3 years before MP	Silicon & platform design	Forecast RPB
EVT	9-12 months before MP	Tooling bring-up	Forecast RPB
DVT	6 months before MP	App test & power plan	Forecast RPB
PVT	3 months before MP	Production evaluation	Initial RPB
MP		Mass production	Initial RPB
MP+1 year		Scale deployment	Refined RPB

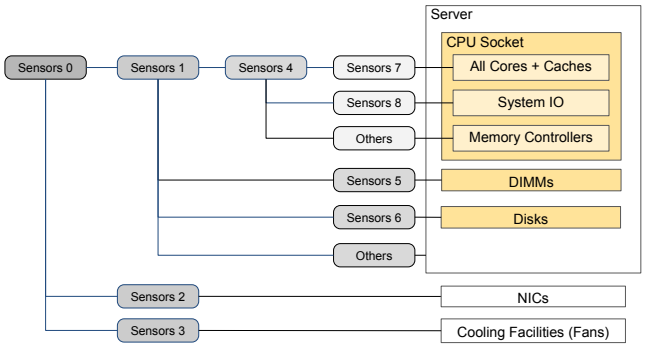


Figure 2: Telemetry sensors in Meta's datacenters. Sensors are deployed at different levels to measure power across different components and subsystems.

design and pre-silicon performance evaluation. In the *engineering validation test (EVT)* phase, where hardware is available, efforts shift to system bring-up and performance benchmarking. The subsequent *design validation test (DVT)* and *production validation test (PVT)* phases involve application testing, power planning, and production validation. During this period, servers are seamlessly equipped with baseboard management controllers (BMCs) to enable reliable power data collection through physical power sensors deployed at various system levels, as shown in Figure 2. After approximately nine months of extensive testing, the platform enters the mass production (MP) phase. Even during mass deployment, machine configurations – such as CPU frequency – are continuously tuned to maximize performance-per-Watt and overall energy efficiency (MP + 1 year).

Datacenter power distribution hierarchy: Figure 3 shows the hierarchical power distribution architecture in Meta's datacenters, which enables efficient power delivery and centralized management across the fleet. At the top, the main switch delivers up to ∼2.5 MW to IT equipment. Downstream, intermediate switchboards draw ∼1.25 MW each and feed multiple leaf-level panels, each sustaining up to ∼190 kW. These panels power tens of *heterogeneous* racks hosting diverse machine types hosting different services [27, 52].

Definition of design power: In datacenters, *power control is typically managed at higher aggregation points, such as main*

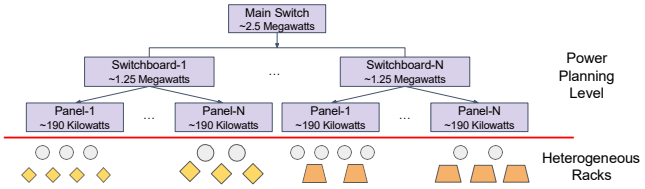

Figure 3: Power distribution hierarchy of the fleet.

switches, switchboards, or panels, rather than at individual racks [27, 52, 77]. This simplifies power management by reducing the number of monitored units. However, each rack still has a fixed power limit set by its electrical design, and the total power drawn by all components, including servers and the top-of-rack (TOR) switch, must stay within this limit. To enforce this constraint, datacenter operators define the concept of *design power*, denoted as D, which captures the peak power usage of all servers under the most demanding workload, plus overheads such as TOR switch power.

Definition of rack density: In datacenter power planning, an important metric alongside *design power* is *rack density*, defined as the maximum number of servers, denoted as n, that can be deployed without exceeding the *design power* of each rack. A typical method to calculate rack density involves three steps: (a) determine the peak server power, P_s, under the most power-intensive workload; (b) account for the power consumed by other rack components, such as TOR switch, P_{TOR}; and (c) calculate n accordingly: $n = (D - P_{\text{TOR}})/P_s$.

Definition of rack power budget: In practice, the *design power* of a rack is often unattainable, as not all services can fully stress every server component simultaneously [27, 34, 64, 77]. To this end, we define the *rack power budget* (RPB) as the expected power draw of a given rack type during peak traffic, accounting for worst-case fleet-level failure scenarios. We routinely update RPB throughout the hardware lifecycle (see Table 1) to optimize overall datacenter power utilization. Additionally, accurate RPB planning is essential for new hardware during the early stages of its lifecycle, as these initial estimates play a key role in determining whether additional datacenters are needed to support increased fleet capacity. *However, this process is challenging due to the lack of fleet-wide power sensor data before massive production.*

3 Understanding Power at Hyperscale

Leveraging fleet-wide performance counters and per-component power sensors available on recent platforms, we characterize the power consumption of hyperscale workloads in Meta's production datacenters. We cover experimental setup (§ 3.1), benchmarks vs. production services (§ 3.2), power variance across services (§ 3.3), cross-generational trends (§ 3.4), and performance-power correlations (§ 3.5).

Table 2: Machine configurations of all types of services (* denotes a variant configuration).

Service	CPU Gen	GPU Gen	Data Drive	# of configs
Compute	CPU-A, CPU-B, CPU-C, CPU-D, CPU-E	N/A	N/A	13
Storage	CPU-B*, CPU-C*, CPU-F	N/A	SSDs	10
AI (Inference)	CPU-C*, CPU-G	GPU-A, GPU-B	SSDs	9
AI (Training)	CPU-C*, CPU-F, CPU-H	GPU-A*, GPU-B*	SSDs	10

3.1 Experimental Setup

Our study focuses on hyperscale workloads running on millions of machines, encompassing thousands of services, from traditional web and network services [33, 34, 62, 63, 81] to AI-related workloads [50, 51, 65]. We specifically analyze the power consumption of in-production servers handling live production traffic spanning eight CPU generations (Intel Xeon and AMD EPYC architectures) and two GPU generations (GPU-A and GPU-B, corresponding to NVIDIA Ampere and Hopper architectures, respectively) running (general) compute, storage, and AI services[2]. We list machine configurations in Table 2 (further details are publicly available in the Open Compute Project [2]). Compute services run on nodes that have CPUs and boot drives (see Table 3). Storage services use servers equipped with flash devices. AI services, both inference and training, operate on hosts provisioned with GPUs. In total, we used 42 machine configurations with different combinations of core counts and socket counts, as well as cache and DRAM capacities to conduct our study[3].

We measured each service in the production environment under its default deployment configuration and collected system-level performance counters by running a lightweight daemon process *dynolog* on each production server [1]. This infrastructure setup allows us to query historical performance metrics data from a massive database that contains information from millions of machines. We read system module power from Sensor 0 (measuring module input power), server power from Sensor 1 (measuring server power including CPU sockets, DIMMs, and disks), and CPU socket power from Sensor 4 (measuring processor die power) using an internal datacenter-wide power management system that monitors the entire fleet power hierarchy [77], as labeled in Figure 2, which shows the physical placement of each sensor in the power delivery path.

[2]Each type of service is deployed on a specific cluster of machines, with each cluster having its own unique machine configuration.

[3]We did not count a machine configuration with different data drive capacity as a new configuration, but if considered, there would be over 100 distinct machine configurations in total.

Table 3: CPU configs across compute server generations.

CPU Gen	CPU-A	CPU-B	CPU-C	CPU-D	CPU-E
Year Deployed	2016	2018	2021	2022	2023
# of Cores	16	18	26	36	88
DRAM Tech	DDR4	DDR4	DDR4	DDR4	DDR5
DRAM Capacity	32	32	64	64	256
DRAM Channels	2	4	4	4	8
DRAM Speed	2133	2400	2666	2933	4800

3.2 Benchmarks vs Production Services

In the early stages of power planning, benchmarks are commonly used as proxies for in-production services to estimate system design power. However, standard benchmark suites often underestimate design power, as they fail to match the power intensity of hyperscale workloads. This section examines the differences in power characteristics between hyperscale services and conventional benchmarks.

From the thousands of services in the fleet, we select representative ones[4] to conduct in-depth case studies.

Compute Services: *Web1* and *Web2* are web servers implemented using HipHop Virtual Machine (HHVM) deployed across the fleet [5, 46, 61, 62, 81]. *Feed* is a key microservice for the News feed service [61, 62, 84]. *Ads* maintains user-specific data, ranks advertisements, and determines their retrieval order [61, 62]. *Video* is a service for video transcoding.

Storage Services: *UDB* is a user database service built on MySQL and deployed under a distributed data store architecture. *ZippyDB* is a distributed key-value store that builds on RocksDB to ensure data consistency and reliability [14].

Benchmarks: We use *SPEC CPU2017* [13, 18] to compare its performance and power characteristics with hyperscale workloads. If not specified, we run *int rate* using n copies, where n represents the number of cores in the system.

While *SPEC CPU2017* benchmarks are designed to represent a broad range of computing tasks, hyperscale workloads are tailored to specific applications and exhibit unique power consumption patterns. Figure 4 shows that *SPEC* workloads exhibit lower power consumption, whereas hyperscale workloads operate closer to the design power. On average, hyperscale workloads utilize 85.6% of design power, whereas *SPEC* workloads reach only 75.5%, approximately 11.8% lower in relative terms. In contrast, hyperscale workloads exhibit higher power consumption for (a) SoC non-core power, namely network-on-chip, system IO, and memory controller power; (b) memory power; and (c) other power such as network interface, rack top-of-switch power, and fan power. This is because hyperscale workloads typically have a larger in-

[4]The microservices deployed at Meta's datacenters follow a long-tail distribution, where a small subset of workloads accounts for the majority of hosts within a given rack type [67]. For instance, in the latest compute rack, the top ten workloads collectively occupy 55% of all hosts.

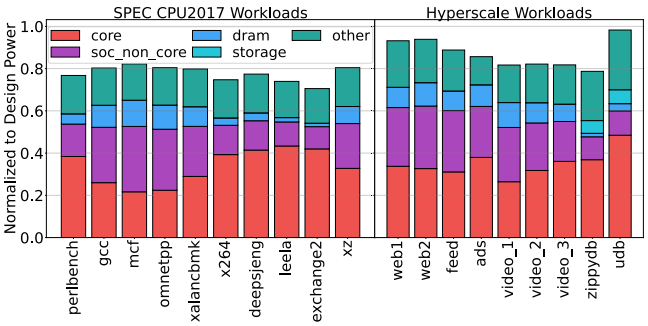

Figure 4: Power breakdown of *SPEC CPU2017* benchmarks and Hyperscale workloads. Hyperscale workloads consume similar core power but higher system power than *SPEC* benchmarks. On average, hyperscale workloads reach 85.60% of design power, whereas *SPEC* benchmarks reach only 75.51%.

struction footprint, which places greater demands on the memory subsystem [33, 43, 62].

Takeaway 1: (1) Conventional benchmarks, like *SPEC CPU2017*, can effectively measure core power consumption but often fail to capture the power profile of the whole system. (2) By leveraging live production data for power planning, we avoid underestimating design power by 11.8% compared to relying solely on standard benchmarks.

3.3 Power Variance Across Services

Instead of general-purpose benchmarks, we characterize the power consumption of production services. In Figure 5a, we show a snapshot of system power usage for thousands of live traffic services running on millions of machines in the fleet, including compute, storage, and AI services. Typically, services operate within 40-70% of their design power capacity. However, our analysis reveals that actual power consumption can fluctuate substantially, ranging from as low as 20% to as high as 90% of design power for different machine variants. The power variance shown in Figure 5a reflects both *inter-service* and *intra-service* differences. Different services can place varying demands on system components (e.g., a memory-intensive caching service vs. a compute-bound video transcoding service), and even instances of the same service can exhibit power variation due to regional load imbalances and hardware configuration differences. The significant variation in power consumption resulting from fluctuating system loads in commercial datacenters [27, 51, 52, 64, 65] highlights the importance of using data from the entire fleet to accurately characterize system power.

Takeaway 2: The system power varies significantly during runtime (varies between 20%-90% of the design power), which poses great challenges for datacenter RPB planning.

Challenges in RPB planning: Workload power consumption varies substantially, with different workloads using different proportions of their design power capacity (Figure 5a). Consequently, servers within a compute rack show considerable variation in power usage (Figure 5b). Notably, only about 85% of compute rack servers – similar to those in storage and AI racks – operate above 50% of their design power as shown in Figure 5b. This variability highlights a key limitation of relying solely on *design power* for datacenter power budgeting, as it can lead to underutilized power capacity and inefficient resource allocation. To address this, we continuously refine the RPB throughout the entire hardware lifecycle (§ 4).

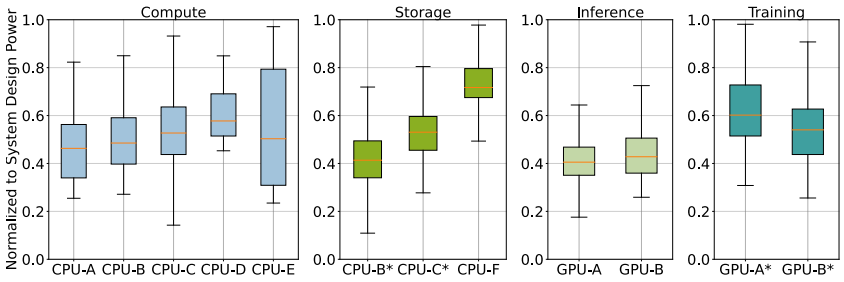
3.4 Power Trend Across Machine Generations

The characterization results in the previous section show that each machine generation in the fleet has its unique power characteristics, but there is also a noticeable trend across generations that can provide valuable insights for hardware architects planning future datacenter capacity. For instance, as shown in Figure 5a, newer machine generations like CPU-E exhibit increased variability in system power consumption. This wider spread is driven by the broader diversity of workload profiles supported by newer platforms – with significantly more cores (e.g., 88 cores in CPU-E vs. 18 in CPU-B) and memory channels. As a result, some services run compute-bound while others are memory- or I/O-dominant, leading to a wider range of component utilization levels and thus a wider power distribution even when normalized to design power.

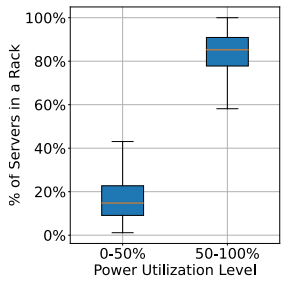
In addition to overall system power consumption, we also observe trends across machine generations for individual components within the system. Figure 6a shows the trend of CPU power consumption per unit of throughput (measured as committed instructions per time frame) across various machine generations. Our analysis reveals that as the number of cores increases across machine generations, the per-throughput socket power decreases. This trend is particularly prominent when comparing later machine generations, such as CPU-E, where we see nearly a 2× reduction in per-throughput CPU socket power compared to CPU-B (CPU-E has roughly 5× more cores than CPU-B and about 2.5× more cores than CPU-D). In contrast, components of the memory subsystem in servers did not improve at the same rate as cores (only 1.2× when comparing DDR5 versus DDR4, as shown in Figure 6b). As a result, there is a shift in power distribution across different system components over time.

Figures 7a (focus on compute servers) and Figures 7b (focus on AI training servers) illustrate the trend in system power breakdown for each component across machine generations. The proportion of memory components over system power has increased significantly over time[5]. Notably, the next-generation pre-production system, CPU-X and GPU-X (GPU-0 represents the previous decommissioned generation), exhibits an even more pronounced trend, indicating that mem-

[5]The only exception is the transition from GPU-A to GPU-B, where advancements in HBM technology enhanced power efficiency (the power efficiency of HBM3 has improved by more than 50% compared to HBM2 [36]).

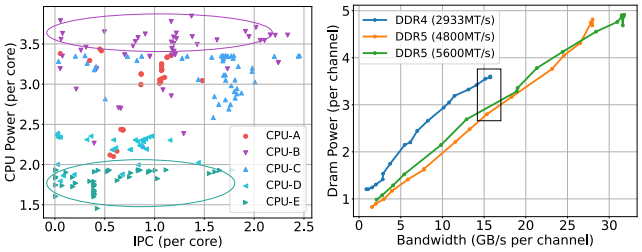


(a) Fleet-wide service system power distribution for all machine generations.



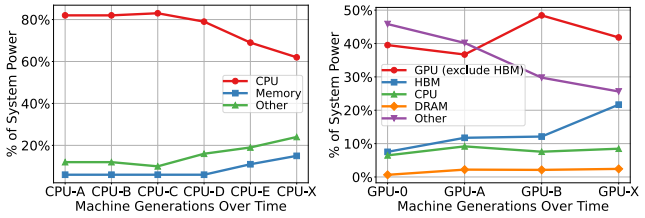
(b) Server distribution within a rack.

Figure 5: (a) Service power distribution across the fleet shows significant variability across all service types. (b) Server distribution within a compute rack with different levels of design power utilization. 15%+ of servers have relatively low power utilization (less than 50% of design power).



(a) CPU power. (b) Memory power.

Figure 6: CPU core power and memory power trend across machine generations at different performance levels. Core power drops by ∼2× in newer systems at the same IPC level (CPU-E vs. CPU-B), while memory power shows a more modest reduction of ∼1.2× when delivering equivalent bandwidth (DDR5 vs. DDR4).



(a) Components (Compute). (b) Components (AI Training).

Figure 7: System power breakdown across machine generations – (a) compute (Memory line) and (b) AI training servers (HBM line) – shows memory components contributing increasingly over time.

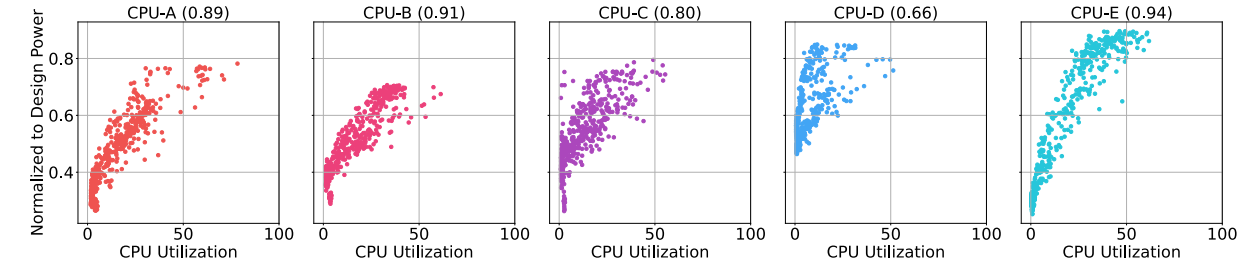
ory components will continue to play an increasingly important role in overall system power usage.

This trend has two competing effects on future power planning. On one hand, memory power exhibits a relatively stable relationship with bandwidth utilization (Figure 6b), which may simplify power prediction as a larger share of system power becomes more predictable. On the other hand, the growing memory power fraction suggests that memory-aware power management techniques will become increasingly important. The effectiveness of such techniques depends on workload characteristics, as different services place varying demands on the memory subsystem, and memory behavior of each workload may change over time [33, 43, 62]. This motivates program-phase-aware power management solutions that could, for example, dynamically reallocate power from the memory subsystem to CPUs or other components during memory-light phases, improving performance under the same power budget.

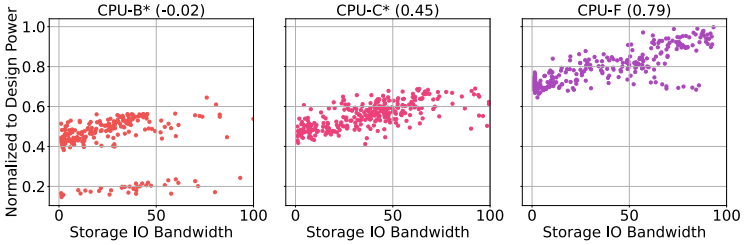
Takeaway 3: (1) The power efficiency of system components evolves at different rates. Over time, memory power has grown to form an increasing percentage of total system power (>20% in the latest generation), which presents both an opportunity (more predictable power fraction) and a challenge (need for memory-aware power management techniques) for datacenter power management. (2) Rather than focusing solely on CPU power, we include all system components in power planning across hardware lifecycles. In recent platform generations, we have added dedicated power sensors for the memory subsystem to account for the evolving hardware trend (see Figure 2).

3.5 Perf. Metrics – System Power Correlation

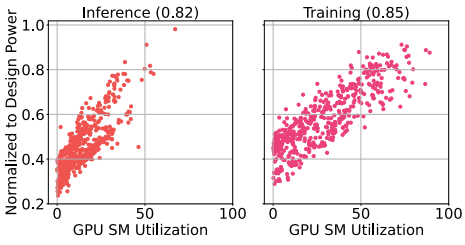
In addition to studying system power breakdown trends across machine generations, we analyze correlations between performance metrics and system power to gain deeper insights into the challenges of power modeling. We find that the system power is affected by multiple performance metrics, and this relationship differs across machine generations. For instance, in some generations like CPU-A, peak system power is reached at approximately 70% CPU utilization, whereas in others, such as CPU-E, peak power occurs at a much lower utilization level, around 40% (as shown in Figure 8a). One explanation for this is that newer CPUs optimize SoC power usage by maximizing frequency, which enables them to reach



(a) Correlations between CPU utilization and system power.



(b) Correlations between storage IO utilization and system power.



(c) GPU utilization and system power.

Figure 8: Fleet-wide correlations between CPU utilization, Storage IO bandwidth, GPU utilization, and system power. No single metric can decide the system power, and the correlation (listed in figure titles) changes across machine generations.

maximum power at lower utilization levels. The relationships between storage IO bandwidth, GPU SM utilization, and system power in storage and AI services also exhibit complex patterns, emphasizing the need for a multi-metric approach to accurately characterize system power.

Takeaway 4: (1) Modeling the power of an entire system requires multiple inputs beyond just the metrics of the main components (e.g., CPUs/GPUs), and thus firmware-level readings, such as NVIDIA Nsight Systems reporting only GPU power, are insufficient. *To address this, we deploy a lightweight daemon process dynolog [1] on each server to collect performance counters of all components in the system.* (2) It is unreliable to directly extrapolate power models from current systems to future platforms. *A holistic power model capable of predicting the power consumption of future compute, storage, and AI servers is necessary to support the hardware heterogeneity in datacenters [15, 52].*

4 Hardware Lifecycle-aware Power Planning

Having characterized power at the individual machine level (§ 3), we turn to higher-level planning. Although each service and machine exhibits a distinct power profile, effective datacenter power planning requires decisions at coarser granularities, such as the rack. To address this, we have developed a methodology for oversubscribing rack power across the hardware lifecycle, accounting for both workload and hardware heterogeneity (§ 4.1). In early deployment stages, however, power sensors may not yet be available, necessitating a cross-architecture model for power prediction (§ 4.2).

4.1 Oversubscribe RPB across Hardware Lifecycles

The wide variation in power consumption across machines and services (Figure 5a) demonstrates the drawbacks of relying solely on design power for capacity planning, as this results in stranded power capacity throughout the fleet. In practice, all machines within a rack rarely operate at their peak power simultaneously (Figure 5b). Consequently, datacenter planners can safely set the RPB below design power, which improves overall power utilization across the fleet. Setting the right RPB requires balancing multiple competing constraints. If the RPB is set too low, more racks are placed under each power device, and aggregate power draw may exceed upstream device limits (RPP, SB, MSB), which triggers power capping [23, 77] and degrades both performance and efficiency. Conversely, an RPB set too high leaves provisioned power capacity unused, requiring more datacenters to be built for the same total compute capacity, which raises costs and environmental impact. In this section, we present our RPB planning methodology, deployed at scale for over a decade, that spans the full hardware lifecycle from early design through production optimization.

Forecast RPB (Pre-EVT/EVT/DVT): In the early stages of hardware lifecycles, datacenter planners must estimate the RPB to anticipate future power demands as machines begin to arrive. Accurate forecasting is critical: (a) underestimating forecasted RPB means deployed racks may exceed the power provisioned for their location, forcing a late RPB increase that reduces rack density per power device and necessitating rack relocations to stay within device limits; (b) overestimating

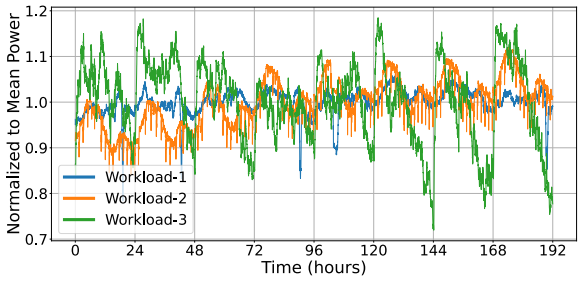


Figure 9: Power variance of three top services over a week. Each workload reaches its peak power at different time.

RPB under-projects compute density, potentially triggering unnecessary datacenter construction. Without measured data, this projection relies on the maximum power ratings defined in the electrical specifications of each rack, adjusted using derating factors based on historical experience.

Initial RPB (PVT/MP): Once systems are delivered, we work with service owners, who have detailed knowledge of their workloads, to determine the RPB. Service owners first conduct load tests to identify the highest sustainable load before performance degradation occurs. They then measure the utilization of the most critical resource (e.g., CPU, GPU, or disk), referred to as the target utilization, for that specific rack type. We use values supplied by service owners to calculate the power budget for each service. By generating a power-versus-utilization curve for every workload and applying the target utilization value, we determine the corresponding power demand, denoted as p_w. In addition to p_w, we also calculate a weighted average distribution of each workload within the rack, denoted as f_w. Finally, we derive the RPB (Equation 1)[6], where each w denotes a distinct workload, n indicates the number of hosts and P_{TOR} represents additional power consumed by TOR switches.

$$RPB = \sum_{w=0}^{W-1} (f_w \times p_w) \times n + P_{\text{TOR}} \tag{1}$$

Refined RPB (MP+1 year): The initial RPB would be sufficient if all services deployed within a rack reach their peak power consumption simultaneously. However, this rarely happens even during peak periods under worst-case failure scenarios due to the workload heterogeneity [27]. To illustrate this, Figure 9 presents the system power consumption of three key workloads over one week. The data shows that peak power periods for individual workloads typically do not overlap, enabling opportunities for power *oversubscription* and creating a "power buffer" that can be leveraged to optimize power allocation. This buffer cannot be identified during initial RPB planning, as only a limited number of services can be profiled and proxy data may have to be used in the absence of fleet-wide production traffic. To quantify the size of this power buffer, we introduce a metric called the inter-workload max correlation score, denoted as *CR* (Equation 2).

$$CR = \frac{\sum_{i=0}^{W} \max_{0 \le t < T} w_{i,t}}{\max_{0 \le t < T} \sum_{i=0}^{W} w_{i,t}} \tag{2}$$

The numerator sums the worst-case power consumption of each workload (w) over a given time window ($0 \le t < T$), without considering when these peaks occur. The denominator captures the maximum total power drawn by all workloads at any single point in time within that window. Because peak power demands of different workloads usually occur at different times, the *CR* is typically greater than one. A higher *CR* reflects a larger "power buffer", introducing opportunities for power oversubscription without violating power constraints. We refine the RPB[7] formula by including the *CR* as follows:

$$RPB = \frac{\sum_{w=0}^{W-1} (f_w \times p_w)}{CR} \times n + P_{\text{TOR}} \tag{3}$$

The refined RPB in Equation 3 incorporates the power oversubscription principles from Equation 1 and Equation 2. It first addresses spatial power oversubscription, which involves the distribution of power usage across various workloads operating on different servers (see Equation 1 and Figure 5b). Additionally, it accounts for temporal power oversubscription, considering the timing and occurrence of peak power consumption events (see Equation 2 and Figure 9).

The refined RPB methodology allows us to expand overall fleet capacity. As illustrated in Figure 10, we compare design power with both forecast RPB and refined RPB across various rack types. By using forecast RPB, the fleet can achieve a 13% power oversubscription compared to using only design power. Furthermore, the refined RPB enables safe power oversubscription by an additional 11% beyond the forecast power budget, across compute, storage, and AI racks. This increased power oversubscription unlocks additional datacenter capacity, so more racks can be installed within the constraints of the power devices (see Figure 3). As a result, this approach allows us to make better use of the existing power capacity within our current fleet and reduces the need to construct new datacenters in the future.

Notably, this methodology has proven robust even as the fleet's workload mix evolved over time [16, 58, 69, 79]. The anticipated growth of AI training and inference workloads would not fundamentally alter our power planning methodology, but would introduce new rack types (AI training and inference) with distinct power profiles. The core refined RPB methodology applies uniformly across compute, storage, and

[6] The weighted-average f_w in Equation 1 reflects the planned workload distribution for each rack type, enforced by scheduling systems such as SmoothOperator [27] that actively prevent "hot rack" scenarios. The target utilization used to derive p_w is set conservatively based on load-test peaks, and the refined RPB (Equation 3) further guards against worst-case temporal alignment through the *CR* metric.

[7] Since it relies on fleet-wide historical service load and power data, the decision making of the refined RPB is deferred until MP+1 year.

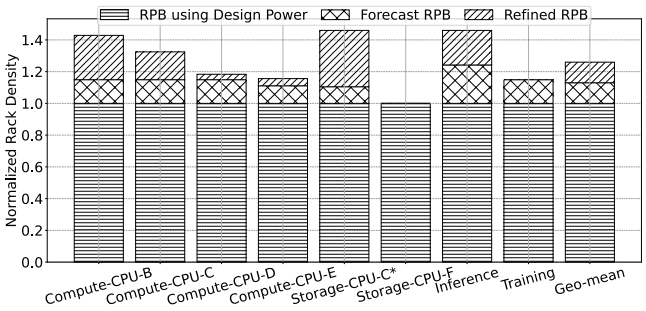

Figure 10: Lifecyle-aware RPB planning expands the fleet capacity. Using the forecast RPB increases rack density by 13% compared to design power (middle shade), while the refined RPB provides an additional 11% gain over the forecast RPB (top shade).

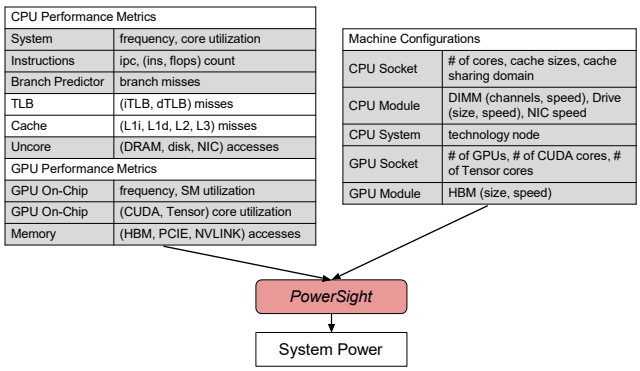

Figure 11: Performance metrics and machine configurations (input) to predict system power (output) for *PowerSight*. Highlights are representative input features (less than 0.1% accuracy loss compared using the full set).

AI racks. However, AI workloads introduce two main differences: (1) GPU-dominated racks may exhibit less temporal power variance than CPU-dominated racks as training jobs sustain high utilization for longer periods, resulting in lower CR values; and (2) the introduction of AI racks increased overall fleet heterogeneity, reinforcing the need for a cross-architecture power model that can generalize across compute, storage, and AI servers (§ 5).

Beyond power budgeting, the refined RPB approach is also compatible with workload placement and scheduling strategies, such as SmoothOperator [27] and Twine [70]. In addition to initial workload placement, our refined RPB approach considers the entire hardware lifecycle. As service loads fluctuate over time, we periodically adjust the RPB, even after mass production (MP + 1 year), to ensure continued alignment with evolving workload demands. Additionally, by taking advantage of rack heterogeneity (each power device can accommodate different types of racks, as illustrated in Figure 3), the refined RPB allows each power panel to support more racks while reducing power fragmentation.

4.2 System Power Forecasting is Necessary

While the refined RPB has enabled provisioning of approximately 20% more racks in our global fleet (based on the weighted average of power oversubscription and rack power footprints), it has a key limitation: it requires (a) fleet-wide workload information to determine f_w and (b) ground-truth power readings from sensors to determine p_w, which would not be available at early stages of hardware lifecycles.

Accurate RPB estimation is essential for effective datacenter power planning, even during the early stages of the hardware lifecycle. Unlike service-demand variance, which determines how many servers are needed, RPB accuracy determines how many racks fit within fixed power infrastructure – even a few percentage points of overestimation can translate to thousands of fewer racks fleet-wide, making it a critical input to datacenter capacity planning. Currently, *our power budget model requires power sensor data, which typically becomes available only in later phases (DVT/PVT).* However, the RPB must be determined much earlier to guide datacenter layout and support decisions such as whether to build new datacenters, a process that takes years. We introduce *PowerSight*, a system that forecasts power consumption without power sensors during the early hardware lifecycle stages (§ 5).

5 Future Power Budgeting Practice

Commercial datacenter planners need to make early tradeoffs between power and performance of future systems to mitigate the risk of selecting a power-inefficient configuration. In this section, we present our practice on power budgeting for future machine generations at earlier phases of hardware lifecycles, where power sensor readings are generally not available (before DVT/PVT phases).

As discussed in Table 1, machine configurations are finalized at pre-EVT (2–3 years before mass production), while engineering samples with calibrated power sensors typically become available only at DVT (6 months before mass production). To bridge this 12–18 month gap, we introduce *PowerSight* (§ 5.1), an ML-based power model to predict system power consumption of compute, storage, and AI servers (§ 5.2). *PowerSight can be easily deployed at scale, as it requires only machine configuration and performance counter data—both of which can be collected with minimal performance overhead using existing datacenter infrastructure [30, 31, 75], and are obtainable from early EVT samples before reliable power sensor data exists. PowerSight* can also facilitate informed decision-making during future system power planning (§ 5.3).

5.1 *PowerSight* Overview

5.1.1 *PowerSight* Prediction Target

The primary objective of *PowerSight* is to accurately predict machine system power (a continuous numerical value). We formulate this as a regression problem and train ML-based models for prediction.

5.1.2 *PowerSight* Inputs and Outputs

PowerSight takes both workload and machine characteristics as inputs (as our characterization results in § 3.5 show that the system power is determined by multiple factors) to predict system power consumption as its output. Figure 11 shows the different machine characteristics and performance events that *PowerSight* is built upon, all of which can be collected efficiently with minimal overhead using existing datacenter performance monitoring infrastructures [1, 30, 31, 75]. To enable large-scale deployment in production environments, we excluded kernel-level GPU performance counters, as profiling such events incurs significant runtime profiling overhead [26, 66, 78]. To model system power more accurately, we include DRAM/HBM, drives, and network accesses in addition to core performance metrics used in prior studies [82]. For machine configurations, we consider a comprehensive range of features to include not only the core architecture characteristics but also other non-core properties. Using these inputs, *PowerSight* employs an ML-based regression model to predict system power as its output.

Input Feature Selection: To improve accuracy while keeping training effort manageable (retraining or fine-tuning *PowerSight* can further enhance accuracy, more in § 5.2.5), we carefully choose the input features. Although incorporating more performance metrics into ML models can generally improve accuracy, prior research has shown that many performance counters are strongly correlated [12, 40, 54], indicating that not all features contribute equally to power prediction[8]. We apply principal component analysis-based clustering methods [38, 48, 54] to select a representative subset of input features (as highlighted in Figure 11). This approach achieves nearly the same accuracy – within 0.1% difference – as using the full set of input features.

5.1.3 *PowerSight* Machine Learning Formulation

To accurately predict system power using ML-based regression models, *PowerSight* requires selecting the most suitable regression model and training on high-quality datasets.

ML Model Type: We evaluate six common ML models used in performance and power modeling to predict system power consumption [3, 7, 83], including *Lasso Regression (Lasso), Ridge Regression (Ridge), SVM Regression (SVR), Decision Tree Regression (DT), Gradient Boosting Decision Tree Regression (GBDT), and MLP Regression (MLP)*. Our evaluation process consists of three stages. Initially, we evaluate each model by using it to predict system-level power for the same generation of hardware on which it was trained, providing a preliminary assessment of its accuracy. This initial evaluation helps us narrow down our selection to the top-performing models, specifically DT, GBDT, and MLP (§ 5.2.3). Next, we expand our evaluation to assess the performance of models across multiple generations for all compute, storage, and AI services. This step allows us to evaluate the robustness of *PowerSight* (§ 5.2.4). Finally, we conduct a rigorous test by evaluating the model on a machine generation it has never seen before. Based on this ultimate evaluation, we select MLP as the ML model for *PowerSight* (§ 5.2.5).

ML Model Training Dataset: We demonstrate the effectiveness of *PowerSight* by leveraging a vast dataset, collected by existing datacenter performance monitoring infrastructures [1, 30, 31, 75]. The dataset comprises real-world data from in-production services running on millions of diverse machines (more in § 5.2.2). This comprehensive dataset enables *PowerSight* to achieve good accuracy.

5.2 Training and Evaluating *PowerSight*

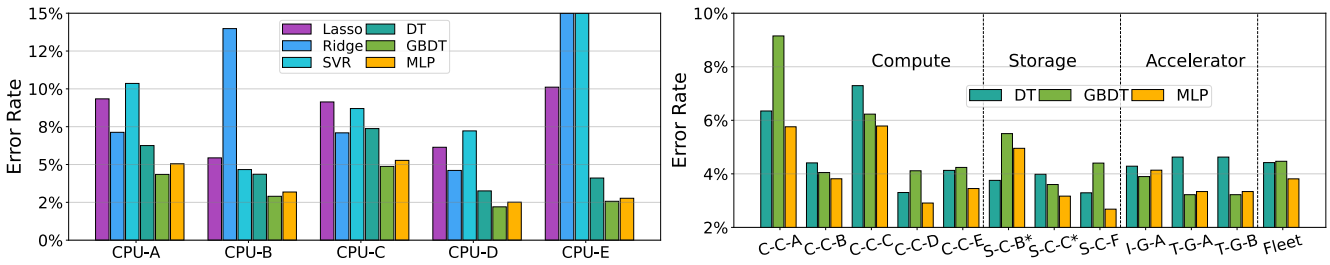
5.2.1 Training Methodology

To optimize the performance of each model, we use a *grid search* approach to select the most suitable model parameters that yield good accuracy. We train the models on live production data from actual measurements of performance counters and power sensors. At fleet scale, such data inevitably contains measurement noise–including temperature-related variance across server locations, manufacturing variability across silicon batches, and sensor calibration differences across BMC firmware versions. We mitigate these effects by aggregating across thousands of machines per configuration and applying standard data cleaning (e.g., removing outliers). As shown in § 5.2.2, the scale of our dataset provides inherent robustness against per-machine noise. To evaluate the accuracy of the models, we use data from separate days that was not used during training. This ensures that our evaluation is robust and unbiased, providing a true assessment of the predictive capability of each model.

5.2.2 *PowerSight* Training Dataset

The accuracy of a machine learning model depends heavily on the training dataset size. *PowerSight* leverages an extensive dataset consisting of millions of in-production data points collected from the entire datacenter fleet, which allows *PowerSight* to achieve high accuracy in predicting system power.

[8] There is also an opposite case where profiling and training overhead can be ignored while accuracy is the top priority. However, this is not the focus of this paper, as fleet-wide increasing even one counter would result in significant storage overhead when deploying *PowerSight* at scale.



(a) Single architecture.

(b) Multiple architectures.

Figure 12: System power prediction error rate (MAPE) of (a) trained and test on the same architecture; (b) train on all types of services and test on each architecture. DT, GBDT, and MLP achieve better accuracy than Lasso, Ridge, and SVM.

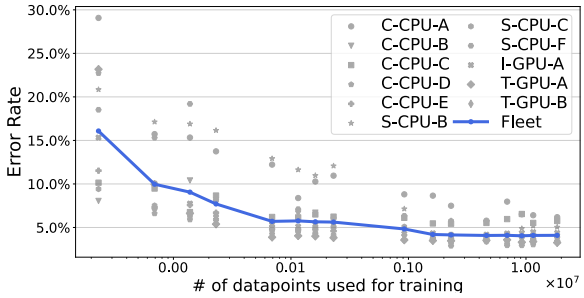


Figure 13: System power prediction MAPE (on testing dataset) when training *PowerSight* using different number of data points. The accuracy improves with more data points.

To demonstrate the effect of dataset size on model accuracy, we train *PowerSight* using varying numbers of data points from our entire fleet and present the results in Figure 13. Our analysis reveals that expanding the training dataset leads to significant improvements in the accuracy of *PowerSight*. However, when the model is trained with relatively small datasets (tens of thousands of data points), it yields a system power prediction error rate of over 10%. To attain optimal performance, we recommend training the model with at least several million data points. This ensures *PowerSight* uses sufficient data to learn effectively and make accurate predictions.

5.2.3 Single-Architecture Power Prediction

We begin with the simplest evaluation scenario: predicting system-level power for a single architecture, where the model is trained and tested on the same generation. Figure 12a shows the prediction error rate for all machine generations running compute services.

Among the six ML models, DT, GBDT, and MLP consistently outperform Lasso, Ridge, and SVM across all machine generations. DT, GBDT, and MLP achieve above 95% system power prediction accuracy for all machine generations. This is because prior works have shown that the power model may exhibit non-linear correlations between performance metrics [12] and linear regression models are particularly sensitive to the variability introduced by multiple machine configurations [9, 11]. Although SVM achieves good accuracy, its training time complexity increases quadratically with the number of samples, making it difficult to scale to large datasets with millions of data points (we had to subsample only 1% of the data to train SVM for this evaluation). Given that the accuracy of *PowerSight* benefits from using a large dataset with millions of in-production data points (more in § 5.2.2), the scalability limitations of SVM make it less suitable for this application. Therefore, DT, GBDT, and MLP are more effective for power prediction compared to other linear and support vector models, and we use these three models for our later analysis in this section.

5.2.4 Multiple-Architecture Power Prediction

As DT, GBDT, and MLP demonstrate better accuracy for single-architecture power prediction, we evaluate these three ML models using the fleet-wide data for all machine generations. We show the mean absolute percentage error (MAPE) of each model for all types of services (Figure 12b).

When applying the three models for all compute, storage, and AI services, all three models achieve good system power prediction accuracy (MLP achieves 96.19% accuracy, while DT and GBDT achieve 95.59% and 95.53% accuracy, respectively). This is consistent with their robustness to outliers, as also observed when training on individual machine generations. The tens of machine configurations (Table 2) introduce additional noise into the data, but neural network methods (MLP) can improve generalization by reducing overfitting compared to tree-based methodologies (DT and GBDT) [12, 19, 82]. In addition, the good accuracy of MLP can be attributed to the large dataset, comprising millions of data points across thousands of services and tens of machine configurations.

5.2.5 Predicting the power of a new system

To further assess the effectiveness of *PowerSight*, we evaluate and compare the performance of DT, GBDT, and MLP by predicting the system power of an inference platform

Table 4: Comparing ML models in predicting the power of existing architectures but new workload and new architectures unseen in the training set. MLP achieves the best accuracy.

Prediction Scenario	Model	Error Rate
Existing Architectures New Workload	DT	4.41%
	GBDT	4.47%
	MLP	3.81%
New Architecture New Workload	DT	9.39%
	GBDT	11.26%
	MLP	7.89%

equipped with CPU-H and GPU-B. Notably, these components were not included in our training dataset, which makes this evaluation a robust assessment of the ability of *PowerSight* to generalize to new scenarios. Specifically, CPU-H features significant upgrades compared to CPU-E, including more cores and increased memory bandwidth. Meanwhile, GPU-B also has different HBM configurations compared with GPU-B*.

We compare the performance of different ML models in two scenarios: predicting power consumption for existing architectures (top part of Table 4) and predicting power consumption for a new, unseen system not included in the training data (bottom part of Table 4)[9]. The results indicate that MLP achieves the highest accuracy in both cases, as it is capable of learning complex, nonlinear relationships between features when provided with enough data [60]. Given its robust performance in predicting system power across different machine generations, including those not seen during training, we ultimately select MLP as the ML model for *PowerSight*. Its ability to generalize well across various architectures and workloads makes it an ideal choice for our system power prediction framework.

5.3 Use Cases of *PowerSight*

In this section, we present case studies demonstrating how *PowerSight* supports future power budget projections in datacenters. *PowerSight* can be used to estimate the rack density (§ 5.3.1), estimate the rack power budget (§ 5.3.2), and identify optimal system configurations based on performance-per-Watt (Perf/W) metrics (§ 5.3.3) during the early phases of hardware lifecycles.

5.3.1 Rack Density

PowerSight can help estimate rack density during the pre-production phase, specifically *before the availability of power telemetry in the DVT/PVT stage.* Using *PowerSight* at this early stage allows datacenter planners to expedite rack demand projections and purchase planning, reducing the wait time by several months. We validate rack density prediction by training *PowerSight* on all machine generations except CPU-E and comparing its predictions against the current CPU-E planning. We use the vendor-labeled power for P_{TOR} (defined in § 2) as prior knowledge. Eventually, *PowerSight* can predict the rack design power with an average error rate (MAPE) of 1.7%, which results in an estimate of n with an error of 8.7%.

Although *PowerSight* may overestimate or underestimate power, which results in fewer or more machines per rack than ideal, these estimates are sufficiently accurate to guide early-stage power planning. When power is overestimated and fewer servers are deployed than necessary, it is relatively straightforward to add more servers to a rack during the mass production phase[10]. Conversely, if power is underestimated, datacenter planners can utilize techniques such as DVFS or other methods to further expand the planned capacity [52, 62].

5.3.2 Rack Power Budget

In addition to rack density, *PowerSight* can also be used to estimate the RPB early in the PVT phase. Before power telemetry is available, *PowerSight* can predict the p_w in the RPB formula $RPB = \sum_{w=0}^{W-1}(f_w \times p_w) \times n + P_{\text{TOR}}$ (details in § 4.1). We use the same P_{TOR} and n as when predicting the rack density using *PowerSight* (§ 5.3.1). We use the fraction of hosts for a given workload, f_w, based on the previous hardware generation as prior knowledge. With all information, *PowerSight* can predict p_w for each of the workloads and eventually predict the *RPB*. Finally, *PowerSight* achieves an *RPB* prediction with a 2.5% error, demonstrating its capability to be incorporated into the production flow. This level of accuracy provides datacenter planners with reliable guidance, such as determining whether new datacenters need to be constructed.

5.3.3 System Configuration

PowerSight can also be used within the same machine generation to identify a more efficient system configuration, e.g., searching for the optimal core frequency to maximize Perf/W.

Within a fixed power budget per rack, datacenter planners can use Dynamic Voltage and Frequency Scaling (DVFS) to optimize energy efficiency [34, 52, 62, 64]. One approach to achieving this is to sweep through all frequencies of a workload to identify the most efficient one. However, given the thousands of services running in a datacenter fleet, it is impractical to perform such a sweep study for every case.

[9] Results in Table 4 indicate a slight decrease in accuracy for newer systems, primarily because *PowerSight* is trained without vendor-specific hardware information. Once power sensor data from new platforms becomes available, we retrain the model to prevent such error accumulation.

[10] We adopt a conservative strategy by initially setting a higher RPB to accommodate unexpected increases. This approach is preferred because raising RPB later may require physically relocating many racks, which is operationally costly.

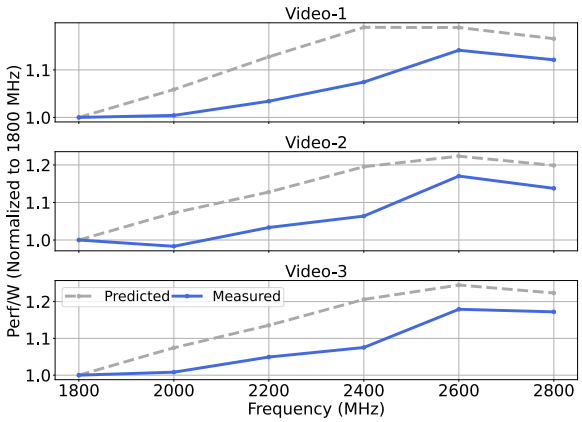

Figure 14: *PowerSight* can predict most Perf/W efficient frequency. While the absolute power has errors, *PowerSight* effectively captures the trend across different frequencies.

To address this challenge, *PowerSight* can predict the Perf/W of each workload based on its performance metrics at its current frequency. We verify this capability by using the *Video* workload as an example. As shown in Figure 14, real measurements indicate that 2.6 GHz is the most energy-efficient frequency for this workload. *PowerSight* predicts the most Perf/W efficient frequency as 2.4GHz-2.8GHz, closely aligning with the actual optimal value. In production environments, this prediction can serve as a starting point for fine-tuning frequency within a narrow range. This significantly streamlines the optimization process, enabling datacenter planners to efficiently identify the optimal frequency (or other system configurations) for each workload.

6 Related Work

Datacenter Power: Although prior studies have examined both machine-level [20, 28, 39, 41, 42, 62, 83] and rack-level [21, 55, 57, 59, 77, 80] power budgeting in datacenters, they largely focus on improving workload energy efficiency but overlook the impact of hardware and workload heterogeneity. Although some studies, such as SmoothOperator [27], have touched on workload heterogeneity, we are the first to introduce the concept of *hardware lifecycles* and a power budgeting methodology that can be adapted across different lifecycle phases.

Workload Coverage: Previous studies have primarily focused on power of specific workloads. For instance, works such as [23, 27, 34, 35, 64] studied general benchmarks and web services, while others [50, 65] targeted large language models. Our study encompasses thousands of AI and non-AI services, evaluated under live production traffic at scale across datacenters with millions of machines.

Power Modeling: Prior works have focused on predicting the power of either CPUs [17, 29, 37, 47, 49, 53, 71] or GPUs [6, 32, 45, 76]. Though a few have discussed the entire system power, these analyses were limited to either small-scale systems or existing machine generations [12, 19, 82]. Although using Running Average Power Limit (RAPL) counters is another common approach to estimate power, RAPL is not supported by all vendors and may omit components such as system voltage regulators [8]. *PowerSight* takes a more holistic approach by considering the power of the entire system, including memory, storage, accelerator, and other components. *Additionally, we are the first to demonstrate the real use cases of machine learning for power modeling by incorporating the context of hardware lifecycles in datacenters, particularly when power sensors are unavailable.*

Our work is distinct from prior studies: we are the first to (a) present a comprehensive power characterization study across machine generations, showing how these insights can guide power planning at scale; (b) introduce the concept of hardware lifecycle in datacenters, showing how power planning is tailored to the specific characteristics of the heterogeneous hardware and workload in each phase; and (c) employ ML-based models for early-stage datacenter power budgeting before power sensor data is available, and provide case studies on future power budget strategies.

7 Conclusion

As commercial hyperscale datacenters continue to grow, power planning must account for multiple hardware generations and their lifecycles. In this paper, we first present a comprehensive power characterization on hyperscale workloads, based on measurements collected from thousands of services using live production traffic across generations of servers in Meta's datacenters. We present our hardware *lifecycle-aware* datacenter power planning strategies leveraging characterization insights, enabling us to achieve large-scale power oversubscription. We also introduce *PowerSight*, which employs ML-based models to predict system power consumption for early-stage datacenter power budgeting, even before power sensor data is available. Our ultimate goal is to advance sustainable hyperscale datacenters that meet growing computing demands while minimizing environmental impact.

Acknowledgment

The authors would like to thank the anonymous reviewers for their constructive feedback. We would like to thank the current and former Meta engineers who contributed to this project, especially Vjekoslav Svilan. We also thank Kalyan Subramanian, Shobhit Kanaujia, and Chunqiang (CQ) Tang for the management support.

Kareus: Joint Reduction of Dynamic and Static Energy in Large Model Training

Ruofan Wu Jae-Won Chung Mosharaf Chowdhury
University of Michigan

Abstract

The computing demand of AI is growing at an unprecedented rate, but energy supply is not keeping pace. As a result, energy has become an expensive and contended resource that requires explicit management and optimization. Although recent works have made significant progress in large model training optimization, they focus on optimizing either dynamic or static energy consumption.

We find that fine-grained kernel scheduling and frequency scaling *jointly* and *interdependently* impact both dynamic and static energy consumption. Based on this finding, we design Kareus, a training system that pushes the time–energy tradeoff frontier by optimizing both aspects. Kareus decomposes the intractable joint optimization problem into local, partition-based subproblems. It then uses a multi-pass multi-objective optimization algorithm to find execution schedules that push the time–energy tradeoff frontier. Compared to the state of the art, Kareus reduces training energy by up to 28.3% at the same training time, or reduces training time by up to 27.5% at the same energy consumption.[1]

1 Introduction

Today, energy is the ultimate bottleneck for scaling AI [7, 31, 42]. The energy demand of training large models and serving them to millions is growing at an unprecedented rate [21, 33, 37], with projections indicating that by 2035, nearly 10% of US electricity demand could be from datacenters [31]. However, procuring energy at scale is slow, e.g., three years for natural gas and five to ten years for nuclear [46]. This mismatch makes energy an expensive and contended resource that must be explicitly budgeted, managed, and allocated with efficient systems and optimization methods.

In this context, large model training is a key target for optimization; a single training run can consume enough energy to power more than 24,000 average US households for a month [1, 33]. To understand the current state of large model training optimizations, we analyze them through the lens of *dynamic* energy (consumed by actual work) and *static* energy (consumed at all times regardless of work) consumption of GPUs (§2). Practically, dynamic energy can be reduced by lowering GPU frequency or activity, while static energy can be reduced by shortening iteration time. Perseus [15] reduces dynamic energy by scaling the frequency of computations off the critical path, but does not reschedule kernels. Recent works in fine-grained kernel scheduling [18, 20, 48, 49, 57] reduce static energy by overlapping computation and communication, but they ignore dynamic energy and frequency scaling. Therefore, we ask: can we combine both approaches to *jointly* reduce dynamic and static energy?

To answer this question, we study how *execution schedules* affect the time and energy consumption of large model training (§3). Any large model training iteration boils down to computation and communication kernels launched on the GPU. We define an *execution schedule* as the combination of three factors: (1) the *timing* of when communication kernels are launched within a sequence of computation kernels, (2) the *number of GPU Streaming Multiprocessors (SMs)* allocated to communication kernels, and (3) the *GPU frequency*.

We demonstrate that these factors *jointly* and *interdependently* determine time and energy consumption. Different execution schedules lead to different time and energy consumption—varying by as much as 3.29×—even when the total amount of work remains the same. The optimal schedule is achieved by carefully balancing the resource consumption of computation and communication kernels, which depends on the interplay of all three factors. Crucially, *the best SM allocation and kernel launch timing depend on GPU frequency*; even for the same sequence of kernels, we cannot use the same SM allocation and launch timing at different frequencies. Intuitively, frequency changes how overlapping kernels contend for resources: lowering frequency slows computation while leaving memory and communication bandwidth largely unchanged, thereby reshaping the optimal SM allocation and kernel launch timing. Existing solutions for kernel scheduling [18, 20, 48, 49, 57] and frequency scaling [15] optimize disjoint subsets of these factors, and combining them naively is suboptimal for pushing the time–energy tradeoff frontier.

Based on these observations, we present *Kareus*, an energy-efficient large model training system that automatically finds the best execution schedule by jointly optimizing SM allocation, launch timing, and GPU frequency (§4). For all kernels in the training iteration, it identifies (1) the right number of SMs for communication kernels, and (2) the right amount of computation–communication overlap, both in a frequency-specific manner. A collateral benefit is that executions on the critical path also speeds up due to improved overlap, reducing training time and thus shifting the entire time–energy tradeoff frontier toward the origin.

[1] Kareus is open-source at https://github.com/ml-energy/kareus.

Unfortunately, jointly optimizing all three factors via exhaustive search is impractical. The search space is prohibitively large to profile each configuration. Worse, profiling heats up the GPU, and without sufficient cooling intervals, one configuration's measurement affects subsequent ones.

Kareus addresses these challenges by introducing the *partitioned overlap* execution model. The execution graphs of forward and backward passes are divided into fixed partitions, decomposing the global optimization problem into local subproblems. Partitioned overlap generalizes recent *nanobatching* techniques [18,20,48,49,57] and adds fine-grained control over all three execution schedule factors, enabling precise control over the overlap between each communication kernel and its surrounding computation. For each partition, Kareus uses a multi-pass multi-objective optimization algorithm to identify candidates on the time–energy tradeoff frontier. It then hierarchically composes local (partition-level) frontiers into a global (iteration-level) one for the entire training iteration.

We implement Kareus by integrating with Perseus [15] and Megatron-LM [35] (§5). Kareus's optimizer is informed by time and energy profiling results from our *thermally stable* profiler, which minimizes thermal interference between different configurations during profiling. Once the best execution schedule is identified, Kareus interacts with Perseus and Megatron-LM to realize the plan throughout the entire training execution.

We evaluate Kareus across 14 representative workloads, including real testbed training on Llama 3.2 3B and Qwen 3 1.7B, and large-scale emulation on Llama 3.3 70B (§6). Compared to the state-of-the-art Perseus, Kareus reduces energy by up to 28.3% under the same time budget, or reduces time by up to 27.5% under the same energy budget.

In summary, we make the following contributions:

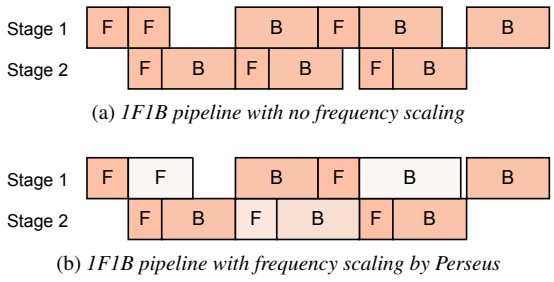
- We show that SM allocation, launch timing, and GPU frequency jointly determine time and energy consumption, and that existing solutions optimizing subsets of these factors and naive combinations thereof are suboptimal.
- We design Kareus around the *partitioned overlap* execution model, decomposing the global optimization problem into tractable local subproblems.
- We evaluate Kareus on large model training workloads, demonstrating significant time and energy reduction compared to the state-of-the-art.

2 Background

We begin by providing a brief background on GPU power consumption (§2.1). Then, we compare existing training systems in terms of their goals and techniques (§2.2), and discuss implications for training iteration time and energy (§2.3).

2.1 GPU Power Consumption

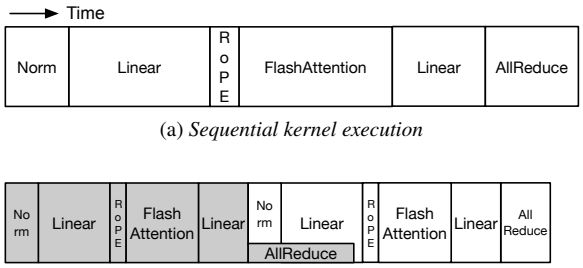
A GPU's power consumption can be divided into two components: *dynamic power and static power* [15, 32, 41]. Dynamic power is the power consumed by the chip's *compute and memory activity*; it is proportional to core frequency and the square of voltage. In contrast, static power is consumed by *all parts of the chip* at all times regardless of utilization or activity.



(a) *1F1B pipeline with no frequency scaling*

(b) *1F1B pipeline with frequency scaling by Perseus*

Figure 1: ***Existing training systems running the 1F1B pipeline schedule [35]. Redder colors indicate higher GPU frequency and power draw. (a) Megatron-LM [35] does not perform any frequency scaling, whereas (b) Perseus [15] scales GPU frequencies of non-critical forward and backward computations to reduce energy consumption while maintaining the same latency.***



(a) *Sequential kernel execution*

(b) *Nanobatching*

Figure 2: ***Transformer [47] Attention layer with tensor parallelism run with different execution models. (a) The sequential kernel execution model only runs one kernel at a time strictly following data dependencies. (b) Nanobatching [18, 20, 48, 49, 57] splits a pipeline microbatch into two nanobatches (illustrated with different colors) and staggers their execution, creating opportunities to overlap communication and computation.***

2.2 Existing Training Systems

Large model training relies on multi-GPU parallelism, which distributes model weights and computation while introducing communication. On each GPU, kernel scheduling determines how computation and communication are executed. Figure 1a illustrates Megatron-LM's [35] implementation of the 1F1B pipeline schedule. Each pipeline microbatch (boxes labeled F and B) contains multiple Transformer [47] blocks, each with an Attention layer and a feed-forward (MLP) layer. Figure 2a shows the sequential kernel execution model adopted by Megatron-LM [35], where kernels execute one after another following data dependencies.

Beyond parallelizing work across devices [5, 14, 25, 28, 35, 54], recent works have optimized latency with *nanobatching* [18, 20, 48, 49, 57], where a single pipeline microbatch is split into two equal-sized *nanobatches* with no data dependencies between them. This creates opportunities to over-

Table 1: ***Training iteration time (seconds) and energy breakdown (Joules) of Megatron-LM, Nanobatching, and each combined with Perseus, training Qwen 3 1.7B on 16 NVIDIA A100 GPUs. Megatron-LM achieves 99.0 TFLOP/s/GPU.***

	Iteration time	Static energy	Dynamic energy	Total energy
Megatron-LM	5.60	5,372	21,374	26,745
Megatron-LM + Perseus	5.60	5,374	19,531	24,905
Nanobatching	5.31	5,096	21,445	26,541
Nanobatching + Perseus	5.37	5,160	19,729	24,889

lap communication and computation kernels from different nanobatches,[2] as shown in Figure 2b.

A separate line of work has optimized the energy consumption of large model training by scaling GPU frequencies [13, 15, 51]. Notably, Perseus [15] dynamically reduces the GPU frequencies of microbatches off the critical path of computation, as shown in Figure 1b, to reduce energy consumption while keeping overall training iteration time the same. However, it follows the sequential kernel execution model (Figure 2a), missing opportunities from fine-grained kernel scheduling like nanobatching.

2.3 Breaking Down Training Energy Consumption

We can better understand the energy consumption of existing training systems and techniques by breaking down energy into static and dynamic components. Table 1 presents such a breakdown along with iteration time for Qwen 3 1.7B [44] training on 16 NVIDIA A100 GPUs.[3] Static energy is static power[4] multiplied by iteration time, and dynamic energy is static energy subtracted from total energy.

Compared to baseline Megatron-LM (first row), Nanobatching (third row) reduces iteration time, which directly lowers static energy. Dynamic energy is slightly higher because nanobatching incurs additional GPU activity from more memory accesses and extra gradient accumulations per nanobatch. Perseus applied to Megatron-LM (second row) reduces dynamic energy through explicit frequency scaling while keeping iteration time nearly the same, so static energy remains unchanged. Applying Perseus on top of Nanobatching (fourth row) combines both benefits: reduced static energy from shorter time and dynamic energy from frequency scaling.

However, we find that there is further opportunity to reduce energy beyond what is achieved by simply combining Nanobatching and Perseus. To understand this gap, we analyze how communication and kernel scheduling affect energy consumption (§3). The opportunities we find motivate the design of Kareus, which jointly optimizes kernel scheduling and frequency scaling (§4).

[2]Computation and communication exert different GPU resources, so overlapping them increases overall GPU utilization and can lead to speedup.

[3]Trained with 8 microbatches, each with size 16 and sequence length 4K, using pipeline parallelism 2, context parallelism 2, and tensor parallelism 4. The same experiment also appears in Table 3, Table 4, and Figure 11.

[4]Static power is set to be the GPU's power draw when it is in *ready* state (power state P0) without running any significant computations.

3 Energy Impact of Execution Schedules

We investigate the relationship between energy consumption and execution schedule. We first discuss how different execution schedules for the same *work* can lead to different energy consumption (§3.1), and then analyze the impact of key factors through case studies (§3.2). This reveals the necessity of joint control and the opportunity for significant energy savings (§3.3).

3.1 Execution Schedule and Energy Consumption

Regardless of *how* work (computation, memory access, and communication) is performed, the total amount of work done is the same. However, different execution schedules can still lead to different energy consumption.

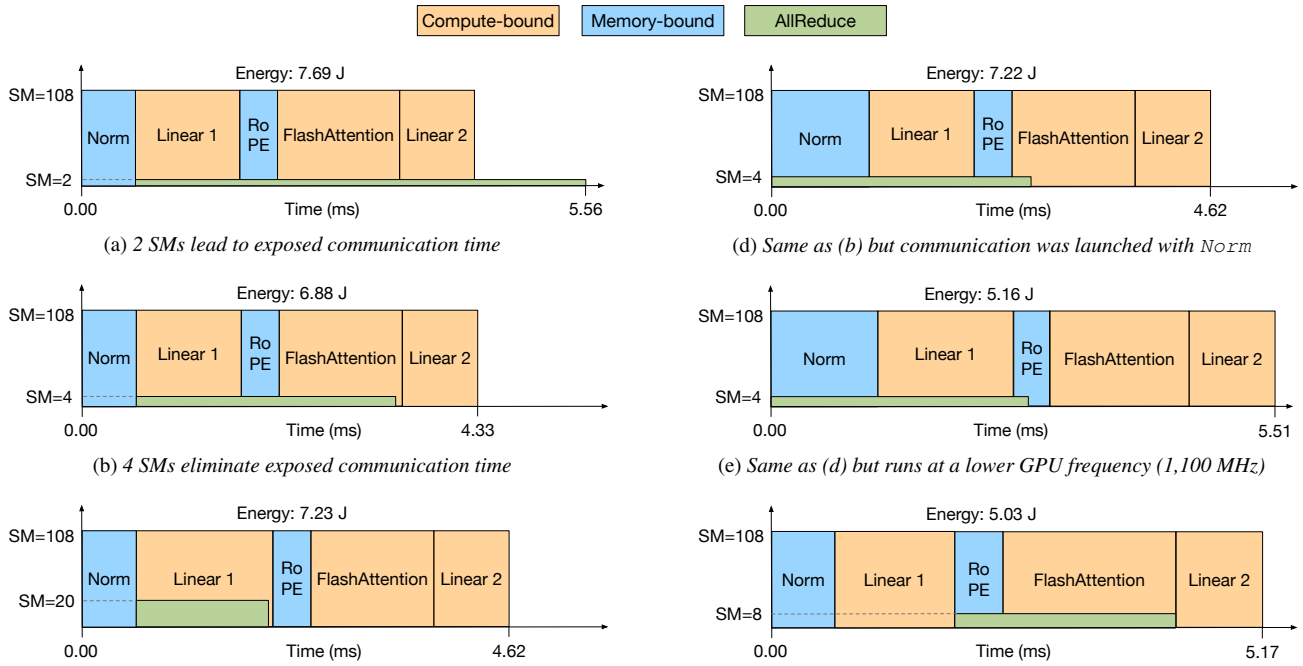
The distinction between dynamic and static power is key to understanding this. Dynamic energy reflects the total work done on the hardware (i.e., transistors switching from computation, memory access, and communication). At *the same GPU frequency*, it remains largely constant across execution schedules. In contrast, all parts of the hardware consume static power as long as they are powered on. Compute components (e.g., SMs) account for a significant portion of chip area and thus static power. When GPU resources are underutilized, static power is still dissipated without as much useful work being done, increasing total energy consumption.

In sum, GPU frequency primarily influences dynamic energy, whereas execution schedules largely determine static energy by changing end-to-end execution time. However, these factors are interdependent and cannot be decoupled and optimized separately, as we show next.

3.2 Interdependent Factors in Execution Schedules

Execution schedules differ in which kernels run concurrently on the GPU, how they split GPU resources, and at what GPU frequency they run. We study the impact of execution schedules on time and energy consumption by varying three key factors that correspond to each: (1) communication kernel launch timing, (2) number of SMs allocated to the communication kernel, and (3) GPU frequency. This definition of execution schedule generalizes nanobatching. The original nanobatching model (1) launches communication kernels as soon as possible, (2) uses default communication kernels like NCCL optimized for sequential execution (which may use excessive SMs assuming no concurrent kernels), and (3) does not perform GPU frequency scaling.

Figure 3 shows the timelines and total energy consumption of different execution schedules for a single Transformer Attention layer of Llama 3.2 3B [33], with tensor parallelism degree 4 on four fully-connected NVIDIA A100 GPUs. For simplicity of exposition, we focus on a single repeating segment: the computation kernels of one nanobatch and the communication kernel of the *previous* nanobatch. Thus, the communication kernel has no data dependencies with any



(a) *2 SMs lead to exposed communication time*

(b) *4 SMs eliminate exposed communication time*

(c) *20 SMs reduce communication latency but lead to compute interference*

(d) *Same as (b) but communication was launched with* `Norm`

(e) *Same as (d) but runs at a lower GPU frequency (1,100 MHz)*

(f) *Lower frequency (1,100 MHz) changes the energy-optimal schedule*

Figure 3: ***The time and total energy consumption of execution schedules for one Transformer Attention layer forward pass with varying SM allocation, communication launch timing, and GPU frequency. (a)–(c) show the effect of allocating different numbers of SMs to the communication kernel at 1,410 MHz, with (b) being the energy-optimal schedule. (d) is the same as (b), except that communication was launched earlier together with*** `Norm`***. Finally, (e) and (f) run at a lower GPU frequency of 1,100 MHz. (e) is the same as (d) other than frequency, whereas (f) is the energy-optimal schedule at 1,100 MHz, which is different from the schedule in (b).***

of the computation kernels in the same segment. This is the common-case execution pattern throughout training.

3.2.1 SM Allocation

First, we study the impact of GPU resource sharing via SM allocation. Allocating more SMs to communication kernels leaves fewer SMs for overlapped computation kernels given a fixed number of SMs. Figures 3a, 3b, and 3c show execution schedules that vary only in the number of SMs allocated to the communication kernel (2, 4, and 20 SMs, respectively) while launching the communication kernel together with `Linear 1`. With two SMs allocated to the communication kernel (Figure 3a), the communication does not complete before the computations finish, leaving an exposed communication period during which 106 SMs are idle. Static power is wasted during this exposed communication time, increasing total energy consumption. Increasing the number of SMs to four (Figure 3b) lets the communication kernel complete before the computation kernels, minimizing static power wastage and total energy consumption. However, further increasing the number of SMs to 20 (Figure 3c) speeds up communication only at the cost of taking SMs away from `Linear 1`, which ultimately increases total time and energy consumption. This is because the excess SMs allocated to the communication kernel slow down computation while remaining nearly idle themselves, again wasting static power.

3.2.2 Communication Launch Timing

Next, we study the impact of kernels that run together by changing when to launch the communication kernel. Figure 3d shows an execution schedule where the communication kernel runs with four SMs (the same as Figure 3b) but starts with `Norm` instead of `Linear 1`. As shown in colors, `Norm` and `RoPE` kernels are memory-bound, and with sufficient SMs, the communication kernel also requires high memory bandwidth to write the communicated data to memory. When such a communication kernel starts together with another memory-bound kernel like `Norm`, the two compete for memory bandwidth, prolonging both. This extends the period where compute resources are underutilized, wasting static power. Furthermore, compared to Figure 3b, memory bandwidth is underutilized during `FlashAttention`, wasting static power in memory components.

3.2.3 Varying GPU Frequency

Finally, we study the impact of changing the GPU frequency. Reducing GPU frequency lowers dynamic energy [15, 51]. More importantly, the energy-optimal execution schedule changes at lower frequencies. At lower frequencies, all kernels become relatively more compute-bound because reducing frequency only affects computation throughput and not memory

Table 2: ***Summary of factors and observations from case studies on the energy impact of execution schedules.***

Factor	Observation	Explanation
SM allocation	A middle-ground sweet spot exists	Too few SMs for a kernel can lead to periods where only one small kernel is running, wasting static power; too many SMs slow down other kernels without significantly speeding up the target kernel.
Launch timing	Resource demands of kernels running together matter	Communication, which can be memory-bound, running together with memory-bound operations (e.g., `Norm`, `RoPE`) causes bandwidth contention and slowdown for everyone.
GPU frequency	Changes relative kernel resource demands	Lower frequency makes kernels relatively more compute-bound, changing which kernels benefit from overlapping; it also amplifies static power's relative impact, making exposed communication more harmful.
All three	Time & energy impacts of all factors are interdependent	The energy-optimal SM allocation and launch timing depend on the GPU frequency; changing one factor shifts the energy-optimal configurations of the others.

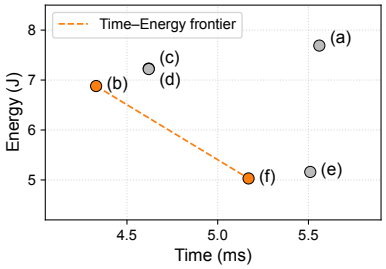


Figure 4: ***Time and energy consumption of the execution schedules in Figure 3 (a)–(f).***

throughput [38].[5] Thus, running the communication kernel with a memory-bound kernel causes less interference since memory bandwidth is less contended. Conversely, running it with a compute-bound kernel and taking SMs away from it causes more severe interference, with larger slowdowns and more static power wastage.

Figure 3e is the same as Figure 3d, but runs at a lower frequency (1,100 MHz). Reduced dynamic energy contributes substantially to lower total energy. However, execution time increases significantly because the communication kernel takes SMs away from `Linear 1`, which is now even more compute-bound at the lower frequency. The energy-optimal schedule at this frequency, shown in Figure 3f, launches communication together with `RoPE`. This lets the compute-bound `Linear` kernels run without interference, reducing total execution time and static power wastage. Figure 4 plots the time–energy frontier of the six execution schedules.

We also note that exposed communication time is relatively more harmful at lower frequencies. Dynamic power decreases significantly with frequency while static power does not—this increases static power's proportion in total power draw and thus its relative impact when wasted.

3.3 Joint Control and Opportunities

Table 2 summarizes observations from the case studies. The three factors that determine the execution schedule—SM allocation, communication launch timing, and GPU frequency—are (1) interdependent: changing one shifts the energy-optimal configuration of the others, and (2) highly impactful, with up to a 3.29× gap in time and energy consumption across the observed schedules. Therefore, optimizing time and energy requires *joint control* of all three. This is the key insight motivating the design of Kareus's optimization algorithm.

In fact, joint control of GPU frequency and kernel scheduling is provably more energy-efficient than leaving GPU frequency control to the hardware's power controller (Appendix A). The intuition is that since dynamic power grows roughly with the cube of frequency,[6] high-frequency periods cost more energy than what low-frequency periods save, so removing frequency variation reduces total dynamic energy.

Our analysis also shows that opportunities for energy savings with execution schedule control are significant. For simplicity of analysis, we have studied a single Attention layer with modest communication volume (tensor parallelism degree 4). Even in this setting, without any GPU frequency scaling, the energy-optimal execution schedule (Figure 3b) reduces energy consumption by 24.3% and time by 12.3% compared to Megatron-LM, and 7.1% energy and 5.4% time compared to Nanobatching. Larger models, more GPUs, and additional parallelism dimensions (e.g., context parallelism) provide even greater opportunities, as we show in Section 6.

4 Algorithm Design

In this section, we present the optimization algorithm of Kareus, whose goal is to find the time–energy tradeoff frontier of executing computation and communication kernels of large model training. We begin by formulating the optimization problem (§4.1), and then introduce the partitioned overlap execution model, which decomposes the problem into tractable subproblems (§4.2). Building on this model, Kareus efficiently explores the execution schedule space to derive the time–energy frontier for each subproblem (§4.3), and composes these local frontiers into a global frontier that characterizes the training iteration (§4.4). Finally, we discuss how Kareus generalizes to broader computation and communication patterns (§4.5).

[5] Essentially, the hardware roofline model's horizontal compute-bound ceiling is lowered, making it easier for kernels to be compute-bound.

[6] Dynamic power is proportional to $V^2 f$. In NVIDIA GPUs, voltage scales roughly linearly with frequency (up to a certain point), so $V^2 f$ becomes f^3.

4.1 Optimization Formulation

Objective. The goal of Kareus is to find an efficient time–energy frontier for the training iteration. Finding the whole frontier, instead of just the minimum-time point, is valuable because it allows users to select tradeoff points that meet job-level requirements (e.g., time deadlines, energy budgets) or perform dynamic adaptation to changing environments (e.g., stragglers) [15, 51]. Since the iteration frontier can be constructed by combining *microbatch* (forward and backward) frontiers (§4.4), Kareus's objective reduces to finding microbatch time–energy frontiers that Pareto-dominate those of prior works.

Decision variables. We consider three decision variables corresponding to the three key factors that influence time and energy (§3): (1) the number of SMs allocated to communication kernels; (2) kernel launch timing, which determines the execution order and overlap between kernels while respecting data dependencies; and (3) GPU frequency.

Solution space. Unfortunately, the combined solution space of these three factors is extremely large. For a typical Transformer-based LLM on an A100 GPU, this space comprises 85K candidate configurations (details in Appendix B). Each candidate in this large search space requires lengthy profiling for accurate energy measurements—on average, 13 seconds per candidate—for thermal stability (§5). An exhaustive search over the entire solution space can take up to 4,912 GPU-hours!

4.2 Partitioned Overlap Execution Model

To shrink the search space, we identify *repeating patterns* in computation and communication sequences, optimize them independently, and compose them into a global schedule.

Partition. Kareus groups kernels executing in repeating patterns into *partitions*. A partition consists of one communication kernel from one nanobatch and the longest contiguous sequence of computation kernels from the other nanobatch. There are no data dependencies between the communication kernel and the computation kernels in the same partition. This allows the communication kernel to overlap with any contiguous subsequence of computation kernels in the partition.

The second row of Figure 5 illustrates the repeating pattern of partitions. The two orange boxes (Attention–AllReduce partition) are identical, as are the two blue boxes (MLP–AllReduce partition), and both partition types repeat across all Transformer blocks.

Optimization overview. After automatically detecting the partitions, Kareus's optimizer first characterizes the time–energy frontier of each partition (§4.3), as shown in the fourth row of Figure 5. Each point on the frontier represents an efficient execution schedule for that partition, like the one depicted in the third row of Figure 5. The time–energy frontiers of all partitions are then combined to form the time–energy frontier of each forward and backward microbatch, and then combined again to form the global, iteration-level time–energy frontier (§4.4).

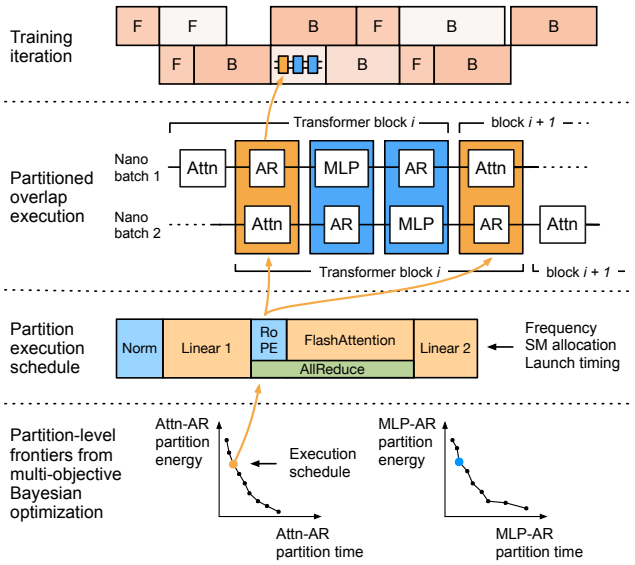

Figure 5: ***Kareus execution and optimization overview. The first row shows one training iteration with the 1F1B pipeline schedule. Inside each microbatch, partitions are sequentially executed; the second row illustrates this with the Transformer forward pass with tensor parallelism. The third row shows the execution schedule of the Attention–AllReduce partition. Each partition's execution schedule is chosen from the partition-level time–energy frontiers (fourth row) characterized by Kareus's optimization algorithm.***

4.3 Multi-Objective Bayesian Optimization

4.3.1 Bayesian Optimization Primer

For one partition, our optimization problem still involves a complex search space with mixed discrete and categorical variables. Importantly, the time and energy of each configuration have no known closed-form expression and can only be obtained through profiling. Bayesian Optimization (BO) is well-suited to this setting; it optimizes objectives over complex search spaces where the objective is unknown in form and costly to evaluate [19].

A BO algorithm has two key components. First, a *surrogate model* is trained on evaluated candidates to approximate the objective function. It is initialized with random candidates and updated as new candidates are evaluated. Second, an *acquisition function* uses the surrogate model to rank candidates and select the next one(s) to evaluate. BO then proceeds iteratively: it selects a batch of candidates using the acquisition function, evaluates them, updates the surrogate model, and repeats until convergence.

4.3.2 Kareus's MBO Algorithm

Although BO has been widely applied to systems problems [6, 11, 22, 52], it does not fit our setting as is. Standard BO targets a single objective, whereas we seek the Pareto frontier of time

and energy. We therefore design a Multi-objective Bayesian Optimization (MBO) algorithm with two tailored components: separate surrogate models for time and energy prediction, and a multi-pass candidate selection procedure that explores the frontier from multiple directions.

Surrogate model. We train two surrogate models: $\widehat{T}(x)$ for time and $\widehat{E}(x)$ for dynamic energy,[7] where x is a candidate configuration. Since time is primarily influenced by SM allocation and launch timing and dynamic energy by GPU frequency, the two models are largely orthogonal. Total energy consumption can then be computed as $\widehat{T}(x) \cdot P_{\text{static}} + \widehat{E}(x)$, where P_{static} is the GPU's static power consumption.

We adopt gradient-boosted decision trees (XGBoost) [10] as the surrogate model for two reasons. First, XGBoost training scales linearly with data points (versus cubic for Gaussian Processes), allowing fast retraining. Second, its tree-based structure handles discrete (GPU frequencies and SM allocations) and categorical (launch timing) parameters well.

Multi-pass candidate selection. Since our MBO aims to find solutions on the time–energy Pareto frontier rather than a single optimum, we design a *multi-pass* candidate selection procedure. At each iteration of MBO, we select a batch of k candidates to evaluate next. The batch consists of candidates selected based on multiple different acquisition functions that are designed to (1) cover complementary regions of the time–energy tradeoff space and (2) perform both exploration and exploitation to avoid over- or under-exploring certain regions.

Exploitation with hypervolume improvement. The acquisition functions for exploitation are based on *hypervolume improvement* (HVI), which quantifies how much a candidate can expand the current time–energy frontier toward lower time and energy (Figure 6). It is defined as

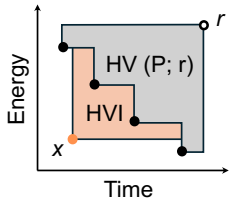

Figure 6: ***HVI.***

$$\text{HVI}(x) = \text{HV}\left(\mathcal{P} \cup \left\{\left(\widehat{T}(x), \text{Energy}(x)\right)\right\}; r\right) - \text{HV}(\mathcal{P}; r)$$

where $\mathcal{P}$ is the current set of candidates on the time–energy frontier, and r is a reference point set slightly worse (outward) than the worst observed points so that the hypervolume (HV) is computable. By switching the definition of $\text{Energy}(x)$ to total energy, dynamic energy, or static energy, each derived or taken as is from the surrogate models $\widehat{T}(x)$ and $\widehat{E}(x)$, we obtain three HVI acquisition functions. Each function guides frontier expansion in a distinct direction: dynamic energy favors lower-frequency candidates, static energy favors faster candidates, and total energy lies in the middle.

Exploration with uncertainty. To reduce the risk of under-exploring certain regions of the search space, we add an uncertainty-based acquisition function. We quantify uncertainty with *bootstrap ensembles*: multiple surrogate models trained on resampled datasets. The degree of *disagreement* between the surrogate models serves as a proxy for predictive uncertainty (i.e., how uncertain we are about the prediction). To promote exploration in either objective, we use the sum of per-objective standard deviations (rather than variances) as the acquisition score to prioritize candidates with high uncertainty.

[7] We use the hat notation to denote predictions, not true measurements.

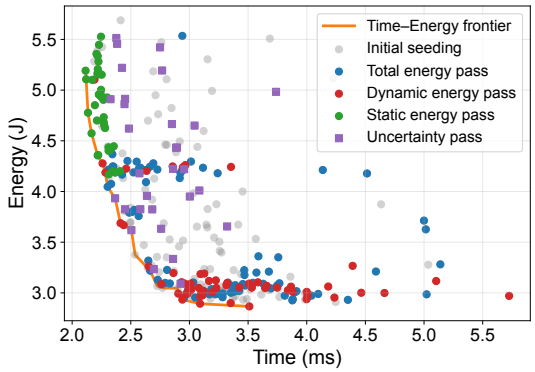

Figure 7: ***Multi-pass MBO in action with the Llama 3.2 3B model's MLP–AllReduce partition. The three exploitation passes (total energy, dynamic energy, static energy) and the exploration pass expand the efficient frontier in complementary directions, as shown by the colors of the points that land on the time–energy frontier.***

The full picture. Figure 7 illustrates frontier expansion for the Llama 3.2 3B model's MLP–AllReduce partition.[8]

Each pass expands the frontier in a complementary direction aligned with its acquisition function: dynamic energy pushes the frontier downward (lower energy), static energy leftward (lower time), and total energy toward the origin. In contrast, a single acquisition function as used in standard BO is fundamentally insufficient for MBO, as it only targets one direction. Algorithm 1 summarizes the overall Kareus MBO procedure for one partition, and this is repeated for each type of partition independently. Appendix C provides detailed settings of hyperparameters including initial random sample size, batch size, ensemble size, and stopping criteria.

4.4 Composing Frontiers

With each partition's time–energy frontier in hand, Kareus composes them into microbatch frontiers, and then into the iteration frontier.

Partition frontiers to microbatch frontier. A microbatch consists of multiple partitions executed sequentially. To construct the microbatch frontier, Kareus enumerates combinations of partition execution schedules (frequency, SM allocation, launch timing), sums their time and energy, and prunes suboptimal combinations. Algorithm 2 illustrates this process.

Two design decisions keep enumeration tractable. First, Kareus enforces a uniform GPU frequency across all partitions within a microbatch, since frequency switching takes several milliseconds and is non-negligible compared to the

[8] Microbatch size 8, sequence length 4K, and tensor parallelism degree 8.

Algorithm 1: Multi-pass multi-objective Bayesian Optimization for one partition

// Construct initial dataset for surrogate models
$\mathcal{D} \leftarrow N_{\text{init}}$ random candidates sampled and evaluated
for $b = 1, 2, \ldots, B_{\max}$ **do**
  Train surrogate models $\widehat{T}(x)$ and $\widehat{E}(x)$ on $\mathcal{D}$.
  // Exploitation: Hypervolume improvement
  foreach $x \in \mathcal{X} \setminus \mathcal{D}$ **do**
    Compute $\text{HVI}_{\text{tot}}(x)$, $\text{HVI}_{\text{dyn}}(x)$, $\text{HVI}_{\text{stat}}(x)$.
  // Exploration: Uncertainty via bootstrap ensemble
  for $m = 1$ **to** M **do**
    Train $\widehat{T}^m(x)$ and $\widehat{E}^m(x)$ on resampled $\mathcal{D}$
  foreach $x \in \mathcal{X} \setminus \mathcal{D}$ **do**
    $\text{Unc}(x) \leftarrow \sigma(\{\widehat{T}^m(x)\}) + \sigma(\{\widehat{E}^m(x)\})$
  // Multi-pass candidate selection
  $\mathcal{C} \leftarrow \text{TopK}(\{\text{HVI}_{\text{tot}}(x) : \forall x \in \mathcal{X} \setminus \mathcal{D}\}, k_1)$
  $\mathcal{C} \leftarrow \mathcal{C} \cup \text{TopK}(\{\text{HVI}_{\text{dyn}}(x) : \forall x \in \mathcal{X} \setminus \mathcal{D}\}, k_2)$
  $\mathcal{C} \leftarrow \mathcal{C} \cup \text{TopK}(\{\text{HVI}_{\text{stat}}(x) : \forall x \in \mathcal{X} \setminus \mathcal{D}\}, k_3)$
  $\mathcal{C} \leftarrow \mathcal{C} \cup \text{TopK}(\{\text{Unc}(x) : \forall x \in \mathcal{X} \setminus \mathcal{D} \setminus \mathcal{C}\}, k - |\mathcal{C}|)$
  // Evaluate candidates and update dataset
  $\mathcal{D} \leftarrow \mathcal{D} \cup \{(x, T(x), E(x)) : x \in \mathcal{C}\}$
  // Stopping condition
  $\Delta \leftarrow$ Average HV improvement over R batches
  if $\Delta < \varepsilon$ **then**
    break
return GetFrontier($\mathcal{D}$)

latency of one partition. Second, partitions of the same type share the same SM allocation and launch timing. For instance, all Attention–AllReduce partitions in Figure 5 use identical configurations. Allowing per-partition configurations would grow the search space exponentially in the number of partitions with little benefit.

Microbatch frontiers to iteration frontier. The first row of Figure 5 shows an example of how forward (F) and backward (B) microbatches are scheduled across pipeline stages. Iteration time is the sum of microbatch latencies along the critical path, while iteration energy combines the energy of all microbatches and the static energy consumed during idle times. Kareus adopts Perseus's iterative algorithm [15] to construct the training iteration frontier from microbatch frontiers.

4.5 Generalizations

Multiple communication kernels. Section 4.2 illustrated partitions using tensor parallelism as a running example. Real workloads, however, present more complex patterns. When consecutive communication kernels appear (e.g., multiple All-Gather operations under context parallelism to aggregate key and value tensors [14, 33]), Kareus fuses them into a single kernel that shares an SM allocation. This reduces kernel launch overhead and keeps scheduling tractable. With this, any model and communication scheme reduces to alternating sequences of computations and a single (possibly fused) communication, fitting the partitioned overlap model.

Algorithm 2: Microbatch frontier construction

$\mathcal{C} \leftarrow \emptyset$ // All feasible (time, energy) pairs for microbatch
foreach $f \in$ GPU frequencies **do**
  // Cartesian product of configs across all partitions
  $\Theta \leftarrow \prod_{p \in \mathcal{P}} (\text{SM allocations} \times \text{launch timings})_p$
  foreach $\theta \in \Theta$ **do**
    // Accumulate time and energy for microbatch
    $T_m \leftarrow 0, E_m \leftarrow 0$
    foreach *partition* $p \in \mathcal{P}$ **do**
      $T_m \leftarrow T_m + T_p(f, \theta[p])$
      $E_m \leftarrow E_m + E_p(f, \theta[p])$
    foreach *non-partition component* c **do**
      $T_m \leftarrow T_m + T_c(f)$
      $E_m \leftarrow E_m + E_c(f)$
    $\mathcal{C} \leftarrow \mathcal{C} \cup \{(T_m, E_m)\}$
return GetFrontier($\mathcal{C}$)

Short consecutive memory-bound computations. When multiple short, memory-bound operations appear consecutively (e.g., `BiasDropoutAdd` followed by `Norm`), Kareus groups them into one logical operation. Treating them separately would expand the launch-timing search space with only marginal gains in solution quality.

Execution model switching. Partitioned overlap is not universally superior. When the amount of work within a microbatch is small (e.g., small models or small microbatch sizes), splitting the microbatch can further reduce arithmetic intensity, leading to compute underutilization and higher static power wastage. In these cases, sequential execution can be more energy-efficient. To capture this, Kareus also profiles each sequentially executed microbatch at each frontier and includes them as candidates when constructing the microbatch time–energy frontier. Thus, the final microbatch frontier will automatically be constructed with the better execution model.

GPU power model. Kareus adopts a simplified two-component GPU power model that decomposes GPU power into dynamic power and constant static power [15, 32, 41], which suffices for reasoning about GPU energy consumption in large model training. There are finer-grained models that further divide static power into chip leakage and constant power [29, 45], where chip leakage is sensitive to voltage. We leave extending Kareus to such models as future work.

5 Implementation

5.1 System Overview

Figure 8 shows an overview of the Kareus system. Given a workload, Kareus identifies partitions (❶; §4.2) and runs multi-objective Bayesian optimization per partition (❷; §4.3), evaluating candidates with the thermally stable profiler (§5.3).

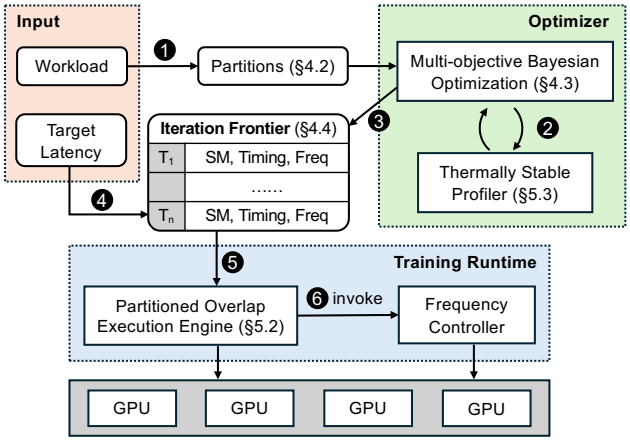

Figure 8: ***Kareus system overview.***

The per-partition frontiers are then composed into the iteration time–energy frontier (❸; §4.4). At runtime, given a target iteration latency, Kareus selects an execution schedule from the frontier (❹) and deploys it to the partitioned overlap execution engine (❺; §5.2), which invokes the GPU frequency controller to switch each GPU's frequency asynchronously as planned (❻).

5.2 Partitioned Overlap Execution Engine

Kareus's training execution engine builds on Megatron-LM [35], executing Transformer blocks as a sequence of partitions. Before each microbatch execution, Kareus loads the corresponding microbatch configuration, switches between Megatron-LM's default sequential execution and our partitioned overlap execution mode, and configures the SM allocation and launch timing for partitioned overlap execution. A custom `torch.autograd.Function` wraps all partitions of a Transformer block, allowing different partitions and partition schedules for forward and backward passes.

Communication kernels in Kareus are implemented with MSCCL++ [2,23], which provides fine-grained SM allocation control with grid size. Computation and communication run on separate CUDA streams to enable overlap, and CUDA events control launch timing. The GPU frequency controller is adapted from Perseus's open-source implementation [4,15].

5.3 Thermally Stable Profiling

Kareus measures the time and energy of a partition during MBO using Zeus [4,51], which internally uses NVML [3]. Accurate energy measurements require care; we present a detailed experimental analysis in Section 6.7.

Measurement window. NVML's sampling interval on NVIDIA GPUs is approximately 100 ms, so millisecond-scale measurements incur large errors. Kareus executes each partition repeatedly over a 5-second window, after which energy measurements stabilize.

Thermal cooldown. The power consumption of any hardware is temperature-dependent. Without cooldown between candidates, profiles of earlier partitions may heat up the GPU and bias subsequent measurements. Kareus inserts a 5-second cooldown period, which reliably brings the GPU below 32°C in our environment; the required duration depends on the server's cooling capability. In sum, profiling each candidate takes approximately 13 seconds in our setup, including initialization, warm-up, measurement, and cooldown.

6 Evaluation

We evaluate Kareus on 14 workloads and compare it against state-of-the-art baselines. Our key findings are as follows:

- Kareus achieves a superior time–energy frontier compared to prior approaches. In end-to-end training on real GPUs, it delivers up to 28.3% energy reduction under the same time budget and up to 27.5% time reduction under the same energy budget compared to the baselines (§6.2).
- In emulated large-scale training, Kareus consistently outperforms the baselines, achieving time and energy reductions comparable to real-world training results (§6.3).
- Ablation and sensitivity analyses show that jointly optimizing dynamic and static energy is necessary (§6.4) and is effective across a range of microbatch sizes (§6.5).
- Kareus's MBO algorithm constructs the time–energy frontier with reasonable overhead, and each pass in multi-pass candidate selection is indispensable (§6.6); the thermally stable profiler delivers stable energy measurements (§6.7).

6.1 Experimental Setup

Testbed. Experiments are conducted on 16 NVIDIA A100 40GB GPUs deployed across two AWS p4d.24xlarge instances. GPUs are fully connected intra-node via NVSwitch, and cross-node bandwidth is 400 Gbps.

Workloads. We evaluate Kareus on Llama 3.2 3B [33] and Qwen 3 1.7B [44] on the physical testbed, and perform large-scale emulation for Llama 3.3 70B [33]. For pipeline parallelism, we manually partition stages such that stages are as balanced as possible, following Perseus [15]. For context parallelism, we follow the scheme used in Llama 3 [33], where key–value tensors are collected across GPUs via AllGather. We use activation checkpointing to reduce memory pressure.

Baselines. We mainly compare against three baselines:

- **Megatron-LM ("M").** Baseline Megatron-LM [35] with the sequential execution model and maximum GPU frequency. Produces a single point on the time–energy plane.
- **Megatron-LM + Perseus ("M+P").** Perseus [15] applied to the above. This produces a time–energy frontier.
- **Nanobatching + Perseus ("N+P").** A training engine based on Megatron-LM that implements nanobatching, a special case of Kareus's partitioned overlap execution model (§3.2), integrated with Perseus like the above. This also produces a time–energy frontier.

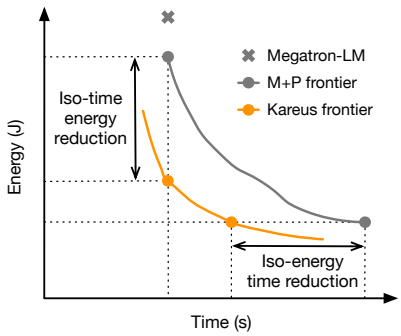

Figure 9: ***Illustrative example showing iteration time–energy frontiers. For the max-throughput comparison, we compare the leftmost points of each frontier with Megatron-LM. For frontier improvement, we report the iso-time energy reduction and iso-energy time reduction compared to Megatron-LM + Perseus.***

Metrics. Kareus's gain is fundamentally a superior time–energy tradeoff frontier, which cannot be fully captured by a single number. Therefore, we define two modes of comparison based on two viable use cases.

- **Max-throughput comparison.** When iteration time constraints (e.g., deadlines, stragglers) are not present, the training pipeline operates in maximum-throughput mode. For methods that produce a time–energy frontier, this means operating at the leftmost (lowest time) point. We set Megatron-LM as the baseline, and report iteration time and energy reduction (%) of M+P, N+P, and Kareus.
- **Frontier improvement.** We set M+P as the baseline, and define two metrics that quantify frontier improvements for N+P and Kareus (Figure 9): (1) *Iso-time energy reduction* (%): energy reduction with iteration time deadline set as M+P's minimum iteration time; and (2) *Iso-energy time reduction* (%): time reduction with iteration energy budget set as M+P's minimum iteration energy.

6.2 End-to-End Results

In this section, we evaluate the iteration time and energy performance on the testbed GPUs for the max-throughput (§6.2.1) and frontier improvement (§6.2.2) comparisons. The workload configurations (parallelism, microbatch size, and sequence length) can be found in Table 3.

6.2.1 Max-Throughput Comparison

Table 3 reports the iteration time and energy reductions achieved by all methods under the max-throughput regime. Overall, Kareus achieves up to 14.9% reduction in iteration time and 22.1% reduction in energy consumption compared to Megatron-LM, strictly outperforming the baselines on time and energy.

Time reduction. The time reduction mainly comes from reducing SM idle time caused by resource underutilization due to exposed communication or resource contention by poorly scheduled kernel overlaps. As a result, the time reduction trend largely follows the communication overhead induced by different model configurations. Compared to Megatron-LM, both overlap execution models achieve larger gains under tensor parallelism (TP) than under context parallelism with tensor parallelism (CP+TP). Moreover, increasing the microbatch size yields greater time reduction than increasing the sequence length, since the former introduces relatively higher communication overhead.

When compared to Nanobatching, Kareus provides larger additional gains under CP+TP than under TP alone, because fine-grained control of communication scheduling becomes more critical for complex communication patterns. Moreover, Nanobatching can significantly slow down computation (e.g., on Qwen 1.7B with CP2+TP4, microbatch size 8, and sequence length 4K), as it leads to GPU underutilization when the workload is small. In contrast, Kareus can automatically switch to the sequential execution model (§4.5).

Energy reduction. Energy reflects the combined effects of time and power, which is why energy reduction trends do not always track time reduction trends. In many cases, Nanobatching + Perseus reduces time but yields smaller energy reduction than Megatron-LM + Perseus, because overlap raises GPU utilization and thus also power, and the power increase offsets time reduction. In contrast, Kareus achieves larger energy reductions by simultaneously optimizing overlap and GPU frequency, enabling greater time reduction while also identifying opportunities to reduce power, as the following case studies show.

Case studies. We find an interesting case in Qwen 3 1.7B with TP8, microbatch size 8, and sequence length 4K. Both baselines operate the critical-path microbatch at 1,410 MHz (the maximum GPU frequency). However, Kareus discovers an overlap configuration that runs at 1,350 MHz yet attains the fastest latency, resulting in an additional 10.7% energy reduction over Nanobatching + Perseus. This happens because nanobatching overlap at 1,410 MHz improves resource utilization but raises instantaneous power, which triggers GPU frequency throttling. Thus, the time-averaged GPU frequency (which determines execution time) is close to 1,350 MHz, while the time-averaged dynamic power (which determines dynamic energy) remains closer to that of 1,410 MHz. Operating at a constant frequency provably consumes less energy than operating at a fluctuating frequency with the same average, which highlights the importance of jointly optimizing kernel scheduling and GPU frequency scaling (§3.3).

Figure 10 further illustrates representative partition execution schedules across microbatches of the aforementioned configuration. In the forward and backward Attention–AllReduce partitions, Kareus decides not to overlap `AllReduce` with memory-bound kernels (e.g., `Norm`) at a higher frequency (1,350 MHz); instead, it shifts the overlap to more memory-bound kernels at a lower frequency (1,290 MHz), consistent with the analysis in Section 3. For the MLP–AllReduce partitions, the selected configurations differ due to variations

Table 3: ***[Experiment] Iteration time and energy reductions (%) relative to Megatron-LM (higher is better) for all methods under the max-throughput configuration. Pipeline parallelism degree is fixed at 2, and number of microbatches is fixed at 8. `OOM` indicates that the GPU runs out of memory at the corresponding settings. Negative values indicate increased time or energy relative to the baseline.***

in kernel lengths and types. Kareus starts overlap from the beginning and allocates only 6 SMs to `AllReduce` at 1,350 MHz, which provides enough time to hide communication while leaving most SMs available for the long compute-bound `Linear 1` kernels.

6.2.2 Frontier Improvement

Table 4 reports the iso-time energy reduction and iso-energy time reduction for Nanobatching + Perseus and Kareus, which demonstrate the expansion of the time–energy frontier. Overall, Kareus achieves up to 28.3% iso-time energy reduction and 27.5% iso-energy time reduction compared to Megatron-LM + Perseus, establishing a strictly better time–energy tradeoff over Nanobatching + Perseus. Figure 11 shows a representative frontier comparison for Qwen 3 1.7B with CP2, TP4, microbatch size 16, and sequence length 4K. We present the complete frontier comparison plots for all model configurations in Appendix D.

Under the same time budget, where static energy is fixed, Kareus achieves higher GPU utilization and can therefore execute at lower GPU frequencies to complete the workload, reducing dynamic energy consumption. Conversely, under the same energy budget, Kareus minimizes static energy wastage, allowing more energy to be allocated to dynamic execution at higher GPU frequencies to complete the workload faster.

6.3 Large-Scale Emulation

In this section, we conduct large-scale emulation of Llama 3.3 70B based on smaller-scale profiling on our testbed hardware and compare against Megatron-LM + Perseus. We use the emulator from Perseus [15]. Results show that trends in time and energy reduction are consistent with those in Section 6.2 measured on testbed GPUs.

Methodology and parameters. For Kareus, we obtain the iteration-level time–energy frontier using the MBO algorithm described in Section 4 by composing partition-level frontiers.

Table 4: ***[Experiment] Iso-time energy reduction (%) and iso-energy time reduction (%) relative to Megatron-LM + Perseus for Nanobatching + Perseus and Kareus. "−" indicates that no configuration satisfies that constraint. For example, if Nanobatching + Perseus has a longer iteration time than Megatron-LM + Perseus at the leftmost point, then no iso-time point exists.***

				Iso-Time Energy Reduction (%)		Iso-Energy Time Reduction (%)

1.7B	CP2TP4	8	4K	–	0.0	–	5.1
		8	8K	−0.7	15.0	−0.4	12.1
		16	4K	8.9	20.1	8.4	19.7

For Megatron-LM + Perseus, we profile the time and energy of each Transformer block using the same profiling methodology described in Section 5.3, and construct the iteration-level frontier. We perform strong scaling as we vary the number of GPUs (Table 5), while fixing the global batch size to 2048, which is adopted in the Llama 3 training [33]. We use pipeline parallelism degree 10 and tensor parallelism degree 8, with microbatch size 4 and sequence length 4K [33].

Max-throughput comparison. We report the max-throughput comparison results for Megatron-LM + Perseus and Kareus across different numbers of microbatches in Table 6, and plot the corresponding iteration-level time–energy frontiers in Appendix E. The energy reductions achieved by both methods are generally higher than those observed in the

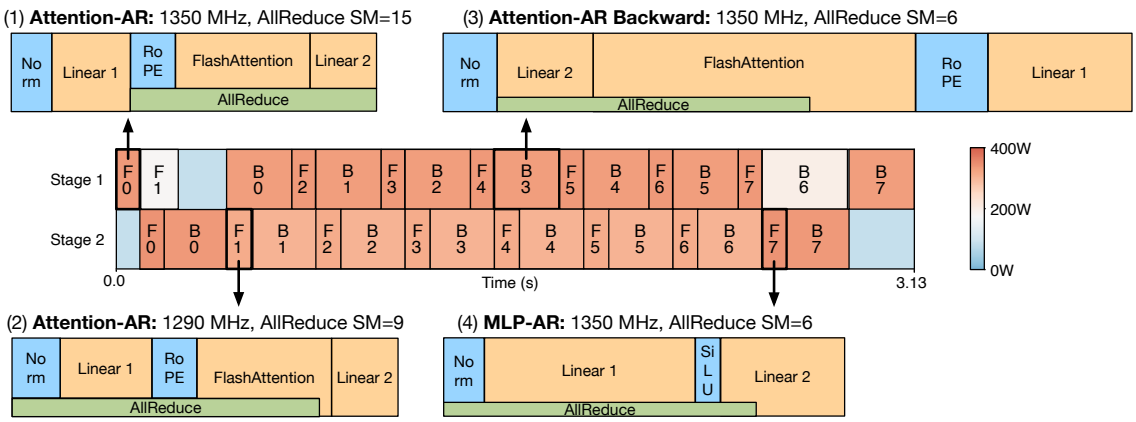

Figure 10: *Case study of Qwen 3 1.7B with TP8, microbatch size 8, and sequence length 4K. The pipeline schedule is colored by average GPU power draw, and the partition execution schedules are drawn to scale for time. (1) and (2) compare the forward Attention–AllReduce partition at 1,350 MHz and 1,290 MHz, respectively. (3) and (4) show the backward Attention–AllReduce and forward MLP–AllReduce partitions at 1,350 MHz. Backward microbatch is partitioned following the definition in Section 4.2;* `Norm` *is treated as the first kernel because it follows the AllReduce kernel in the transformer block, and other kernels are ordered in reverse.*

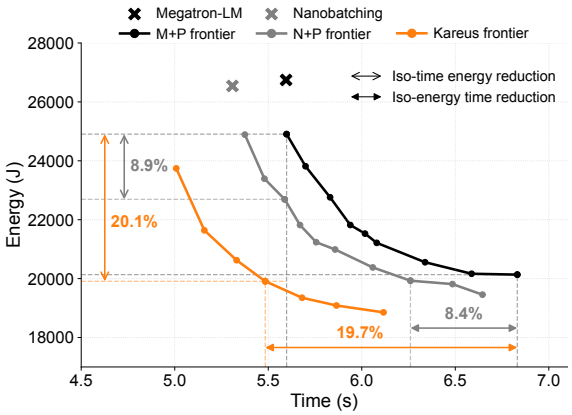

Figure 11: *[Experiment] Representative iteration time–energy frontier comparison for Qwen 3 1.7B with CP2, TP4, microbatch size 16, and sequence length 4K.*

Table 5: *Strong scaling configurations for large-scale emulation.*

# GPUs	# Pipelines	# Microbatches Per Pipeline	Global Batch Size
10240	128	16	2048
5120	64	32	
2560	32	64	
1280	16	128	

testbed experiments, because the larger number of pipeline stages and microbatches on non-critical paths can be slowed down to save dynamic energy. As the number of microbatches increases, the relative portion of pipeline bubbles during the warm-up and cooldown phases—which are normally reduced down to the lowest frequency—decreases, leading to a slight decrease in energy reduction. The time reduction achieved by Kareus is slightly lower than that of the TP=8 case in the testbed experiments, because a smaller microbatch size is used in this setting due to the GPU memory constraints.

Table 6: *[Emulation] Iteration time and energy reduction (%) relative to Megatron-LM of Megatron-LM + Perseus and Kareus under the max-throughput configuration for Llama 3.3 70B.*

# Microbatches	Time Reduction (%)		Energy Reduction (%)	
	M+P	Kareus	M+P	Kareus
16	0.0	9.3	15.0	20.2
32	0.0	9.2	14.3	20.0
64	0.0	9.1	13.8	19.8
128	0.0	9.1	13.5	19.7

Table 7: *[Emulation] Iso-time energy reduction (%) and iso-energy time reduction (%) relative to Megatron-LM + Perseus of Kareus for Llama 3.3 70B.*

	# Microbatches			
	16	32	64	128
Iso-Time Energy Reduction (%)	11.6	14.1	15.3	15.1
Iso-Energy Time Reduction (%)	19.1	16.8	16.4	16.0

Frontier improvement. We report the frontier improvement results for Kareus across different numbers of microbatches in Table 7. As the number of microbatches increases, the iso-time energy reduction improves, because the absolute iteration time grows, providing more slack for dynamic energy savings. In contrast, the iso-energy time reduction decreases, since static energy consumes a larger fraction of the fixed energy budget.

6.4 Ablation Study on Search Space

In this section, we conduct an ablation study to demonstrate the necessity of jointly optimizing dynamic and static energy in Kareus. We compare Kareus against three ablated variants: removing dynamic energy optimization (i.e., frequency scaling), removing static energy optimization (i.e., kernel scheduling with SM allocation and launch timing), and removing both (i.e., Nanobatching). We evaluate all systems on Qwen 3 1.7B with PP=2, TP=8, 8 microbatches of size

Table 8: ***[Experiment] Iteration time and energy increase (%) of ablated variants relative to Kareus under the max-throughput configuration.***

System	Time Inc. (%)	Energy Inc. (%)
Kareus w/o frequency	1.0	12.9
Kareus w/o kernel schedule	8.2	10.8
Nanobatching	7.8	20.6

8, and sequence length 4K, the same configuration used in end-to-end experiments (Tables 3 and 4).

Table 8 reports the iteration time and energy increases of each ablated variant relative to Kareus under the max-throughput configuration. Removing frequency scaling results in a 12.9% increase in energy, and removing kernel scheduling leads to a 10.8% increase in energy. As expected, removing either of the optimization dimensions fails to deliver the full optimization potential of Kareus, demonstrating the necessity of joint optimization of both dynamic and static energy.

6.5 Sensitivity to Microbatch Size

In this section, we further study how the microbatch size, an important training parameter that directly affects computation arithmetic intensity, the ratio of communication to computation, and pipeline imbalance, affects the effectiveness of Kareus. We choose Qwen 3 1.7B with TP=8 and sequence length 4K as in Section 6.4 and vary the microbatch size from 8 to 20.[9] Tables 9 and 10 report the max-throughput comparison and frontier improvement results, respectively; Appendix F shows the corresponding time–energy frontiers.

Overall, Kareus demonstrates consistent effectiveness across varying microbatch sizes. As microbatch size increases, Kareus achieves greater time reduction (Table 9), as communication–computation overlap more effectively utilizes SMs when decomposing microbatches into nanobatches. This is also why microbatch size 20 achieves the best iso-time and iso-energy reductions (Table 10). Max-throughput energy reduction (Table 9) shows a more complex trend for two reasons. First, microbatch size 8 has a pronounced energy reduction due to the same reason as the case study in Section 6.2.1, where Kareus discovers a more energy-efficient critical path execution schedule that runs at a lower frequency. Second, changing the microbatch size impacts pipeline stage imbalance, which affects the potential for energy savings by slowing down non-critical microbatches—this worked in favor of microbatch size 12 and 20 by increasing imbalance and allowing more energy savings.

6.6 MBO Analysis

Overhead and breakdown. Kareus's MBO (§4.3) obtains the time–energy frontier for each partition. In our testbed experiments, MBO for different partitions is conducted in parallel and takes 2 hours (32 GPU hours) on average. This overhead is substantially lower than that of exhaustive search (307 hours, as discussed in Section 4.1), and is negligible compared to typical end-to-end training times (e.g., 54 days for Llama 3 [33]).

The overhead of MBO is dominated by thermally stable profiling of candidates (§5.3), accounting for 97% of the total overhead. For a typical partition in our setting, which evaluates a batch of 32 candidates per MBO iteration, thermally stable profiling takes 6.9 minutes on average, while surrogate model training and acquisition function evaluation takes 11 seconds on average.

Multi-pass candidate selection. After random candidate initialization, MBO selects candidates across four passes: total energy pass, dynamic energy pass, static energy pass, and uncertainty pass (§4.3). On average, random initialization contributes 35% of the selected candidates—they happen to be on the frontier. The other 65% of the selected candidates are discovered by the total energy pass, dynamic energy pass, static energy pass, and uncertainty pass, each 25%, 22%, 12%, and 6% of the selected candidates, respectively. All passes contribute a non-negligible portion of the final candidates.

[9] Larger microbatch sizes are not evaluated due to GPU memory capacity.

Table 9: ***[Experiment] Iteration time and energy reduction (%) relative to Megatron-LM of Megatron-LM + Perseus and Kareus across different microbatch sizes.***

ubatch Size	Time Reduction (%)		Energy Reduction (%)	
	M+P	Kareus	M+P	Kareus
8	-0.5	12.2	7.7	22.1
12	-0.4	14.7	9.4	17.6
16	-0.1	14.8	7.6	17.3
20	-0.2	18.1	9.4	18.8

Table 10: ***[Experiment] Iso-time energy reduction (%) and iso-energy time reduction (%) relative to Megatron-LM + Perseus of Kareus across different microbatch sizes.***

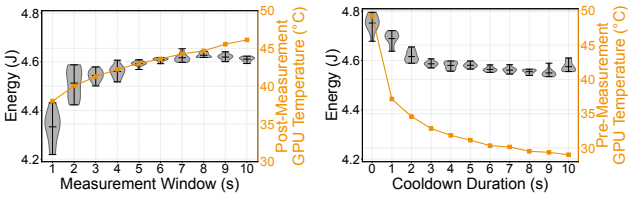
	Microbatch Size			
	8	12	16	20
Iso-Time Energy Reduction (%)	26.8	28.6	28.3	29.8
Iso-Energy Time Reduction (%)	27.5	27.3	26.7	28.8

6.7 Thermally Stable Profiler

During MBO, Kareus adopts thermally stable profiling to measure the time and energy of each candidate (§5.3). We conduct an experimental study using the Attention–AllReduce partition of Llama 3.2 3B on 8 NVIDIA A100 GPUs[10] to analyze the impact of measurement window and cooldown duration on the energy measurement accuracy.

Measurement duration. We fix the cooldown duration to 5 seconds and vary the measurement window from 1 second to 10 seconds, each with 10 repeated profiling trials. Figure 12a shows the distribution of measured energy consumption under different measurement windows, together with the average GPU temperature *after* each measurement. With very short

[10] Batch size is 4 and sequence length is 4K, with tensor parallelism degree 8, running at 1,410 MHz.



(a) *Measurement duration* (b) *Cooldown duration*

Figure 12: ***Impact of changing (a) measurement duration and (b) cooldown duration for the Thermally Stable Profiler. We report the distribution of energy across 10 repeated trials, along with the average GPU temperature before and after measurement.***

measurement windows (e.g., below 2 seconds), energy measurements exhibit large variability due to the 100 ms NVML counter update interval, and have a lower mean because the GPU has not fully warmed up. Energy measurement stabilizes from 5 seconds onward, which is why we chose 5 seconds as our measurement duration.

Cooldown duration. Cooldown duration is the waiting time between profiling consecutive partitions. We fix the measurement duration to 5 seconds and vary the cooldown duration from 0 second (no cooldown) to 10 seconds, with 10 repeated profiling trials. Figure 12b shows the distribution of measured energy consumption under different cooldown durations, along with the average GPU temperature *before* each measurement. We observe that mean energy consumption strongly correlates with the GPU temperature at the start of measurement, making sufficient cooldown essential for accurate measurement. Temperature and measurements stabilize from 5 seconds onward, so we cool down for 5 seconds between partitions. We note that the optimal cooldown duration would require tuning for different computing environments.

7 Related Work

7.1 ML Energy Optimization

The energy consumption of ML workloads has attracted extensive attention, prompting a growing body of work on energy measurement and optimization [13, 15–17, 24, 40, 43, 51, 53]. In particular, the time–energy tradeoff frontier has been a key tool for reasoning about performance and energy efficiency. For LLM serving, DynamoLLM [43] explores time–energy tradeoffs via model parallelism and GPU frequency scaling under latency constraints. The ML.ENERGY benchmark [16] characterizes the time–energy frontier across deployment configurations to guide latency-aware energy optimization. On the training side, Zeus [51] identifies job-level time–energy tradeoffs on recurring training workloads. Perseus [15] dynamically scales GPU frequency per microbatch to optimize energy under pipeline iteration time deadlines. However, these approaches often yield suboptimal frontiers because they overlook the impact of low-level execution scheduling, such as communication and computation overlap. Jayaweera et al. [27] propose energy-aware tile size selection for GPU kernels, but do not consider interactions with system-level latency targets, limiting the potential for energy optimization.

7.2 Communication Scheduling

As model scale grows, communication incurs increasingly significant overhead, motivating extensive work on overlapping communication with computation [8, 9, 12, 18, 20, 26, 28, 34, 36, 39, 48–50, 55–57]. Nanobatching is a key technique that removes data dependencies and enables overlap opportunities. In LLM serving, NanoFlow [57], TokenWeave [20], and vLLM Dual Batch Overlap [48] improve throughput via nanobatching with fine-grained kernel overlap. For training, DeepSpeed Domino [49] applies nanobatching to overlap tensor-parallel communication, while DeepSeek DualPipe [18] pipelines forward and backward nanobatches for communication overlap. Concerto [12] optimizes communication scheduling from a compiler perspective and adopts partial nanobatching when data dependencies are present. Other hand-crafted kernels fuse communication into computation [8, 36, 55, 56], but are tightly tied to specific parallelism strategies and operators. For example, Megatron-LM supports tensor-parallel communication overlap [36], which relies on its native sequence parallelism [30]. From the energy perspective, these approaches reduce static energy by reducing time, but do not explicitly optimize energy in their design. Kareus reveals the energy impact of communication scheduling and generalizes the nanobatching strategy to enable fine-grained SM allocation and launch-timing control, further minimizing static energy while jointly reducing dynamic energy by optimizing GPU frequency.

8 Conclusion

We present Kareus, an execution-aware energy optimizer for large model training. Kareus demonstrates that SM allocation, kernel launch timing, and GPU frequency jointly influence static and dynamic energy, and that the optimal time–energy frontier cannot be attained by optimizing them in isolation. Building on this insight, Kareus introduces a partitioned overlap execution model and a multi-objective Bayesian optimization framework that jointly searches over execution schedules, exposing a strictly better time–energy tradeoff frontier than prior systems.

Looking forward, we believe energy-aware execution scheduling should be a first-class concern in ML systems, not an afterthought. As AI scaling continues and energy constraints tighten for gigawatt-scale AI datacenters, systems that co-optimize computation, communication, and power will be essential, not just for cost savings but for enabling training runs that would otherwise be infeasible. Kareus takes a step in this direction, and we hope it spurs further work on energy as a core system design metric.

A Energy Efficiency of Constant Frequency

Below, we formalize why steady GPU frequency minimizes energy at a fixed average frequency.

Theorem 1 (Energy Efficiency of Constant Frequency)**.** *Let $f(t)$ denote the GPU frequency over a time interval $[0,T]$, and let $\bar{f} = \frac{1}{T}\int_0^T f(t)\,dt$ be its time-average. Under the following assumptions:*

1. *Dynamic power scales cubically with frequency: $P_{dyn}(t) = k \cdot f(t)^3$ for some constant $k > 0$.*
2. *Static power is constant: $P_{static}(t) = P_s$ for some constant $P_s \geq 0$.*
3. *Execution time depends only on average frequency: workloads with the same average frequency $\bar{f}$ complete in the same time T. This is supported by empirical observations from Kareus optimization results.*

Then the total energy consumption is minimized when frequency is held constant at $\bar{f}$.

Proof. Total energy is the sum of dynamic and static energy:

$$E_{\text{total}} = E_{\text{dyn}} + E_{\text{static}} = \int_0^T k \cdot f(t)^3\,dt + P_s \cdot T.$$

By Assumption 3, T is identical for both the fluctuating and constant frequency cases. Thus, static energy $E_{\text{static}} = P_s \cdot T$ is equal in both cases.

For dynamic energy, consider the function $g(x) = x^3$, which is convex for $x > 0$ since $g''(x) = 6x > 0$. By Jensen's Inequality:

$$g(\bar{f}) = \bar{f}^3 \leq \frac{1}{T}\int_0^T f(t)^3\,dt.$$

Multiplying both sides by kT:

$$E_{\text{dyn}}^{\text{constant}} = kT \cdot \bar{f}^3 \leq k\int_0^T f(t)^3\,dt = E_{\text{dyn}}^{\text{fluctuating}}.$$

Equality holds if and only if $f(t) = \bar{f}$ almost everywhere, i.e., when frequency is constant. Therefore:

$$E_{\text{total}}^{\text{constant}} \leq E_{\text{total}}^{\text{fluctuating}},$$

with strict inequality when $f(t)$ varies over time. □

Implications for GPU frequency scaling. This theorem explains why frequency fluctuation due to power limits can be energy-inefficient. When a GPU operates at a high frequency and triggers power throttling, the instantaneous frequency fluctuates, while the time-averaged frequency remains close to what could be achieved by operating steadily at a lower frequency. Consequently, the execution time—and thus static energy consumption—are the same as those under steady lower-frequency operation. However, this fluctuation incurs higher dynamic energy consumption because dynamic power is a strictly convex function of frequency. By Jensen's Inequality, any variance in frequency increases the expected dynamic energy consumption.

B Global Solution Space

The global solution space of combining GPU frequency, SM allocation, and kernel launch timing is extremely large. In this section, we illustrate the space using the NVIDIA A100 GPU as an example.

GPU frequencies. Supported GPU frequencies by A100 are from 210 MHz to 1,410 MHz at a stride of 15 MHz. We restrict the search space to 900 MHz–1,410 MHz (35 choices) because lowering the frequency below 900 MHz no longer reduces energy.[11]

SM allocations. A100 has 108 SMs, and we restrict the search space to up to 30 SMs because allocating additional SMs beyond this empirically no longer improved communication latency. This leaves 30 choices for SM allocation.

Kernel launch timing. Finally, given a sequence of computation and communication kernels, possible execution orders can be expressed as a recurrence relation, which enumerates the number of subproblems. We elaborate on this formulation in the following paragraphs. In summary, for a typical LLM composed of Transformer blocks, this can result in 81 possible groupings, leading to a *global solution space* with in total 85,050 candidates.

Formulation of launch timing. Kareus generalizes the nanobatching scheme to eliminate dependencies between computation and communication, which enables overlap and results in two operation sequences:

$$\mathcal{S}_1 = \{O_0, O_1, \ldots, O_i\}, \qquad \mathcal{S}_2 = \{O'_0, O'_1, \ldots, O'_j\}.$$

where operations within the same sequence must be executed in order, while operations across sequences are independent and may overlap. We regard the consecutive communication operations as a single operation. The time–energy frontier of the launch timing schedule can be formulated as a dynamic programming (DP) recurrence:

$$\mathcal{P}(i,j) = \min_{\text{Pareto}} \begin{cases} (E(O_i) + E(\mathcal{P}(i+1,j)),\ T(O_i) + T(\mathcal{P}(i+1,j))) \\ (E(O'_j) + E(\mathcal{P}(i,j+1)),\ T(O'_j) + T(\mathcal{P}(i,j+1))) \\ (E(O_i \parallel O'_{j..j+k}),\ T(O_i \parallel O'_{j..j+k})) + \mathcal{P}(i+1,j+k) \\ (E(O'_j \parallel O_{i..i+k}),\ T(O'_j \parallel O_{i..i+k})) + \mathcal{P}(i+k,j+1) \end{cases}$$

Here, $O_i \parallel O'_{j..j+k}$ means overlapping operation O_i with a subsequence $\{O'_j, \ldots, O'_{j+k}\}$; the notation is symmetric for the opposite case, $O'_j \parallel O_{i..i+k}$. The cost functions $E(\cdot)$ and $T(\cdot)$ account for the interference when overlapping.

This recurrence enumerates the time and energy of all single operations and all feasible overlap patterns between the

[11] Power reduction slows down but time increases, leading to higher energy.

two sequences. For a typical Transformer block with 9 computation operations and 1 AllReduce, if we restrict overlap to occur only between communication and computation and cap the maximum overlap length at 9 (assuming the communication is no longer than a full Transformer block), there are 81 possible overlap patterns. Including the non-overlapped cases, this yields a total of 91 subproblems.

C Adaptation of MBO Hyperparameters

In this section, we describe how Kareus configures MBO hyperparameters. Some are adapted across different partitions based on partition complexity, while others remain fixed.

Search space. For GPU frequency, we restrict the search space to 900–1,410 MHz with a stride of 30 MHz, since the time and energy differences between adjacent 15 MHz settings are marginal. For SM allocation, the search space is determined by the communication group size. If the number of GPUs in a communication group is fewer than 4, we search SM allocations from 1 to 20 with a stride of 1. If the group size is 4 or larger (e.g., the common cases of 4 and 8), we search SM allocations from 3 to 30 with a stride of 3. For launch timing, we enumerate all computation operators within a partition and exclude options that always lead to exposed communication, such as launching AllReduce from Linear2 in Figure 3a.

Sample size. Our goal is to control the total profiling time while preserving the quality of the time–energy frontier. We adopt a relatively large initialization set for informative exploration and scale the batch search budget based on partition complexity. Specifically, we classify partitions into three categories: *small* partitions containing only one computation, *medium* partitions containing 2–3 computations, and *large* partitions containing more than three computations. We then configure the sample sizes as follows: initial sample size $N_{\text{init}} = 36$, maximum number of batches $B_{\max} = 3$, batch size $k = 16$ for small partition; $N_{\text{init}} = 48$, $B_{\max} = 4$, $k = 16$ for medium partition; $N_{\text{init}} = 96$, $B_{\max} = 4$, $k = 32$ for large partition. We set the proportions of the total energy pass, dynamic energy pass, static energy pass, and uncertainty pass to 0.4, 0.2, 0.2, and 0.2, respectively. As shown in Section 6.6, the MBO overhead of Kareus is controlled within two hours on average.

XGBoost hyperparameters. Since the configuration space is three-dimensional, we adopt XGBoost hyperparameter settings commonly used for low-dimensional regression. To ensure fast and stable convergence while avoiding overfitting, we use relatively shallow trees with $max_depth = 6$, a high learning rate $\eta = 0.3$, and a modest model capacity with $num_boost_round = 100$. For the bootstrap ensemble, we set the ensemble size to 5, use a bootstrap sampling fraction of 0.8, and vary the random seed across bootstrap resamples.

HV reference point. At each batch iteration, we compute the HV reference point using values slightly worse than the worst observed measurements to ensure boundedness. Specifically, we set $r = \big(1.1 \times \max T(x),\ 1.1 \times \max E(x)\big)$.

Stopping conditions. The MBO algorithm is terminated when either a sufficient number of samples has been collected or the objective has converged, according to the following criteria: (1) Stop after a fixed number of batches $B_{\max}$. (2) After each batch, compute the dominated hypervolume of the measured frontier. Stop if the moving average of the relative HV improvement over the last R batches falls below ε.

We set the window size in the stopping criterion to $R = 2$ and the convergence threshold to $\varepsilon = 10^{-3}$. Energy and time are normalized throughout the MBO process, ensuring stable stopping behavior across partitions.

D End-to-End Results

Abstract

As AI-driven demand reshapes the data center landscape, external signals—such as energy cost, carbon intensity, power availability, and water usage—are increasingly dictating how much compute is available at any moment. These signals tend to vary over time, challenging traditional cluster schedulers, which implicitly assume stable resource supply, and calls for systems that continuously adapt to time-varying conditions. We focus on batch data-processing workloads, which are delay-tolerant but constitute a healthy fraction of total compute, making them a natural target for such flexibility. The directed acyclic graph (DAG) structure of these data-processing jobs makes decisions uniquely challenging, since delaying certain tasks in the DAG (e.g., bottleneck tasks) can stall entire pipelines. We introduce SPADE, a signal-aware scheduling and provisioning system that jointly considers workload DAG structure and external time-varying signals when deciding how (provisioning) and when (scheduling) to allocate resources. To underscore the importance of coupling these decisions, we evaluate SAP, an ablated system that preserves SPADE's signal-aware provisioning but delegates scheduling to arbitrary signal-agnostic policies. Using a Spark prototype deployed on a 100-node Kubernetes cluster, we show that SPADE reduces a secondary objective (e.g., the cost associated with carbon intensity or energy price) by 32.9% while maintaining overall cluster throughput.

1 Introduction

Data centers are expanding at an unprecedented pace. Global demand for computing infrastructure is projected to more than double this decade [63], with energy consumption expected to rise by over 165% [61]. Yet this growth is increasingly colliding with physical and environmental limits. Several recent high profile disputes, from reports of reduced water pressure and degraded water quality [67] to concerns about increased air pollution associated with a data center [14], highlight that cluster performance can now be constrained as much by external conditions as by internal hardware capacity. As these external signals begin to dictate how much compute capacity a data center can responsibly or affordably use at any moment, cluster management can no longer optimize solely for classic, internally visible objectives such as makespan or latency. Instead, schedulers must continuously adapt execution to conditions that originate outside the cluster itself.

Supporting adaptiveness to these external conditions represents a substantial departure from the status quo. Rather than treating the cluster as an isolated system with fixed resources, a *signal-aware* system must decide how to provision resources, not just when (via scheduling) to allocate them. This shift requires mechanisms that react to external signals and incorporate them directly into job scheduling decisions, allowing clusters to adjust resource usage in response to evolving environmental and operational constraints.

A key challenge is that these external signals are inherently *time-varying*. Carbon intensity evolves with the generation mix on the grid; water demand and cooling efficiency change with ambient temperature [44]; and grid health, often inferred from indicators such as locational marginal prices, varies as a function of power generation and demand [5]. To make response to these dynamics actionable, recent work such as Middlebox [48] proposes receiving (and acting on) a *time-varying signal* broadcast by entities like grid operators [16,18] that indicates when conditions are favorable or unfavorable. The high-level goal is to scale down resource usage during high-cost or high-impact periods and scale up when conditions improve.

Not all workloads are equally suited to respond to such signals. Interactive services are typically not temporally flexible enough to meaningfully shift their demand in response to an external signal. In contrast, non-interactive workloads centrally coordinated by the data center are natural candidates. Prior work has shown that regularly scheduled, highly parallelizable ML training jobs with predictable SLOs can be resized over time to track signals such as carbon intensity without significant performance loss [33]. This suggests a broader opportunity: can we systematically expand these signal-aware concepts to *batch data-processing workloads*?

We focus on batch data-processing jobs (e.g., Apache Spark), which constitute a substantial fraction of data center compute and are often delay-tolerant [1]. These workloads are expressed as directed acyclic graphs (DAGs) of precedence-constrained tasks: the outputs of one stage become the inputs of another [75]. Stages exhibit heterogeneity, with some benefiting from parallelism while others do not [53]. Many production systems already expose these dependencies explicitly in DAG form [11, 36, 59]. To execute these jobs, DAG schedulers (and cluster schedulers broadly) look "internally" to understand dependencies and user requirements when deciding how to schedule and assign resources to the job. However, these schedulers are largely *signal-agnostic*: they optimize for makespan or throughput under an implicitly stable resource supply and do not respond to external signals.

In parallel, several lines of work have proposed signal-aware provisioning schemes [33, 72] that scale resources up and down to leverage temporal signal variations. However, these do not consider "internal" characteristics such as DAG dependencies. In the setting of shared data-processing clusters, this separation is problematic: scaling resources down at the wrong time can stall critical paths and propagate delays, while scaling up prematurely can leave resources idle. As a result, a mechanism that only adapts resources in response to the signal while ignoring DAG structure and job interactions can degrade *both* performance and the secondary objective imposed by the external signal.

DAG structure introduces a three-dimensional trade-off between (i) classic performance metrics such as makespan, (ii) a secondary objective defined by the external signal (e.g., carbon emissions, energy cost, or power overloading), and (iii) how granularly the system engages with the DAG structure of jobs, ranging from *black-box* treatments that defer or scale jobs as a whole to *granular* task-level scheduling that exploits internal dependencies—see Fig. 1 for an illustration of these dynamics for an example job. This third axis is not a free parameter: a black-box treatment of signal-awareness is straightforward to bolt onto an existing scheduler but sacrifices performance on (i) and/or (ii), while granular, task-aware scheduling requires deeper integration and yields a more favorable trade-off on the first two axes.

This motivates a notion of *signal-aware DAG execution*: jointly coordinating task scheduling and resource provisioning as a function of both DAG structure and external time-varying signals. While prior signal-aware systems have identified a trade-off between performance and secondary objectives, they typically operate at coarse granularity (e.g., job-level scaling with deadlines) and do not consider DAG structure. Conversely, systems that incorporate DAG structure (e.g., RL-based schedulers for Spark) do not consider external signals. Existing work that considers both DAGs and signals, such as Caribou [32], targets serverless workflows and exploits spatial variations across regions rather than temporal variation within a single data center. One might hope to merge these two threads simply by composing them, e.g., by layering a signal-aware provisioning policy on top of an off-the-shelf DAG scheduler, or vice versa. This decomposition is insufficient because the two decisions are tightly coupled: whether deferring a given task is beneficial depends jointly on the task's position in the DAG and the current signal value, since deferring a bottleneck task stalls every downstream stage even when the signal momentarily favors doing so. We confirm this empirically in § 5 via our SAP ablation, which retains SPADE's signal-aware provisioning but delegates scheduling to signal-agnostic policies and consistently realizes a strictly worse trade-off between throughput and the secondary objective.

This paper: SPADE. In this work, we ask: *How should a cluster scheduler execute delay-tolerant DAG-structured batch jobs in response to a time-varying external signal?* We introduce SPADE (**S**cheduling and **P**rovisioning for **A**daptive **D**AG **E**xecution), a signal-aware system that unifies scheduling and provisioning for DAG jobs. SPADE introduces the notion of *relative importance*, which allows the system to account for both DAG structure and the dynamics of a time-varying signal. This enables SPADE to make fine-grained trade-offs—for example, continuing to prioritize certain tasks during periods when the signal suggests reducing resource consumption—so that clusters can respect secondary objectives without unnecessarily stalling critical paths. SPADE exposes a single *signal-awareness parameter* to control how much it is willing to sacrifice in throughput to align with a time-varying signal—rather than specifying a deadline for each job, an operator can specify how SPADE prioritizes objectives.

To underscore the importance of coupling these decisions, we also study an ablation, SAP (**S**ignal-**A**ware **P**rovisioning), which varies the available resources while delegating scheduling to a signal-agnostic policy. SAP captures the intuition of scaling down during high-signal periods and vice-versa, but because it ignores inter-task dependencies, its performance is strictly worse: the trade-off it achieves between makespan and the secondary objective is dominated by SPADE.

We implement SPADE and SAP as modules for Spark on Kubernetes and as extensions to a high-fidelity Spark simulator [53]. Our experiments consider real and synthetic workloads from Alibaba traces and TPC-H [2, 69]. We replay several signals, including carbon intensity traces from six regions [23] and available power traces from Google [60]. In our prototype, we implement SPADE and SAP on a 100-node Spark cluster. We report the impact of different signals on the makespan and cost of tested schemes, showing that SPADE's configurable design and joint scheduling and provisioning enables a superior trade-off between the secondary objective and makespan. Our key contributions are as follows:

1. SPADE, a signal-aware DAG execution system that defines a notion of relative importance for tasks, allowing for fine-grained decisions. SPADE jointly considers this importance

with an external signal for each decision, achieving a superior trade-off between cost and performance.

2. We implement SPADE and SAP in a Spark-on-Kubernetes prototype and a realistic Spark simulator (see § 4).
3. A comprehensive evaluation against baselines and a state-of-the-art ML-based scheduler. We show that SPADE achieves significant improvements in secondary objectives (e.g., 32.9% lower carbon emissions and 51% better alignment with an available power signal) while maintaining competitive makespan.

2 Problem and Motivation

This section formalizes the signal-aware DAG scheduling problem and presents insights to contextualize our desiderata.

2.1 Signal-aware DAG scheduling problem

Each job (i.e., a data processing workflow) is represented as a directed acyclic graph (DAG) $\mathcal{J} = \{\mathcal{V}, \mathcal{E}\}$, where each node in $\mathcal{V}$ is one of n tasks, and each edge in $\mathcal{E}$ encodes precedence constraints between tasks, e.g., for tasks $j, j' \in \mathcal{V}$, an edge $j \to j'$ indicates that j' cannot start until after j has completed. A cluster includes $K \geq 1$ executors (or machines). More than one job can simultaneously run on a cluster—e.g., given a set of current jobs $\{\mathcal{J}\}$, the scheduler assigns tasks to executors over time while respecting precedence and capacity constraints. We index continuous time by $t \geq 0$.

The traditional goal is to minimize the *makespan* of a schedule, which is the total time to complete all jobs. In this work, we additionally consider the goal of *signal-awareness*: given a time-varying signal described by $s(t) : t \geq 0$, a signal-aware system's objective is to minimize a combination of typical metrics (i.e., makespan, average job completion time) and the total cost (due to the signal) incurred during execution.

We generally assume that future values of the time-varying signal $s(t)$ are unknown to the system, giving the problem an online nature. We follow prior work [7, 51] and place one minimal assumption on the signal, namely that the signal values are bounded by constants $s_{\min} \leq s(t) \leq s_{\max}$ that are known in advance. In practice, these can be defined based on historical data or short-term forecasts of the signal of interest over a given time horizon. We assume without loss of generality that the system attempts to minimize the signal cost, i.e., so $s_{\min}$ is a "good" signal, and vice versa.

We note a subtle distinction between *signal-awareness* (treating the signal as a secondary objective, as in SPADE) and *signal-adherence* (treating the signal as a hard constraint, e.g., instantaneous power available to the cluster). The two are complementary: when power availability is genuinely constrained due to curtailment or contention, a separate enforcement layer is typically responsible for arbitrating capacity across workloads (e.g., [16]). SPADE's role is to schedule *within* whatever capacity is currently available, and its ideas apply whether the cluster voluntarily uses fewer resources during high-signal periods or is involuntarily curtailed by such an enforcement layer; in both cases, SPADE optimizes makespan with the knowledge that resources may vary over time.

Our code is available at github.com/umass-solar/adaptive-dag.

2.2 Guiding intuition and preliminaries

Modern data-processing frameworks (e.g., Spark) express jobs as DAGs of precedence-constrained stages and, by default, schedule them using straightforward strategies such as first-in, first-out (FIFO) or fair-share [25]. To exploit DAG structure, recent heuristic and reinforcement learning (RL)-based schedulers [30, 31, 37, 43, 53, 74, 77] rank ready tasks by a score or probability distribution—a representation that SPADE leverages directly.

Compared to a classic (i.e., *signal-agnostic*) scheduler, we have two primary metrics of interest: *stretch factor*, which describes the increase in makespan due to signal-aware actions, and *cost savings*, which describes the improvement on the secondary objective due to changes in the schedule. We give formal definitions of both quantities in Appendix B. Between these two metrics, there is an inherent trade-off between e.g., executing a task during the current signal and waiting for potential better signals at the expense of increasing makespan.

This trade-off inherits challenges that are familiar in the online decision-making literature, specifically problems known as *online search*—in these problems, the player must purchase an asset at a price that varies with time [22, 51]. These problems have natural applications in, e.g., financial markets, but they have also been used to model systems problems such as energy cost minimization for data centers [41]. A key challenge in these problems is the inherent uncertainty of future signal values (i.e., prices). The common method to handle this uncertainty is a technique known as *threshold-based design* [6, 40, 72], which defines a threshold function that is used to guide decision-making at each time step.

In the context of our two key metrics, we translate the trade-off between executing and waiting into three basic conditions that a signal-aware system should satisfy, outlined below. In Fig. 1, we give an illustration of this "desired behavior" for SPADE, FIFO, and optimal schedules.

i) If the fluctuation of the time-varying signal is *low* (e.g., $s_{\min}$ and $s_{\max}$ are close), makespan should be similar to a signal-agnostic schedule (i.e., stretch factor close to 1).

ii) If the fluctuation is *high* (e.g., $s_{\min}$ and $s_{\max}$ are not close), the stretch factor should be *finite*, i.e., the scheduler does not wait indefinitely to complete the job.

In existing work on online search and signal-aware schedulers, schemes often satisfy condition **ii)** by imposing a *deadline* on each job, forcing it to execute when the deadline is near [7, 28, 33]. When applicable, per-job deadlines can be a more user-friendly interface than tuning a trade-off parameter, but prior signal-aware deadline-based schemes generally

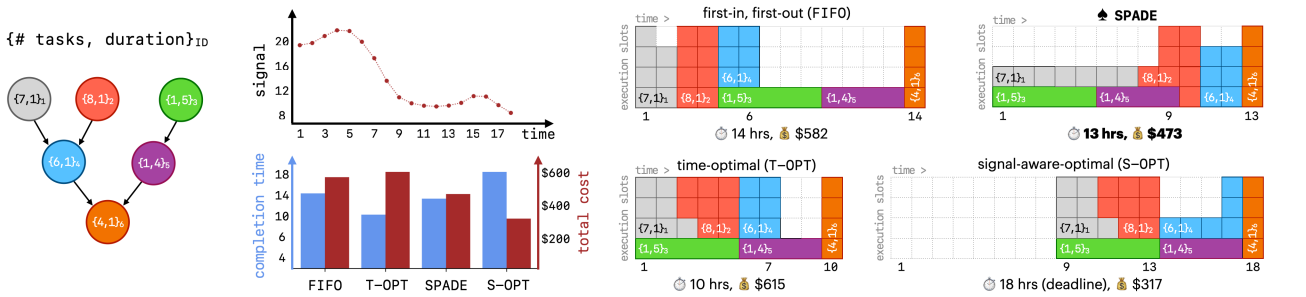

Figure 1: Four schedules for a motivating DAG and 18-hour signal trace (left hand side). When the signal is high, computations are more costly. Compared to an agnostic FIFO scheduler, the time-optimal scheme (T-OPT) prioritizes the green and purple stages of the DAG to reduce overall makespan. A signal-aware-optimal scheme (S-OPT) with a *deadline* to finish the DAG within 18 hours reduces cost by 51.2%, at the expense of increasing time by 28.5% compared to FIFO. By prioritizing green and purple stages when signal is high, SPADE reduces cost by 23.1% and still completes 7% faster than FIFO in this scenario.

consider only one job at a time. Extending this interface to a multi-tenant batch cluster is non-trivial: when multiple jobs with similar deadlines arrive simultaneously and resources are limited, all schedules (signal-aware or otherwise) may be unable to honor every deadline. To address this challenge, our schemes (see § 3) are designed to guarantee a *minimum amount of progress* on jobs as long as the queue is not empty.

The unique precedence-constrained nature of the DAG scheduling problem introduces one additional challenge to consider in our design. In particular, a signal-aware scheduler that does not consider the structure of task graphs may make actions that block important bottleneck tasks from processing, resulting in an outsized negative impact on makespan. This gives a natural third condition:

iii) When the fluctuation is *high* (i.e., $s_{\min}$ and $s_{\max}$ are not close) and the system is in a high-signal period, a scheduler should carefully consider the *structure* of a job's DAG, prioritizing *bottleneck* tasks to use the limited resources.

This condition captures the idea that signal-aware DAG execution must consider the trade-off between executing a task now (unlocking tasks that depend on it sooner), and waiting to execute the task until the signal (may) improve. To approach this trade-off, we combine the notion of threshold-based design, which allows for a rigorous characterization of the trade-off between e.g., executing a given task and waiting for better signals, with the notion of score- or probability-based task prioritization seen in state-of-the-art DAG schedulers. In the following section, we present SPADE, our main system that satisfies conditions **i - iii)** and captures the desired behavior of signal-aware execution for DAG workloads.

3 Design

In this section, we present SPADE (Scheduling and Provisioning for Adaptive DAG Execution), our main system. We also define an ablation study, SAP (Signal-Aware Provisioning) to demonstrate the benefits of the joint scheduling and provisioning decisions made by SPADE.

3.1 SPADE

From the discussion in § 2.2, we seek an interpretable and configurable system that satisfies conditions **i - iii)**. To this end, we introduce SPADE (**S**cheduling and **P**rovisioning for **A**daptive **D**AG **E**xecution). SPADE's key idea is a metric of *relative importance* (Def. 3.2) implicitly embedded in a score distribution or probability distribution over tasks SPADE uses this metric, combined with a configurable signal-aware threshold function, to make fine-grained, per-task scheduling decisions, as illustrated in Fig. 2.

SPADE design. We first define a notion of *score or probability distributions* over tasks that SPADE uses to interpret DAG structure.

Definition 3.1 (Score or Probability Distribution)**.** *At each* ***scheduling event****,*[1] *a score or probability distribution is described by* $\mathcal{D}(t) := \{p_{v,t} : v \in \mathcal{A}_t\}$*, where* $\mathcal{A}_t$ *denotes the set of tasks that are ready to be executed at time* t*.*

Several state-of-the-art DAG schedulers use a variety of heuristic or learning-based techniques to compute score or probability distributions that satisfy Def. 3.1, including Graphene [30], Decima [53], and others [31, 43, 74, 77]. Two notes on this abstraction. *(i)* These score distributions are typically computed over *all* ready-to-execute tasks across *all* active jobs (not per-job) so $\mathcal{D}(t)$ already encodes cross-job prioritization. *(ii)* How the scores are computed varies (Decima learns them via reinforcement learning; Graphene combines critical-path length, packing efficiency, and priority), but SPADE treats the scorer as a black box with one working assumption: high-scoring tasks correspond to bottleneck tasks in the makespan sense. This assumption is inherited: if the scorer fails to identify bottlenecks, it would already perform poorly on makespan, even without any signal-awareness layered on top. Recall from § 2.2 (condition **iii)**) that bottleneck tasks (those with a large score or probability in the above distribution) should be scheduled even during high-signal periods to

[1] Scheduling events include job arrivals, task completions, and executors becoming available.

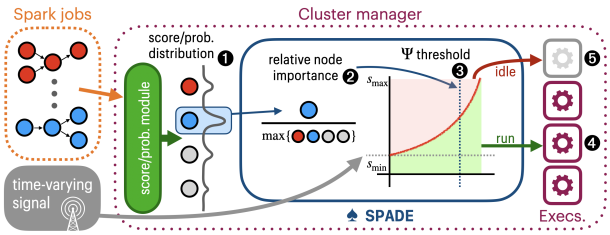

Figure 2: SPADE takes a probability (or score) distribution over tasks as input. Given such a distribution ❶, SPADE computes a *relative importance* score ❷ that is used to determine which tasks should run based on the current signal ❸—e.g., bottleneck tasks run regardless of the signal ❹, while less important ones are deferred to later (low-signal) periods ❺.

preserve makespan. To this end, we formally define a notion of *relative importance* that compares the score/probability assigned to a single task v against other tasks in $\mathcal{A}_t$.

Definition 3.2 (Relative Importance)**.** *Given a time $t \geq 0$ and task $v \in \mathcal{A}_t$, the relative importance $r_{v,t}$ is defined as:*

$$r_{v,t} \coloneqq \frac{p_{v,t}}{\max_{u \in \mathcal{A}_t} p_{u,t}} \in [0,1].$$

If a task's relative importance is closer to 1, the task is relatively *more important*, and a value closer to 0 implies the opposite. Note that if $|\mathcal{A}_t| = 1$ (i.e., only one task can be scheduled), the importance of that task is always 1.

Recall that the goal is to optimize a combination of performance objectives (e.g., makespan, JCT) and a secondary objective that is defined by a time-varying signal. Using the metric of relative importance, we define a *scheduling filter* using a threshold function Ψ_γ that considers the current signal and the importance of a task. $\gamma \in [0,1]$ is a user-specified signal-awareness parameter that controls how "strictly" this function follows the time-varying signal: $\gamma = 0$ recovers signal-agnostic scheduling, while $\gamma = 1$ is maximally signal-aware.

$$\Psi_\gamma(r) = (\gamma s_{\min} + (1-\gamma)s_{\max}) + [\gamma s_{\max} - \gamma s_{\min}] \frac{\exp(\gamma r) - 1}{\exp(\gamma) - 1},$$

Ψ_γ is an exponential function of the relative importance of a task r—this draws on literature from online search [22,78] and captures a trade-off between executing a given task now at the current signal, and the risk that better signals exist in the future. The choice of an exponential inherits a risk-aversion intuition from online search problems such as one-way trading [22]: in these problems, a player who must purchase N units before a deadline at time-varying prices optimally accepts the first unit at a relatively loose threshold (the risk of paying a worst-case price later for the bulk of remaining units dominates) and tightens the threshold exponentially as more units are bought. The optimal reservation-price curve in this class of problems is provably exponential. In our setting, the analogy is as follows: a task with low relative importance (a "first unit") should be deferred only when the signal is unusually bad, since deferring it risks stalling downstream tasks; a task

Algorithm 1 SPADE (Scheduling and Provisioning for Adaptive DAG Execution)

1: **input:** user-specified parameter γ, threshold function Ψ_γ, score/probability distribution $\mathcal{D}(t)$
2: **define:** *invocation* occurs when the signal $s(t)$ changes or when a scheduling event happens
3: **while** cluster active at time $t \geq 0$ **do**
4: **if** invocation at time t **then**
5: Sample $v \in \mathcal{A}_t$ from score/prob. distribution $\mathcal{D}(t)$
6: Compute relative importance $r_{v,t} = \frac{p_{v,t}}{\max_{u \in \mathcal{A}_t} p_{u,t}}$
7: **if** $\Psi_\gamma(r_{v,t}) \geq s(t)$ **or** no executors currently busy **then**
8: Send task v to an available machine at time t
9: **else**
10: Idle until next invocation

with high relative importance (a "last unit") is admitted at almost any signal because the cost of stalling its dependents outweighs paying a high signal cost. [2] We formalize the usage of this function in Algorithm 1. Note that if the input $\mathcal{D}$ is a score distribution, we first use a softmax operation to sample from the corresponding probability distribution over tasks (line 5).

SPADE's signal-awareness filter accomplishes all three of the motivation points defined in § 2.2. It schedules (or defers) tasks based on the current signal $s(t)$, with the effect of reducing execution during high-signal periods. Furthermore, the likelihood of a task being scheduled irrespective of the current signal is proportional to its importance in its DAG. Note that $\Psi_\gamma(1) = s_{\max}$, which means tasks with high relative importance are always scheduled. The choice to *sample* from $\mathcal{D}(t)$ (line 5) rather than taking the argmax is essential: the argmax always has relative importance 1, and $\Psi_\gamma(1) = s_{\max}$, so such a policy would never defer tasks. Sampling lets the algorithm consider lower-scoring tasks proportionally to their probability—when the signal is high, the threshold filter defers these candidates; when the signal is low, they are admitted, opportunistically using available capacity. The bottleneck task is never starved (if sampled, its relative importance of 1 guarantees admission), while low-importance tasks are selectively held back during costly periods. While deferring a task has a negative impact on an individual job's completion time, prioritizing bottleneck tasks across all active jobs allows SPADE to manage the system's overall makespan. To ensure progress on jobs, note that tasks are also scheduled if the entire cluster would otherwise become idle (line 6).

Inherited properties from the underlying scorer. SPADE does not directly enforce fairness, priority classes, or similar cross-job properties; instead, it inherits these from whichever

[2] In our experiments, we briefly considered linear and quadratic threshold functions (normalized to the same range). Threshold shape plays a role similar to γ: a linear threshold sits above the exponential one, so it defers fewer tasks and produces correspondingly smaller signal savings and smaller makespan increases. Because varying the threshold's shape is well-approximated by simply re-tuning γ, we report only the exponential variant.

technique produced the input score/probability distribution $\mathcal{D}(t)$. The relative-importance transform in Def. 3.2 is a per-event normalization by $\max_{u \in \mathcal{A}_t} p_{u,t}$, so it preserves the ordering induced by the scorer: two tasks assigned identical scores are treated identically by SPADE. If the scorer is fairness-aware (e.g., Graphene assigns scores across *all* active jobs to prevent starvation), SPADE preserves that property: rather than greedily picking the top-scoring task, line 5 of Algorithm 1 *samples* from $\mathcal{D}(t)$, which introduces additional randomness across jobs and intuitively maintains or improves the underlying fairness profile. The same observation extends to weighted fairness or priority classes encoded in $\mathcal{D}(t)$.

In Fig. 3, we illustrate the intuitions behind SPADE's signal-awareness filter using two sample job DAGs. In Appendix B.1, we prove that for any signal $\mathbf{s}$ and given K executors, the stretch factor of SPADE is upper bounded by $1 + \frac{\texttt{exp.defs.}(\gamma,\mathbf{s})\cdot K}{2-1/K}$, where $\texttt{exp.defs.}(\gamma,\mathbf{s}) \in [0,1]$ is the expected fraction of tasks deferred under signal $\mathbf{s}$ with parameter γ. Two endpoints anchor the intuition: $\texttt{exp.defs.}(0,\mathbf{s}) = 0$ for any $\mathbf{s}$, so $\gamma = 0$ recovers the underlying scheduler's makespan, and $\texttt{exp.defs.}(\gamma,\mathbf{s}) \leq 1$ always, so the bound remains finite even at $\gamma = 1$. A closed form for general $\gamma, \mathbf{s}$ is not available, but exp.defs. grows monotonically with γ—matching the experimental trends in § 5.

Complementary operator-facing knobs. Beyond γ, SPADE exposes two more design features that allow an operator to control the trade-off between makespan and signal-awareness. *i) Minimum throughput.* Line 7 of Algorithm 1 already requires at least one executor to remain active regardless of $s(t)$, guaranteeing continuous progress on the queue. This constraint generalizes naturally: an operator can mandate that some fraction $\rho \in (0,1]$ of the cluster always runs, regardless of the signal value. A larger ρ keeps more of the cluster productive during high-signal periods (favoring makespan at the cost of signal-responsiveness), while a smaller ρ lets SPADE defer more aggressively. *ii) Target deadlines.* SPADE can also accommodate a relaxed deadline interface: each job is submitted with a *target* deadline, and if it has not completed by that time, it enters a *priority phase* during which its tasks are scheduled regardless of the current signal—combining the interpretability of a deadline with SPADE's signal-aware execution on the path to that deadline. We focus on γ in our experiments, but these knobs are complementary and can be composed with it.

3.2 Ablation design

While SPADE captures all three intuition points from § 2.2 by jointly provisioning the cluster and scheduling tasks in jobs, it is classically more natural to consider the scheduling and provisioning tasks as separate ones. For this reason, we also consider an ablation study of SPADE that isolates these tasks and quantifies the benefits of considering them jointly.

First, note that a "scheduling-only" ablation of SPADE removes its ability to idle executors—instead, tasks are scheduled in descending order of relative importance. This is similar to running the schedulers that computed the original score or probability distribution (i.e., Graphene [30], Decima [53]), and these are baselines in our experiments (see § 5).

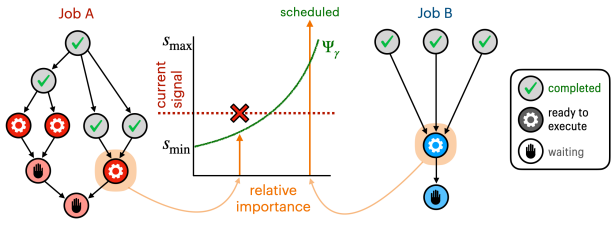

Figure 3: Illustrating the signal-aware filter of SPADE. Jobs A and B are actual DAGs drawn from the TPC-H and Alibaba workloads used in our experiments [2, 69]. Highlighted tasks illustrate two possible outcomes. In A, the sampled task has low relative importance, so it is deferred. In contrast, B's sampled task is a *bottleneck* with high *relative importance*: even during high signal, it is scheduled to avoid increasing makespan.

It is also intuitive to consider a "provisioning-only" ablation that extracts the key resource provisioning ideas implicitly performed by SPADE, while delegating scheduling to another policy. To capture this, we study SAP (**S**ignal-**A**ware **P**rovisioning), which applies a time-varying resource quota to the cluster and coexists with any scheduler (see § 5 for implementations with existing baselines). We detail it below.

SAP design. Given a cluster with K executors, the possible resource quotas are given by $\{0,1,\ldots,K\}$. SAP defines a discrete threshold set analogous to Ψ_γ in SPADE —in this case, the set is defined such that the value of the time-varying signal directly maps to a certain amount of resources that can be used at that time step. Analogous to the signal-awareness parameter γ in SPADE, we define a user-specified minimum quota $B \in \{1,\ldots,K\}$ that always allows the cluster to use up to B executors, ensuring continuous progress on jobs.

Given possible quotas $\mathcal{R} = \{B,\ldots K\}$, the thresholds are a set of values $\{\Phi_i\}_{i\in\mathcal{R}}$, and a quota is set based on how many values are *above* the current signal—see Appendix B.2 for

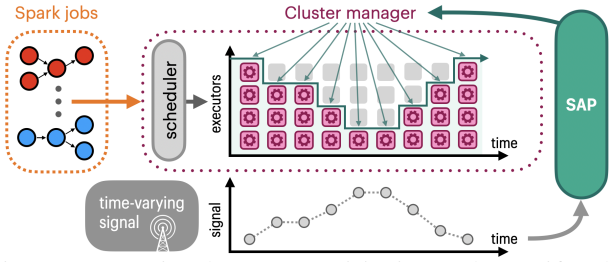

Figure 4: SAP (Signal-Aware Provisioning) only specifies the *resource amount* (e.g., no. of executors) that can be used based on the external signal, interfacing with a cluster manager. SAP can be implemented without changing an existing scheduler.

a formal definition of these.[3] Given signal $s(t)$, the resource quota is $r(t) \leftarrow \arg\max_{i \in \mathcal{R}} \Phi_i : \Phi_i \leq s(t)$. For ease of implementation, this quota is enforced without preemption; when executors become available, new task assignments are only allowed if $r(t)$ is greater than the number of busy executors. In Fig. 4, we illustrate the operation of SAP as an adaptive provisioning module. In Appendix B.2, we give worst-case analytical bounds on the stretch factor for SAP. The B parameter (minimum resource quota) ensures that the stretch factor is finite and decreasing in B, while greater potential cost savings are unlocked as the worst-case stretch factor increases.

4 Implementation

We have implemented proof-of-concepts of SPADE and SAP for Apache Spark on Kubernetes—see § 4.1 for details. We also conduct large-scale experiments in a realistic Spark simulator—see § 4.2 for how we extend a simulation environment [53] to evaluate our signal-aware systems.

4.1 Spark and Kubernetes integration

Resource provisioning & stage scheduling. In Spark deployed on a Kubernetes cluster, each application is submitted to the API server [8] that creates a "driver" running in a pod. We use Spark's dynamic allocation feature, which enables the driver to create executor pods dynamically as needed by the application—these executors connect with the driver and execute application code. Kubernetes handles the scheduling of (driver and executor) pods for each application, while the Spark driver selects stages to execute within an application.

We implemented SPADE as a pluggable scheduling service that coordinates between Spark and Kubernetes. The service includes inference code for a state-of-the-art DAG scheduler Decima [53] that provides probability distributions for SPADE's relative importance calculation. The time-varying signal is obtained from an external API, and context about the cluster and job states is collected from Kubernetes and Spark. To facilitate this, we made the following modifications: First, we implemented a Kubernetes *scheduler plugin* [17] that communicates with SPADE to determine which application should receive available resources. This uses APIs exposed by the default `kube-scheduler` and requires building/configuring a custom scheduler pod. We restrict the scope of our plugin to a dedicated namespace for Spark apps. Next, we made changes to Spark [76] so that each application communicates with SPADE when choosing the next stage to execute—Spark provides scripts to build pod Docker images [55] from source.

To implement the SAP ablation study, we wrote a Python daemon to retrieve the current signal from an API and adjust the resources available to Spark by setting a *resource quota* [3] within a dedicated namespace—our implementation adjusts *CPU and memory* quotas to correspond with a maximum number of executors. When the quota is *lowered*, existing pods are *not* preempted, but new pods are not scheduled until usage falls below the quota.

Setting level of parallelism. In a Spark DAG, each *stage* (i.e., task) includes multiple operations that may be parallelizable over multiple executors. Setting a *parallelism limit* (number of executors working on a stage) is a key component of Spark resource management (e.g., see [53, Section 5.2]). More executors are not necessarily better: assigning many executors to a stage that does not benefit from it will *block* other jobs in the queue. For *signal-awareness*, we enable SPADE and SAP to set new parallelism limits for the current job each time a stage is scheduled, and particularly to set *lower* limits when signal is high (e.g., see **i)** and **ii)**, § 2.2).

In our implementation of SPADE, if a stage is deferred, it *idles* (see Alg. 1) the newly freed executors that prompted a scheduling event. Otherwise, the stage's parallelism limit is set to $P' := \lceil P \cdot \min\{\exp(\gamma(s_{\min} - s(t))), (1-\gamma)\}\rceil$, where P is the limit chosen by the scheduler that generated the input score or probability distribution for SPADE (in our experiments, either Decima or Graphene). This mirrors the exponential trade-off in SPADE's design—e.g., when the current signal $s(t)$ is close to $s_{\min}$, the limit is set to $\lceil (1-\gamma)P \rceil$, and as $s(t)$ grows, the limit decreases exponentially to 1.

For the SAP ablation, if the signal-agnostic scheduler specifies a parallelism limit P, SAP first attempts to schedule a stage with $P' = \lceil P \cdot r(t)/K \rceil$, where $r(t)/K$ is the ratio of the resource quota vs. the total number of executors. If the number of available executors is less than P', the current stage takes all of the remaining available executors.

4.2 Spark simulator environment

Mao et al. [53] developed a faithful simulator of Spark's *standalone mode* (i.e., where Spark is the cluster manager), achieving an error (in run times) of within 5% [53, Fig. 18]. This simulator captures all first-order effects of Spark execution (e.g., delays in executor movement, parallelism overheads)—it has since seen wide use in Spark contexts [4, 27, 35, 46, 54, 64]. We implement SPADE, the SAP ablation study, and additional baselines through the following modifications:

▶ *Accounting:* Each job's cost due to the time-varying signal is measured *ex post facto* to avoid impacting simulator fidelity. After an experiment completes, existing metrics (e.g., executor lifetimes) and a signal trace are used to tally the cost.

▶ SPADE*:* We implement SPADE, which uses score or probability distributions over tasks computed by either Graphene or Decima.

▶ SAP*:* We implement SAP as a wrapper over each *signal-agnostic* scheduler in the simulator—see § 5.1.

▶ *Baselines:* We implement GreenHadoop [28] and Graphene [30] as additional baselines for our experiments. See Appendix A.1 for implementation details.

[3] Recall that a low signal implies using resources is less costly, WLOG.

With these modifications, the simulator allows us to quickly test many scenarios with a high degree of accuracy.

5 Evaluation

We evaluate our proposed system in a prototype cluster and a realistic Spark simulator, using workloads from TPC-H benchmarks [69] and Alibaba production DAG traces [2]. We conduct our main experiments using *carbon intensity* as the time-varying signal, as it is readily available for several regions with different characteristics and exhibits the intra-day variability that motivates systems adapting to time-varying conditions [23]. We also conduct simulator experiments using an *available power* signal obtained from Google cluster traces [73]. In doing so, we answer the following questions:

1. How do SPADE and SAP navigate the trade-off between signal-awareness and makespan?
2. How do SPADE and SAP adapt to changes in signal characteristics (e.g., variation) and workload characteristics?

Table 1: Statistics for carbon signal traces, including the duration, granularity, min., max., mean, and coefficient of variation (*higher value implies more variation*).

Trace	Duration	Unit	Min.	Max.	Mean	Co. var
PJM	01/01/2020-12/31/2022 Hourly granularity 26,304 pts.	$gCO_2eq./kWh$	293	567	425	0.110
CAISO			83	451	274	0.309
ON			12	179	50	0.654
DE			130	765	440	0.280
NSW			267	817	647	0.143
ZA			586	785	713	0.046

5.1 Experimental setup

Signal traces. For carbon intensity, we use historical traces from six regions—each trace provides hourly carbon intensity data in grams of CO_2 equivalent per kilowatt-hour ($gCO_2eq./kWh$) [23]. For these traces, the secondary objective is to reduce the carbon footprint of running jobs. We define the carbon footprint as follows: If the per-time-step energy usage of the Spark cluster at full utilization is given by a constant E, the footprint at time t is given by $s(t) \times E \times u(t)$, where $u(t)$ is the cluster's current executor utilization.

In Table 1 and Fig. 15, we give snapshots of each region, showing how grid characteristics impact the signal. Larger *coefficients of variation* (ratio of the standard deviation to the mean) correspond to greater renewable penetration—for instance, a large fraction of CAISO's capacity is solar PV, while the capacity in ZA is predominantly coal. To better observe the behavior of our signal-aware systems, we follow prior work [28] and scale time and workloads in experiments that use carbon traces such that 1 minute of *real time* corresponds to 1 hour of *simulated time*—since the carbon signal is reported hourly, this approximates a scenario where jobs work with large amounts of data and run for several hours, as is becoming common in e.g., data curation for LLMs [9, 10, 12, 50, 70]. We provide an experiment to characterize the effect of this scaling in Appendix A.1.4.

For the available power signal, we use Google cluster traces [73]—these traces provide power utilization as a percentage at 5-minute intervals in 8 production clusters for May 2019—see Table 5 for statistics of each trace. We use the average power utilization across a single cluster (i.e., "cell") as the time-varying signal, and the secondary objective is to minimize the power overloading due to running jobs. We define power overloading as follows: Each cluster has a minimum and a maximum avg. power utilization, denoted by $s_{\min}$ and $s_{\max}$. Then the overloading is given by $s(t) + (s_{\max} - s_{\min}) \times u(t) - s_{\max}$. Note that the overloading is 0 when our Spark cluster is at full utilization but the broader cluster utilization is minimal (i.e., $s(t) = s_{\min}$).

Workload traces. For workloads, we use TPC-H benchmarks [69] and real DAGs from production Alibaba traces [2]. We construct workloads such that the inter-arrival times follow a Poisson distribution while specific jobs are randomly picked from the respective traces. In the main body, we consider an average inter-arrival time of 30 real-time seconds (30 minutes in the carbon traces), with additional experiments measuring the impact of arrival rate in Appendix A.2.

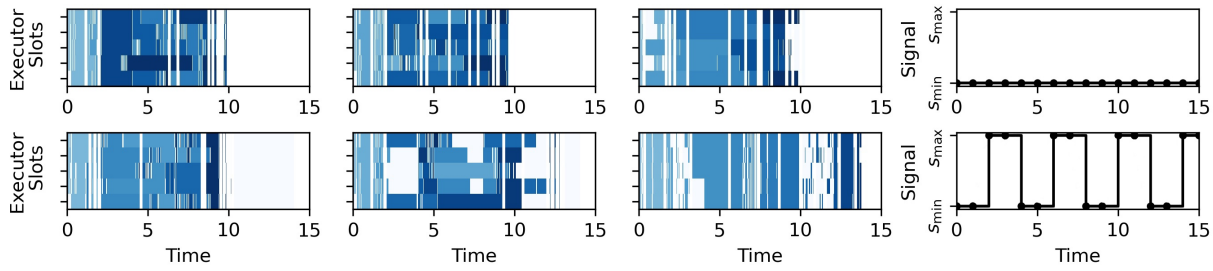
The TPC-H queries we experiment with operate on synthetic data with scales of 2 GB, 10 GB, and 50 GB—these correspond to average real durations of 180 seconds, 386 seconds, and 1,261 seconds when given a single executor. In our prototype experiments, we also construct workloads based on DAG information from the Alibaba trace [2]. These DAGs exhibit a realistic power law distribution (many DAGs of short duration, few DAGs of long duration), they have 66 nodes on average, and an average total duration (on one executor) of 7,989 seconds. We uniformly scale these Alibaba DAG durations by $1/60$ to match our carbon scale—this yields jobs that take 2.2 real-time minutes to complete on average.

In the simulator, each experiment is run over a full trace; each carbon trace is three years of hourly data, while each power trace is one month of 5-minute data. In the prototype, each experiment is run for several trials, where each starts at a uniformly randomly chosen time in a particular carbon trace. Across all experiments, the upper and lower bounds of $s_{\max}$ and $s_{\min}$ are set to the maximum and minimum signal values over a lookahead forecast window of 48 time slots.

Baselines. We compare against the following baselines:

▶ *Default Spark/Kubernetes behavior (default)*: The default behavior of Spark on Kubernetes—Spark uses first in, first out (FIFO) to choose stages within a job, while the Kubernetes scheduler mediates between pods of each job during execution [26]. In the simulator's Spark standalone mode, this baseline implements only the FIFO scheduling.

▶ *Decima*: An RL scheduler for Spark that is optimized for job completion time [53]. We use the simulator's training envi-



(a) Decima *(b)* SPADE-Decima *(c)* SAP-FIFO *(d)* Time-varying signal

Figure 5: Visualizing executor usage over time for three schedules, *(a)* Decima, *(b)* SPADE-Decima, and *(c)* SAP-FIFO in a small simulator with 5 executors and 20 TPC-H jobs arriving over time. The top plot illustrates results when the signal is *flat* during the given time horizon (see ***(d)***), while the bottom plot illustrates results for a signal with *high fluctuations*. In executor plots ***(a-c)***, jobs are unique shades of blue, while "idle" periods are indicated by the white background.

ronment to train Decima for 20,000 epochs. When SPADE uses node probability distributions from Decima's policy network to interpret DAG structure, we denote it as SPADE-Decima.

▶ *Weighted Fair*: A heuristic that assigns executors proportionally to each job's workload, with tuned weights to improve performance on the simulated workloads [53].

▶ *Graphene*: A DAG scheduler optimized for throughput and heterogeneous resource demands [30]. When SPADE uses node score distributions from Graphene's scoring module to interpret DAG structure, we denote it as SPADE-Graphene.

▶ *GreenHadoop:* A MapReduce framework proposed to leverage green energy by matching workloads with the availability of solar [28]. We evaluate this baseline as the closest related work in the carbon experiments. This framework predates Spark, so we adapt its key ideas for DAG scheduling in the simulator—see Appendix A.1 for adaptation details.

Metrics. We use four metrics to evaluate our approaches.

▶ *Carbon Reduction*: When carbon intensity is used as a signal, we report the carbon footprint for each scheduling policy as a percentage decrease relative to the default baseline unless stated otherwise. The values are in the range of [-100%, ∞), with negative values indicating a reduction and positive values indicating an increase relative to the baseline.

▶ *Power Overload (POL) Reduction*: When available power is used as a signal, we report the power overloading for each scheduling policy as a percentage decrease relative to the default baseline unless stated otherwise. Its values lie in the same range as carbon reduction.

▶ *Job Completion Time (JCT)*: We report statistics of job completion time across all the jobs in each experimental run. We report JCT as a fraction of the average JCT for the carbon-agnostic default baseline unless stated otherwise. The values can be in the $(0, \infty)$ range, with below 1 indicating a reduction in JCT and above 1 indicating an increase in JCT.

▶ *Makespan*: We report the total time to complete all the jobs in a given experiment as a fraction of the makespan for the default. Its values lie in the same range as JCT. While JCT focuses on individual jobs, makespan represents the system's overall throughput and efficiency.

5.2 Signal-aware systems in action

Before moving to our main results, we demonstrate signal-aware behavior in Fig. 5, which visualizes the schedules generated by Decima, SPADE-Decima, and SAP-FIFO for two toy example signal traces. In the first (top) case of Fig. 5, the signal is consistently low (i.e., $s_{\min}$), so Decima, SPADE-Decima, and SAP-FIFO all focus on minimizing makespan. Note that FIFO executes jobs in arrival order (light to dark shading) while both Decima and SPADE-Decima pack individual tasks to optimize throughput. The synchronized idle periods visible across all three schedules correspond to intervals when no jobs are in the queue, since jobs arrive over time (with a 15-second inter-arrival in real-time) rather than all at $t = 0$. In the second (bottom) case of Fig. 5, the signal fluctuates between $s_{\max}$ and $s_{\min}$ every two time steps. SPADE-Decima makes fine-grained scheduling decisions to maximize throughput during low-signal periods while idling executors during high-signal periods. This is in contrast to SAP-FIFO, which applies a uniform resource quota across the cluster without consideration of bottlenecks or the remaining processing time of active tasks. As a result, it does not reduce utilization as much during high-signal periods, and still increases overall makespan more than SPADE-Decima.

5.3 Prototype experiments

Our prototype is deployed on an OpenStack cluster running Kubernetes v1.31 and Spark v3.5.3 (both modified per § 4) in Chameleon Cloud [38]. Our testbed consists of 51 `m1.xlarge` virtual machines, each with 8 VCPUs and 16GB of RAM. One VM is designated as the control plane node, while the remaining 50 are workers, each hosting two executor pods. Our Spark configuration allocates 4 VCPUs and 7GB of RAM to each of the 100 executors.[4] To avoid a known issue with Spark's dynamic allocation feature that can cause it to hang on Kubernetes [26], we configure an upper limit of 25 executors that can be allocated to any single job. In the prototype,

[4] Spark's default *memory overhead factor* is 10%. The difference between 7GB (×2) and the 16GB RAM of each worker is to accommodate this [24].

Table 2: Summary of prototype results averaged over all six carbon traces. Each metric is normalized with respect to the Spark / Kubernetes default. SPADE-Decima and SAP-Default are configured to be moderately signal-aware.

Metric *(normalized to Default)*	Default	Decima [53]	SAP-Default	SPADE-Decima
Carbon Reduction (%)	0%	1.2%	24.7%	**32.9%**
Avg. Makespan	1.0	0.857	1.126	**1.013**

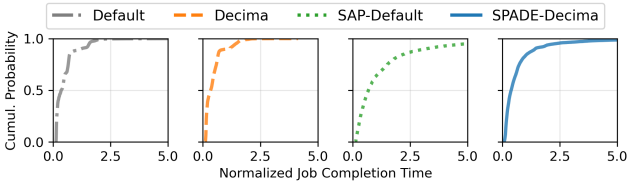


Figure 6: Prototype JCT results aggregated over all six carbon traces, normalized by the average JCT for Default.

we implement a small API that replays given signal traces to test our signal-aware systems, and we implement default and Decima as the baselines. Unless stated otherwise, the results are averaged over batch sizes of 25, 50, and 100 jobs. Furthermore, the results for each experimental configuration are averaged over 10 trials.

Results. Table 2 presents the top-line results for our prototype experiments. SPADE-Decima and SAP-Default configured to be *moderately signal-aware* (γ is set to 0.5 for SPADE and B is set to 20 for SAP) achieve average carbon reductions of 32.9% and 24.7% compared to the default baseline, respectively. Compared to Decima, SPADE-Decima reduces carbon by 32.1%. Fig. 6 plots cumulative distribution functions (CDFs) of the JCT for all four techniques, normalized by the average JCT of default. We find that signal-awareness increases JCT mainly in the tail—for instance, SPADE's median JCT is 7.8% and 11.8% worse with respect to default and Decima, respectively, whereas 95$^{\text{th}}$ percentile JCT is 45.4% and 59.6% worse than default and Decima. SAP sees even larger increases, increasing 95$^{\text{th}}$ percentile JCT by 223% and 254.4% compared to default and Decima, respectively. For signal-awareness, this behavior is expected—for instance, a job that arrives while the signal is high may wait a long time before receiving service. Thus, at a global level, we also consider makespan as a proxy for the cluster's overall efficiency and throughput. SPADE increases average makespan by only 12.4% compared to Decima and 1.3% compared to the default.

Trade-offs between carbon and makespan. We test several parameter settings for SPADE and SAP to configure their signal-awareness in the DE grid region with batches of 50 TPC-H or Alibaba jobs. Fig. 7 plots the carbon-makespan trade-off for five settings of SPADE relative to the Spark/Kubernetes default. Increasing the signal-awareness of SPADE improves savings on the secondary objective at the expense of longer makespan, with a pronounced effect for values of γ approaching 1. Conversely, Fig. 8 plots the same carbon-makespan trade-off for

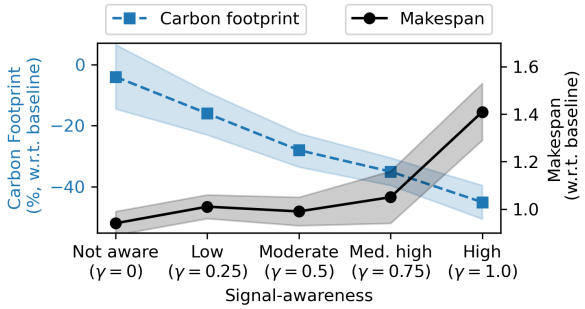

Figure 7: Relative carbon reduction and makespans (w.r.t. the Spark/Kubernetes default) for SPADE-Decima in the prototype, given different degrees of signal-awareness (γ). Shading denotes standard deviation across 10 random trials.

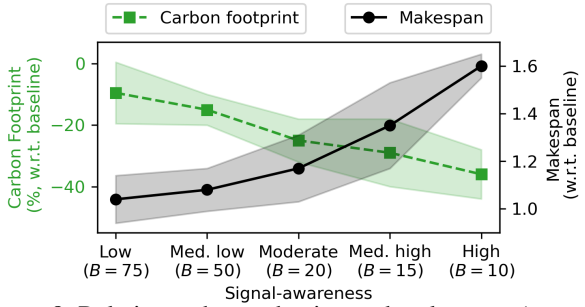

Figure 8: Relative carbon reduction and makespans (w.r.t. the Spark/Kubernetes default) for SAP-Default in the prototype, given different degrees of signal-awareness (B). Shading denotes standard deviation across 10 random trials.

five settings of SAP; SAP sacrifices more in makespan (relative to SPADE) for the same amount of carbon savings (i.e., for the same amount of signal-awareness).

Effects of carbon trace characteristics. Next, we analyze the effect of grid characteristics on our signal-aware systems using subsets of each signal trace (via 30 trials with 25, 50, and 100 jobs). Fig. 9 plots the average carbon reduction and makespan of SPADE, SAP, and Decima. Decima is signal-agnostic and shows a minimal carbon reduction that stays relatively constant across all traces. SPADE and SAP incorporate the external signal into decisions, and we observe a positive relationship between the variability of a trace and the resulting carbon reduction. For example, in ZA where the sig-

Carbon Reduction (%)	0%	12.1%	21.5%	19.3%	8.2%	22.7%	34.2%	31.1%	37.1%	**39.7%**	**40.1%**
POL Reduction (%)	0%	0.9%	31.8%	33.3%	—	16.2%	14.3%	39.8%	41.7%	**43.9%**	**51.0%**
Avg. Makespan	1.0	0.972	0.970	0.983	1.077	1.108	1.011	1.061	1.076	**1.045**	**1.011**

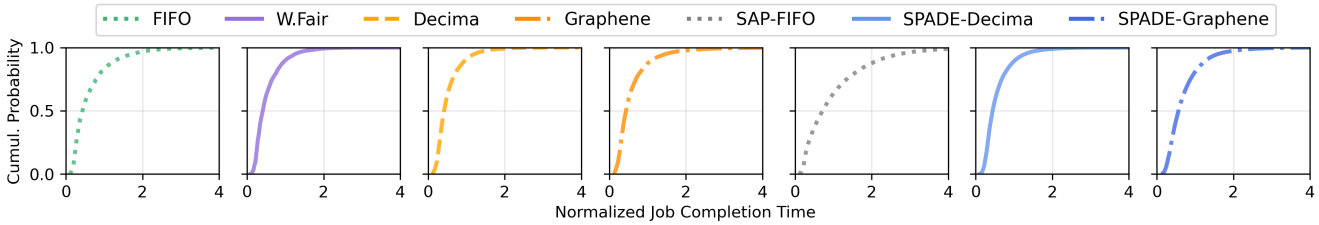

Figure 10: JCT results aggregated over all tested traces, normalized by the average JCT of FIFO.

nal is relatively constant, high-carbon periods do not prompt SPADE to defer tasks since the *potential future reductions* are insignificant. In contrast, high-signal periods in the CAISO grid correspond to nighttime scenarios on the grid, where daytime solar bolsters future reductions. These interactions are also illustrated through makespan—carbon traces with more variable energy mixes drive increases in makespan in exchange for more carbon reduction, since SPADE and SAP *wait* for future low-signal periods.

5.4 Simulator experiments

To conduct large-scale experiments over full traces, we evaluate SPADE in the Spark simulator using TPC-H workloads, comparing it against **Weighted Fair**, **GreenHadoop**, and **Graphene** baselines, in addition to the Decima and default baselines from prototype experiments and SAP ablation study. We refer to the default baseline as FIFO in simulation-based experiments for accurate representation.

Simulator behavior. To quantify differences between our prototype and the simulator (meant to model Spark's standalone mode of operation), we illustrate behavior for an identical batch of 50 TPC-H jobs in Appendix A.1.3. A notable difference between the prototype and the simulator is the relative performance of the built-in baseline (FIFO in the simulator, Spark/Kubernetes default in the prototype). In short, the simulator's FIFO scheduler *over-assigns* executors to individual jobs, blocking others from entering service (thus increasing JCT)—this also increases its relative cost on the secondary objective compared to the default behavior in our prototype.

Table 3 presents the top-line results for simulator experiments using carbon intensity and power traces.

Carbon trace results. We observe that SPADE achieves significant reductions in carbon emissions compared to the baselines—configured to be moderately carbon-aware, SPADE-Decima achieves an average reduction of 23.1% compared to Decima, and a reduction of 39.7% compared to FIFO. SPADE-Graphene achieves reductions of 25.7% compared to Graphene, and a reduction of 40.1% compared to FIFO. Finally, our ablation study SAP achieves an average carbon reduction of 22.7% when implemented on top of FIFO, 25.1% with Weighted Fair, 14.5% with Decima, and 22.1% with Graphene, falling behind SPADE in the latter two cases.

Power trace results. Across experiments that use the available power signal, SPADE significantly reduces the power overloading metric, which corresponds to a *better alignment* with the signal—configured to be moderately signal-aware, SPADE-Decima achieves an average improvement of 17.7% compared to Decima, and 43.9% compared to FIFO. SPADE-Graphene achieves reductions of 26.5% compared to Graphene, and a reduction of 51% compared to FIFO. Finally, our ablation study SAP improves overloading by 16.2% when implemented on top of (and compared to) FIFO, 13.5% with Weighted Fair, 11.7% with Decima, and 12.6% with Graphene.

Makespan & performance. For 25, 50, and 100 jobs, SPADE increases average makespan by 7.7% (Decima) and 2.9% (Graphene), which are only 4.5% and 1.1% degradations compared to FIFO, respectively. For the SAP ablation study, makespan increases by 10.8% when implemented on top of (and compared to) FIFO, 4.0% on top of Weighted Fair, 9.3% on top of Decima, and 9.5% on top of Graphene.

Fig. 10 plots cumulative distribution functions (CDFs) of the JCT for all tested techniques, normalized by the average JCT of FIFO. Similar to the prototype, we find that signal-awareness increases tail JCT: SPADE's median JCT degrades by 6.7% (Decima) and 2.3% (Graphene), while 95th percentile JCT degrades by 42.7% (Decima) and 35.8% (Graphene). For visual clarity, CDFs for the remaining tested policies (GreenHadoop, SAP-Partition, SAP-Decima, and SAP-Graphene) are deferred to Appendix A.2.4; their qualitative behavior matches the trade-offs summarized in Table 3.

Trade-offs between signal-awareness and makespan. In the results summary, we observe improvements in the secondary objective(s) in exchange for degradation in perfor-

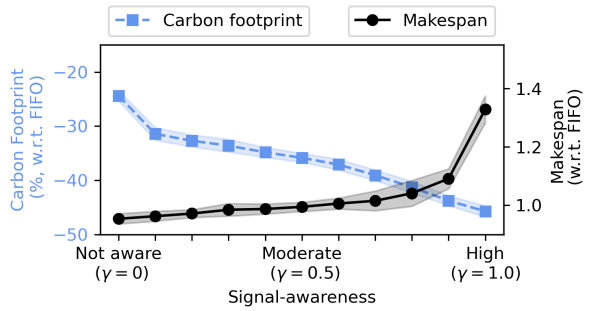

Figure 11: Relative carbon reduction and makespans (with respect to FIFO) for SPADE-Decima in the simulator, given different degrees of signal-awareness (γ). Shading denotes standard deviation across DE carbon trace.

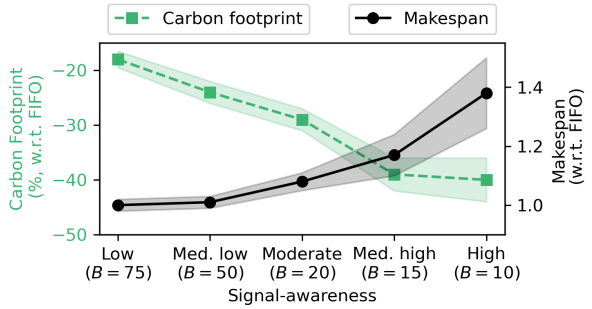

Figure 12: Relative carbon reduction and makespans (with respect to FIFO) for SAP-FIFO in the simulator, given different degrees of signal-awareness (B). Shading denotes standard deviation across DE carbon trace.

mance. Since SPADE and SAP can be configured to be more or less signal-aware, we explore this *trade-off* in the DE carbon trace with batches of 50 jobs. We vary hyperparameters γ (SPADE) and B (SAP) to measure the impact on both objectives. Fig. 11 and Fig. 12 plot the carbon-makespan trade-off for SPADE-Decima and SAP-FIFO, respectively, compared against FIFO. The qualitative trends match the prototype (Fig. 7, Fig. 8), with SAP again sacrificing more makespan than SPADE for the same level of signal-awareness.

A natural follow-up question is whether sweeping γ alone traces the full Pareto frontier of the multi-objective problem. The NP-hardness of DAG scheduling prevents a clean analytical answer, but the experiments give an empirical one: across our parameter sweep, SPADE's carbon-makespan outcomes lie on a frontier that Pareto-dominates the baselines and the SAP ablation (e.g., see Fig. 13), and the $\gamma \sim 0$ endpoint recovers the underlying signal-agnostic scheduler. Sweeping γ from 0 to 1 thus smoothly interpolates between the makespan-optimal and signal-aware regimes along the dominant frontier we observe, though it does not necessarily coincide with the (unknown) true Pareto frontier of the problem.

Advantages of joint scheduling & provisioning. By comparing SPADE against the SAP ablation, we can quantify the advantages of the key DAG scheduling ideas of SPADE, namely relative importance (see § 3.1). We examine this in detail using the DE grid region with batches of 50 jobs. We configure SPADE and SAP with ten parameter settings for varying degrees of signal-awareness. Fig. 13 plots the result of this experiment, where each dot denotes the outcome of one trial—results for Decima are in the left-hand plot, while results for Graphene are in the right-hand plot. We fit a cubic polynomial to the outcomes of all four methods to illustrate the key trend: SPADE exhibits a strictly better trade-off between carbon and makespan. For trials where carbon savings lie between 35% and 45%, SPADE increases makespan by an average of 7.9% (Decima) and 1.2% (Graphene), while SAP increases it by an average of 42.7% (Decima) and 17.7% (Graphene). Conversely, for trials where makespan is increased by between 0% and 10%, SPADE achieves average carbon savings of 35.6% (Decima) and 52.4% (Graphene), while SAP achieves an average savings of only 20.1% (Decima) and 24.8% (Graphene).

Carbon intensity trace characteristics. The top-line results in Table 3 average over all carbon traces—as in the prototype, Fig. 14 plots the carbon reduction and makespan for each of SAP-FIFO, SPADE-Decima, and Decima across each of the six carbon traces. Decima's carbon reduction relative to the baseline is higher relative to that observed in the prototype—this is due to differences between Spark's standalone FIFO scheduler and the Spark/Kubernetes behavior of our prototype (see Appendix A.1.3). Similarly, SPADE's reductions increase alongside Decima's, and SAP-FIFO in the simulator does slightly worse on the secondary objective compared to SAP in the prototype.

When does SPADE help most? SPADE's advantage over structure-agnostic alternatives (e.g., the SAP ablation wrapping FIFO or Weighted Fair) is largest when the workload contains DAGs with non-trivial structure—jobs whose critical path runs through a subset of highly-connected tasks, or jobs with long chains of dependent stages. Both TPC-H and the Alibaba trace contribute such DAGs (Jobs A and B in Fig. 3 are representative), and SPADE's relative-importance metric is what lets it preserve makespan by protecting bottleneck tasks during high-signal periods. Conversely, when the workload is dominated by "flat" DAGs whose ready tasks are essentially

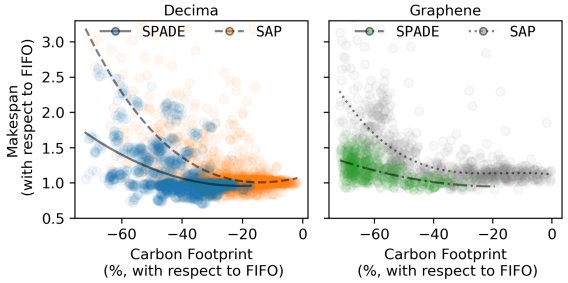

Figure 13: Relative carbon reduction vs. makespan for SPADE and SAP in simulator experiments, given varying parameters $\gamma \in [0.1, 1.0]$ and $B \in \{1, 5, 10, \ldots, 85\}$ that correspond to degrees of signal-awareness. Each dot represents an individual trial, and lines represent a cubic polynomial of best fit.

all available at once (or by effectively single-stage jobs), the notion of a bottleneck task is less informative and SPADE's advantage over a SAP-style wrapper narrows: structure-agnostic provisioning suffices because there is little structure to exploit.

5.5 Takeaways

Through evaluation in a prototype cluster and realistic simulator, we show that SPADE is effective, reducing carbon by 32.9% and reducing power overloading by up to 51% in exchange for modest increases ($< 5\%$) in makespan. SAP, our ablation study, shows that the joint scheduling and provisioning decisions of SPADE are necessary to obtain a favorable trade-off between signal-awareness and performance (see Fig. 13). Intuitively, the behavior of all our signal-aware techniques depends on the characteristics of a particular signal trace—our experiments demonstrate that SPADE works for a variety of signals and exhibits high configurability to meet any desired priority between signal-awareness and performance. An orthogonal route to reducing a secondary objective while maintaining the same performance is to expand cluster capacity (e.g., add additional executors) and ramp up *more* during low-signal periods—prior work has shown that this can hold performance roughly constant while still reducing a secondary objective (such as carbon footprint), at the cost of extra hardware capex (and, in the carbon case, extra embodied emissions) [1, 33, 34, 48]. SPADE accommodates this regime naturally: when additional executors are available during low-signal periods, its filter Ψ_γ admits more tasks as $s(t)$ falls, so the system opportunistically uses this extra capacity without any changes to the system.

6 Related Work

To contextualize the related work, Table 4 summarizes guiding questions that we ask: 1) does the work consider scheduling and/or provisioning in response to an external time-varying signal, 2) does it consider DAG structure (stages and precedence constraints), 3) are batch or interactive workloads considered (if applicable), 4) does the proposed scheme process a single job in isolation or multiple workloads concurrently, 5) has the scheme been implemented in a prototype, and 6) does the work provide any theoretical guarantees about, e.g., the approximation quality of the proposed scheme? SPADE is unique in answering all of the above yes/no questions in the positive for the setting of multiple batch DAG workloads.

For the performance objective of makespan minimization, the scheduling of precedence-constrained tasks (i.e., tasks with DAG structure) has been extensively studied—classic results show that solving the problem optimally is NP-hard even in simple forms [42], so most studies have focused on heuristics and approximations [13, 15, 19–21, 29, 39, 45, 52, 58, 66]. As DAG-structured workloads have gained salience in applications, systems such as Graphene [30], Decima [53], and others [31, 43, 47, 74, 77] have been proposed to optimize the throughput of DAG workflows and/or Spark jobs.

A few works have considered DAG scheduling with other objectives beyond makespan [49, 56, 57, 65, 68]. These balance reducing makespan alongside one other metric, such as energy usage. For example, Su et al. [65] theoretically studied *energy-aware* list scheduling for precedence constrained tasks, giving bounds for a combined objective of energy consumption and performance. However, these works typically focus on a secondary objective such as energy or cost, which do not capture the time-varying dynamics of a signal-aware objective such as carbon emissions or grid integration.

In recent years, several studies have proposed new theo-

retical techniques and schemes for signal-awareness and/or carbon-awareness in different workloads. For example, CarbonScaler [33] is a provisioning scheme for batch workloads that exploits temporal differences in carbon intensity signals, using more parallelism when the signal is low. In the context of this work, CarbonScaler can be interpreted as similar to our ablation study SAP, although the original paper considered a single job at a time and assigns deadlines to each job, rather than offering a tunable trade-off between objectives.

CarbonScaler is one of several studies that explicitly consider external signals such as carbon [34, 40] or power [62], but do not consider the internal DAG structure of workloads. Closer to this work's focus on data processing workloads, GreenHadoop [28] is a MapReduce framework that considers an external signal (available renewable energy) when scheduling, although it does not consider DAG structure because it predates Spark. As outlined in § 2, considering these constraints is important for signal-aware execution of DAG workloads—ignoring this structure yields suboptimal performance on the secondary objective, performance objectives, or both.

One recent system, Caribou [32], considers both carbon signals and the DAG structure of serverless workflows. Caribou optimizes the *geospatial* carbon efficiency of serverless workflows by deploying them across data centers to exploit spatial variations in carbon (e.g., when one region's signal is high, another's may be low). However, since it focuses on interactive workloads, it does not exploit temporal signal variations—in other words, deploying it in one data center would not reduce carbon. Furthermore, applying Caribou to Spark would require "moving" a Spark cluster (including data being processed) across data centers. These differences in the "meaning" of job DAGs change the problem significantly: with SPADE, we do not attempt to exploit spatial differences in the time-varying signal—rather, SPADE attempts to anticipate and respond to uncertain signal values in one location.

7 Conclusion

We introduce SPADE, a signal-aware execution system for data processing workloads designed to address emerging scenarios in data center operations that balance between performance and a secondary objective defined by an external signal, such as power availability, carbon emissions, or water use. Through experiments in a prototype and simulator, we show that SPADE's joint consideration of scheduling tasks and provisioning resources is necessary to achieve a favorable trade-off between these objectives—as a result, our experiments demonstrate that SPADE can improve performance on a secondary objective of interest by 32.9% without prohibitive performance degradation.

Abstract

The escalating demand for Machine Learning (ML) training resources in recent years has resulted in a substantial gap between the high demand and the available supply. Efficient allocation of these scarce and expensive resources is crucial for organizations to maximize their return on investment. Existing resource allocation mechanisms, like Karma [26], are designed to guarantee Pareto efficiency and max-min fairness in settings with dynamic (time-varying) user demands, but fail to preserve these key properties in the presence of demands with heterogeneous values. Given the ubiquity and inevitability of heterogeneity in organizational values of different workloads, effective resource allocation policies must accommodate these variations.

In this paper, we describe the design, implementation, deployment, and theoretical analysis of Quota Marketplace, a market-based mechanism to efficiently allocate ML training chips (like GPUs), explicitly addressing scenarios with demands of heterogeneous value. We detail the implementation of this mechanism within Google and present metrics that demonstrate its impact. We also discuss many business-critical requirements that the Quota Marketplace handles quite effectively, and document the gains and opportunities it has unlocked. We establish theoretically how this market-based approach achieves the essential properties of Pareto efficiency and max-min fairness by allowing the users to express the value of their workloads and enabling dynamic resource pricing based on supply and demand fluctuations. Ultimately, the market facilitates resource allocation that aligns with organizational priorities.

1 Introduction

The demand for Artificial Intelligence (AI) compute has experienced unprecedented growth, increasing by over tenfold annually for eight consecutive years, resulting in a 100 million-fold increase over that 8-year period [1]. Major technology corporations have publicly disclosed substantial capital expenditure (CapEx) budgets, tens of billions of dollars each for 2025, to address this growing demand. This exponential growth in demand creates a widening gap between the demand and supply of AI compute resources, specifically Machine Learning (ML) accelerators like GPUs. Consequently, due to the high cost and limited availability of these resources, organizations must implement return-on-investment (ROI) maximizing, efficient allocation strategies for ML accelerators among individual teams and products. In this paper, we describe Quota Marketplace (QM) – a market-based system designed, implemented, theoretically analyzed, and fully deployed at Google, to allocate ML chips to teams across business units. The deployed system allocates several hundreds of thousands of ML accelerators for *ML training workloads* across all the business units in Google. The footprint of the Quota Marketplace is a double-digit percentage of the *entire ML fleet of Google*.

We begin with an overview of QM's position in the ML scheduling stack and the notion of pools. A detailed description of QM concepts and implementation follow in Section 2.

QM and the ML Training Scheduling Stack in a Nutshell. ML compute resources (ML accelerators or ML chips), much like non-ML compute resources (CPUs), have traditionally been partitioned into *static* pools. Each pool corresponds to a business unit (BU) with distinct goals, cost accounting, and resources, and the pool administrators/planners explicitly assign accelerators to teams within that BU. The demand assessment and prioritization procedure typically takes place quarterly or semi-annually and it determines the allocation of chips across pools and across teams within a given pool. This assignment then remains more or less static (especially the distribution across pools) until the next assessment.

Given the rising prominence of ML training workloads and their need for batch compute (which tolerates preemptions much better than serving workloads)—the Quota Marketplace was conceptualized to make the accelerator allocations both dynamic and agile, and economically more efficient, by incor-

[*]Equal contribution.

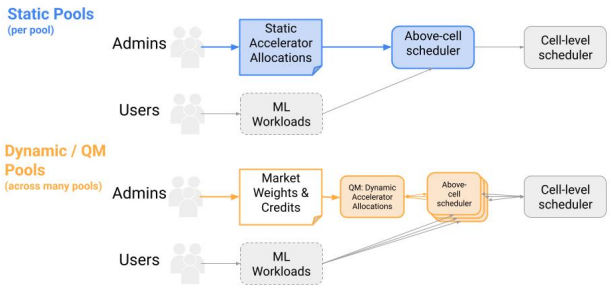

Figure 1: QM in the ML (Training) Scheduling Stack

porating a cross-pool view into allocation decisions. Figure 1 is a short summary of QM's position in the ML scheduling stack. Conceptually, when compared to static pools, there are two main differences in a *dynamic pool* (a) QM replaces static accelerator allocations with dynamic ones, and (b) QM makes these allocation decisions across all the dynamic pools instead of the per-pool allocation decisions in the static pools.

In dynamic pools, which is where QM operates, company-level administrators are tasked with allocating market weights to the different pools that reflect the business impact delivered by these units. Per-pool administrators are tasked with allocating credit, which are location agnostic, resource-type agnostic tokens, to the various teams within their business unit, which again reflect the impact the various teams deliver. The toilsome, communication-heavy, quarter-long human-driven negotiations involved in the traditional prioritization exercises of static allocation are now replaced by supply-demand-based resource allocation decisions both across teams in a pool, and also across pools, at a frequency of roughly every 1 minute. Beyond the several orders of magnitude more-responsive resource allocation that QM brings, QM's cross-pool view while clearing supply and demand automatically makes the allocation economically more efficient.

In a little more detail, QM determines resource allocation by computing clearing prices for each resource type at any given instant. Prices are dynamically chosen to equate *real-time* demand from scheduler queues with the *real-time* supply of the relevant ML accelerator. The market "clears" roughly every minute (often faster than that). By comparing real-time team bids generated by an automated bidding algorithm (that QM provides teams with) against these prices, QM decides which teams receive resources and in what quantity. Consequently, quota in pools (aka dynamic pools) is not guaranteed, but is derived from market conditions, making it well-suited for exploratory workloads and tasks with flexible SLAs, as is the case with most ML training workloads.

We now discuss the many benefits and opportunities unlocked by the QuotaMarketplace.

Agility in the Face of Highly Fluctuating Supply and Demand. The available supply of ML chips is highly dynamic. New hardware capacity comes online daily, often on an imperfect schedule. Resources are also frequently and unpredictably clawed back, at short notice, for a variety of reasons, including, for example, being able to serve production load due to a sudden surge in traffic. On the other hand, human-driven demand assessment and prioritization procedures, as mentioned earlier, are typically conducted quarterly or semi-annually. To maintain allocation speed, various processes used to rely on readily available resource buffers that remain significantly underutilized and unprioritized. A robust system must respond to both rapid capacity addition and swift clawback/reallocation in the order of minutes, rather than quarters. Doing so would directly contribute to significant reduction in the buffer maintained by production teams, as they could promptly claw back resources upon detecting impending traffic surges. As we make the point with data in Section 3, this reclaimed "bonus" capacity is substantial, sometimes on the order of the total committed capacity, and its underprioritized usage results in significant opportunity cost. In other words, QM results in a big increase in company-prioritized occupancy of chips, rather than opportunistic occupancy of chips (which can be thought of as randomly assigning chips), which we demonstrate with data in Section 3. That said, QM also increases the overall occupancy of chips (not just company-prioritized occupancy), because it avoids the siloing inherent to static pools (also demonstrated with data in Section 3). Siloing results in unused capacity, which is often not easily available to use even opportunistically for other pool's workloads.

The demand for ML chips is no less dynamic than their supply. Indeed, deriving the specific ML chip demand for each team directly from the company's business priorities is a challenging task. Our fluctuating usage patterns range from scheduled model training runs to short-duration bursts for demos, exploratory research, and conference submission sprints, exacerbating this problem. Therefore, individuals responsible for resource allocation at a company level (i.e., across all the pools), while knowledgeable about the high-level business goals, often lack granular insight into the time sensitivity, spatial flexibility (i.e., where chips are needed), usage volume, and relative priority of individual requests. Conversely, engineering teams understand the detailed requirements of each workload but lack the broader perspective needed to prioritize across different projects and business units. Therefore, the inherent assumption behind the static pools' prioritization procedures, that we are able to get reasonably accurate predictions of chip requirements for an entire quarter, is highly questionable. Further, regardless of how good our predictions are, a static allocation of chips is very suboptimal in the presence of highly dynamic demand patterns. What's needed is a mechanism to swiftly move allocations in response to real-time demands. QM accomplishes this by enabling continuous, dynamic bidding based on real-time needs.

Enhanced Productivity and Engineering Resource Conservation. QM significantly reduces the frequency of teams having to negotiate with their BU's pool administrators for more capacity in the middle of a quarter or a half year. In static pools, when there is a demand surge (which, as discussed, is not uncommon), it inevitably leads engineers to interact with the administrators to temporarily get more capacity. It is infeasible to solve this problem by statically allocating chips that meets everyone's *peak* demands. Dynamic allocation is inevitable. In QM, these negotiations are relatively rare, and even when it is necessary, QM makes the administrator's tasks much easier — simply increase the credit allocation of the concerned team (if their ask is deemed deserving), without concerns for which team to reclaim chips from, to fund this request. Unlike chips and chip hours, credits are (a) not zero-sum and (b) {resource-type, location}-agnostic. Therefore increasing one team's credits without altering any other team's credits is perfectly valid.

Incentive Alignment in the Face of Intense Scarcity. ML compute resources are very scarce (demand far exceeds supply), and scarcity of resources inevitably drives participants toward strategic behavior. Consequently, a robust resource allocation mechanism must align user incentives with the designer's objectives, such as efficiency and fairness.

To achieve these goals, resource allocation systems should incentivize demand deferral to less congested time periods, geographic locales, or resource-types. A good mechanism should preempt "use-it-or-lose-it" scenarios by incentivizing teams to relinquish resources that they do not have a high value for so that they can be consumed by teams with more pressing needs instead. Similarly, given the variety of available resource types that arises from different accelerator generations, the mechanism should incentivize teams to use less congested types of resources.

Finally, the system must provide clear signals that enable users to plan effectively where and when to run their workloads. In QM, prices serve a dual purpose: they provide (a) economic incentives, and (b) a transparent signal of resource congestion and how it varies across time and location.

Guaranteed Efficiency and Fairness. When allocating scarce resources, a central systems goal is to achieve efficiency and fairness properties. A fundamental notion of efficiency is Pareto efficiency: an allocation is Pareto efficient if there is no other allocation that would result in (a) weakly higher utility for all users and (b) strictly higher utility for at least one user. A less stringent requirement, directly implied by Pareto efficiency, is to avoid situations where resources are unused despite existing demand. In terms of fairness, the standard goal when allocating computational resources is to achieve (approximate) max-min fairness, which aims to maximize the minimum amount of resources (or utility) any user is allocated. In a large organizational context, this is commonly extended to a weighted max-min notion that normalizes the "fair share" for each team based on its potential to positively impact core business priorities. In Section 4 we define Pareto efficiency and max-min fairness precisely, and show how QM guarantees both.

Shock Absorber. QM functions as a shock absorber for the entire corporation, capable of handling significant capacity fluctuations arising from external events. Whether due to the launch of a marquee LLM application that has gained significant traction from customers, requiring hundreds of thousands of accelerators, a high-priority external demo, or surges in cloud customer demand, the system effectively absorbs these shocks without manual intervention. This is not just the earlier point about the agility in handling these requests, but also about distributing the benefits or pains from additions or clawbacks in the fairest way possible according to organizational priority. Shocks can go the other direction as well: QM enables the economically efficient usage of highly fragmented resources added to the system for temporary periods of time, either from serving buffer, or from holding pools.

Prior Approaches. Two broad classes of approaches in prior work are "static allocation" and "chip-hour" mechanisms.

Static allocation. This is the idea behind the traditional static pools discussed earlier. Consider a simple setting with a single type of resource, like an ML accelerator, which has to be divided among a number of users. One of the most popular solutions is to statically allocate [2, 25] this resource by splitting it among the users (or teams) independent of their demands. It effectively creates siloed pools, it gives strong availability isolation, and it upholds fairness. However, crucially, it doesn't satisfy Pareto efficiency because it ignores demands. Max-min fairness [10, 12–16, 19, 20, 22] addresses this problem, and simultaneously achieves Pareto efficiency and fairness, by incorporating demand into decision-making: it maximizes the minimum allocation across all participants, but subject to not allocating more than their demand. But the efficiency guarantees of max-min fairness mechanisms heavily depends on the assumption that user demand is static over time, which is unrealistic for most real world systems [26]. In settings with dynamic demand, static allocations are bound to be far from Pareto efficient.

Chip-hour mechanisms. Aiming for more efficient allocations in the presence of dynamic user demands, "chip-hour" mechanisms determine the amount of access to the resources that each user should be allocated, but provide the users with some flexibility regarding when to use their access rights. A notable example is the Karma mechanism, introduced by Vuppalapati et al. [26], which asks the users to report the amount of resources that they need in each round, and then determines how the resources will be allocated as a function of each user's access history; specifically, this mechanisms strictly prioritizes users who have had the least amount of access to the resources in the past. This elegant mechanism provides incentives for users to request a resource only if they

value it, it allocates resources only to users who need them, and it strives to optimize max-min fairness by prioritizing the user with the minimum amount of resource access in the past. However, despite the very significant improvements that this mechanism achieves, it has an important limitation: it assumes that the user's value for each of these requests is uniform over time and across users, which is quite unrealistic. In fact, as we show in Section 4, the appealing properties of all chip-hour mechanisms break down even for bi-valued instances, where each agent's value for a request can take just one of two values, say HIGH or LOW. Different workloads necessarily hold different values in an organizational context, and it is vital for a resource allocation mechanism to accommodate this. Furthermore, chip-hours are still zero-sum quantities, like chips themselves, because they are still tied to a specific resource type at a specific location. Allocating more chip hours to one team necessarily involves reclaiming these chip hours from some other team(s)[1].

Our Contributions. Our main contributions are:

1. We describe the design, implementation and deployment of Quota Marketplace in Google. The deployed system has several thousands of daily active users, and several billions of accelerator hours already consumed via the system.

2. We provide metrics from the actual deployment of QM.

3. We provide a theoretical analysis in a simplified single-resource setting which exhibits the shortcomings of the chip-hours mechanisms, especially in the presence of heterogeneous user values (an inevitable characteristic of workloads in realistic settings). We analyze our market-based mechanism in the same setting, and show that it guarantees Pareto efficiency and approximate max-min fairness, even in settings with heterogeneous values.

4. Finally, we present several avenues for future work, some that require solving new problems, and others that require careful UX design to ensure that the system does not compromise user-friendliness while aiming to be robust to manipulations. We also describe how we address some of the challenges raised in prior work (e.g. [21]) regarding the integration of markets and systems.

While several benefits of QM have already been discussed earlier, we describe a few more in the paragraphs below.

The Power of Dynamic Pricing. The primary shortcoming of prior works in the face of heterogeneity in values is that they don't provide users a way to express their utility (i.e., their value for being allocated the resource at each point in time), so every user request is treated with the same priority. In the presence of heterogeneous values, we instead need a mechanism which allows users to express these values and then allocate the available resources accordingly. This is precisely what the Quota Marketplace achieves. Given that real-time prices for different resource types are published in a company-wide dashboard, deciding to not start a workload when the price exceeds a certain amount is a definitive way to express that one's value for that workload is below a certain price. Further as already discussed, prices provide a clear incentive for users to shift their demands towards cheaper (and, hence, less congested) resources that they still highly value.

The Benefits of the Credit Abstraction. The role of the credits allotted to the users in our market-based mechanism and their use toward dynamic resource pricing, provide some important benefits relative to static allocation and chip-hour mechanisms. While we briefly alluded to these in the earlier discussion in various contexts, we collect them all below in a little more detail.

First, *credits are fully decoupled from physical resources*: indeed, the sum of credits in circulation by our mechanism is not constrained in any way by the number of available physical resources. This property enables the market to effortlessly handle supply additions and clawbacks: *the addition or clawback of hundreds of thousands of chips does not require the market to adjust the agents' credit balance in any way*: it simply runs the same market clearance algorithm in the next cycle, using the updated supply value when equating supply and demand to compute clearing price. There is no equivalent to this in static allocations or chip-hour mechanisms.

Second, very related to first, but subtly different, *credits are not zero-sum quantities* — this directly enables the market to reprioritize in minutes. For instance, granting a certain team or business unit additional power simply requires minting more credits and handing it over to that team, or increasing the market weight of that BU. In contrast, *chips or chip-hours are both zero-sum* since the physical resources they are tied to are, of course, zero sum. As a result, reprioritization to grant additional power to one team necessarily involves determining which teams to withdraw supply from.

Third, *credits are agnostic to the type, location, or other attributes of each resource, whereas chips and chip-hours are tied to a particular chip and location*. Therefore, when allocating credits, the allocation committee deals with a single-dimensional problem of deciding who gets how much purchasing power. Allocating chips or chip hours, on the other hand, requires a separate resource allocation decision for each chip type and location. Further, it is easy for the allocation committee to measure the return on investment from different teams based on a single-dimensional quantity of credits. Otherwise, the committee has to wrestle with the very hard problem of comparing apples and oranges when evaluating the impact of one team that was allocated one set of chip types in some set of locations relative to another team that received a different set of chip types and locations.

[1] One can resort to oversubscription, but of course that has it limits too, and the core point that chip hours are zero-sum quantities remains the same.

Organization of the Paper. In Section 2, we give a formal description of the Quota Marketplace system and its implementation, along with the features in the market that prevent market abuse. Section 3 presents metrics from the deployment of the Quota Marketplace and demonstrates how the desiderata that we have described thus far are satisfied by the market-based mechanism. In Section 4 we provide our theoretical analysis. In Section 5 we discuss some of the old and new challenges, as well as new opportunities and interesting open problems for future research, and in Section 6 we conclude with an overview of related work.

2 Quota Marketplace System

The Quota Marketplace is an iterative resource allocation system based on dynamic pricing using a generated currency of "credits". To describe how this market operates, we first provide some core concepts.

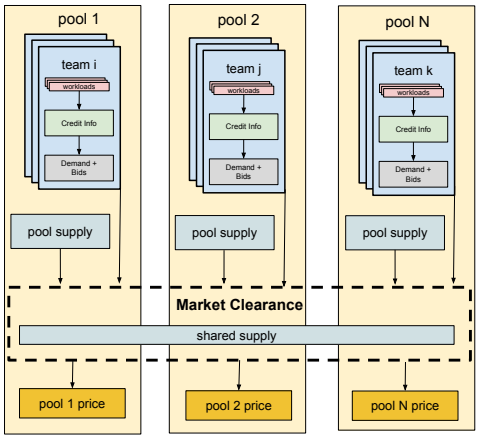

Figure 2: The high-level concepts of Quota Marketplace

Supply. Supply (or resources) of the marketplace correspond to specialized ML-accelerator chips. The chips are distributed across various geographic locations (which we refer to as cells) and are of different generations (which we refer to as resource types or chip types). Each cell has a certain capacity of each chip type, which varies over time.

While the intention of QM is to manage supply shared across all pools, for legacy reasons the system also supports pool-specific supply, which is supply previously purchased and owned by each business unit to which this unit has preferential access. Indeed, Figure 2 shows that market clearance takes into account both pool supply and shared supply.

Teams. Users are grouped into teams and submit demand to the system in the form of individual workloads. As workloads are submitted, they enter the team priority queue, allowing for relative prioritization. The team is the fundamental unit within the system to which resources are allocated.

Pools. Pools are groups of teams representing business units within the larger organization with their own goals, cost accounting, governance, and resources.

Income and Balance. Pool administrators assign credit income to teams to reflect their relative priority in the pool. Income is defined as credits to be deposited into a team's account at a certain rate. As teams incur charges for resource usage, their credit balance gets reduced. Any newly assigned income (say for a new team, or increased income for an existing team) increases the rate of minting new credits, thereby increasing the credits available within the pool.

Each pool independently manages its credit allocation much like a country manages its own currency. However, the total purchasing power of a pool remains fixed regardless of the number of credits minted within the pool. This invariance is enforced by a mechanism called *market weights*.

Market Weights. Google adjusts priority between pools by assigning market weights, which correspond to the total purchasing power of each business unit. This is implemented by mapping the local credits of each pool to a standard global unit, similar to currency conversion in international trade.

Formally, if a pool k with an assigned market weight of W_k, mints an sincome of C_k credits per unit time, each local credit owned by pool k is valued at W_k/C_k standard global units.

This design decouples global prioritization (managed by Google-level administrators via W_k) from intra-pool allocation (managed by local administrators via C_k). However, this exposes teams to monetary dynamics akin to those in international economics. E.g., if pool administrators mint excessive credits (increasing C_k) while the market weight W_k remains constant, the pool experiences inflation and credit devaluation.

User Journey: Reducing Users' Cognitive Burden via Automated Bidding. Incentivizing users to change their behavior necessarily entails imposing at least a small amount of cognitive awareness from the users. That said, QM is designed to offer most of its incentive benefits with very little investment of time from users. A user's journey involves starting a job, using exactly the same workflow as they did in the pre-QM world. Next, the user places their job in a priority queue of active jobs from their team, with the possibility of being asked to adjust their job's position by their team admin, if they so feel. Once a job is on the queue, the most important task of submitting a bid for the job is handled by an automated bidder. The system allows users to set team-level settings and job-level settings for bidding. These include (a) limit orders, which is a job-level setting, letting users specify the maximum price they are willing to pay for that job (b) income-leverage, which is a team-level setting that upper bounds the maximum bid allowed from a team at the product of the team's income and the income-leverage (c) a tool that lets team admins to configure policies for their team's jobs, from a simple priority queue to order their jobs to more sophisticated policies to dy-

namically manage importance of their jobs. Users throughout the company have access to a dashboard with real-time prices of all chip types, price history for the past several months, their team's credit balance, income rate, credit burning rate to help them make informed decisions while deciding on these settings. The automated bidder descends the priority queue for each team, estimates the cost of running each each job, and then, governed by the settings, aggregates costs to compute team level bids. In practice, system provided defaults work quite well for the settings, and indeed most users rely on them, except in periods of high price volatility, which we explicitly mitigate as described in later sections (see "Volatility and Churn" in Section 2.1 for example).

Demand and Bid Formulation. In every market cycle, the system aggregates the demand of queued workloads for each team. We denote d_i^r as the aggregate demand of team i for chips of type r, where r encodes both the hardware generation and the specific cell. The automated bidder translates the team's balance, income rate, and settings into a scalar bid b_i^r according to relative workload priority. This value represents the total credits the team is willing to spend to secure resource r in the current cycle. Because the system resolves markets per resource type, the agent automatically proportions the team's total buying power across the relevant markets before clearing occurs.

Market Clearing. Let b_i^r and d_i^r denote the bid and demand, respectively, of team i for resource type r. For each pool k, we compute a specific clearing price p_k^r to equate the pool's internal demand with its available supply. Pool prices differ from the global market price because pools effectively blend their own static resources (which are free to the pool) with resources purchased from the shared market.

For clarity, we assume all bids are normalized to standard credit units, i.e., we ignore currency conversion rates, as it doesn't change the equations much except for adding notational clutter. Let s_k^r denote the static supply owned by pool k, and let z_k^r denote the supply purchased by the pool from the shared market supply at a reference price p_*^r. The pool sets its internal price p_k^r so that it breaks-even: i.e., the credits it generates from its teams for the $s_k^r + z_k^r$ chips they consume is equal to the credits it has to pay to the central market for having purchased z_k^r credits from it. This yields the following break-even condition:

$$p_k^r(s_k^r + z_k^r) = p_*^r z_k^r \quad \Longrightarrow \quad p_k^r = p_*^r \frac{z_k^r}{s_k^r + z_k^r} \tag{1}$$

Equation (1) highlights the discount effect: if a pool relies entirely on shared resources ($s_k^r = 0$), the pool price equals the reference price ($p_k^r = p_*^r$). Conversely, if a pool relies heavily on owned supply, the internal price is significantly lower than the market reference price.

Given a pool price p_k^r, team i demands $\min(d_i^r, b_i^r/p_k^r)$ units, i.e., a team's demand is simply the minimum of what it actually needs (d_i^r) and what it can afford at a given bid (b_i^r/p_k^r). To clear the pool-local market, the total demand from all teams i in pool k must equal the total available supply:

$$\sum_{i \in \text{Pool } k} \min\left(d_i^r, \frac{b_i^r}{p_k^r}\right) = s_k^r + z_k^r \tag{2}$$

For any fixed reference price p_*^r, Equations (1) and (2) have just two unknowns, namely p_k^r and z_k^r, or more technically $p_k^r(p_*^r)$ and $z_k^r(p_*^r)$ as these are functions of p_*^r. Intuitively, this solution represents the equilibrium between the pool's internal supply-demand clearance and its blended supply cost. Equation (2) is the pool's internal supply-demand clearance, where the LHS is the pool's *aggregate demand curve*, mapping the internal price p_k^r to the total quantity demanded by teams, and the RHS is the pool's total supply arising from it's own supply and purchased supply. Equation (1) represents the *cost-blending curve*, which dictates how the internal price p_k^r must rise as the pool purchases more shared supply z_k^r. The intersection of these two curves determines the unique purchase volume z_k^r and internal price p_k^r for that specific market reference price.

Finally, we are left with determining p_*^r. Let Z^r be the total capacity of resource r available in the shared marketplace. We seek the lowest price p_*^r such that the aggregate demand from all pools does not exceed the shared supply:

$$\sum_k z_k^r(p_*^r) \le Z^r \tag{3}$$

Since the pool demand $z_k^r(p_*^r)$ is monotonically decreasing with respect to price p_*^r, the price p_*^r is efficiently computable using binary search. If demand is low (i.e., even at zero prices there is enough supply: $\sum_k z_k^r(0) \le Z^r$), the price p_*^r is set to zero.

The algorithm described is implementable by a nested binary search, where the inner binary search is used to solve equations (1) and (2) and the outer level to solve equation (3). With the right pre-processing, we implement the algorithm in nearly-linear time using the algorithmic technique in [17].

Resource Allocation. Once the specific pool price p_k^r is established, the allocation x_i^r for each team i is calculated as:

$$x_i^r = \min\left(d_i^r, \frac{b_i^r}{p_k^r}\right)$$

This allocated quota is subsequently passed to the ML scheduler for execution.

Charges and Capacity Import In separate cycles from the market, teams are charged for the resources that they utilize and capacity is read from the resource management system. In the charge cycle, credits are deducted according to the resources that the team actually occupied since the last charge cycle. Capacity for all resource types read are persisted for the market to read in each cycle. Both of these cycles are run less frequently than the market cycle.

2.1 Market Implementation

The Quota Marketplace is implemented as a global coordinator layered atop the hierarchical scheduler stack (comprising above-cell and cell-level schedulers). The system operates as a monolithic binary replicated for availability. While the architecture could theoretically support sharding—distributed bidding across teams and distributed clearing across resource types—we opted for a centralized design to prioritize simplicity and coherency in the initial deployment.

Centralizing the market logic in a single process introduces a potential single point of failure with a large blast radius. We mitigate this risk by decoupling quota generation from job execution. QM does not directly schedule jobs; instead, it generates quota inputs for the underlying scheduler. In the event of an outage, the system gracefully degrades by reverting to static pool scheduling using the last valid quota snapshot calculated by the market. Consequently, while the scheduler may rely more heavily on opportunistic rather than prioritized allocation—reducing efficiency—the system avoids catastrophic downtime.

Modular Design. As illustrated in Figure 3, QM employs a modular architecture where distinct phases of the market cycle are isolated via strict interfaces. While the system communicates with external components—specifically the scheduler and the resource management system—via standard Remote Procedure Calls (RPCs), internal interactions utilize the same framework primitives without incurring the overhead of network serialization. This design choice allows us to inherit robust distributed systems capabilities, such as deadline propagation, request cancellation, structured logging, and monitoring, within a unified process. Figure 3 highlights these external boundaries: the system ingests demand signals from the above-cell scheduler (`SampleDemand()`) and physical capacity data from the resource management system (`ImportCapacity()`), subsequently pushing allocated quotas back to the scheduler (`UpdateSchedulerInput()`).

Periodic Routines. The QM system executes three independent periodic routines: the market cycle, accounting (processing charges and income), and capacity ingestion. Each routine executes within a strict periodic closure that enforces serial execution, preventing overrun. The execution frequencies are tuned to the volatility of the data: the market cycle runs at high frequency ($<$ 1 minute), income and charge accounting runs every 5 minutes, and capacity ingestion occurs roughly hourly ($O(h)$). All critical system state—credits, capacity, quota, and demand—is persisted in a strongly consistent datastore. Market cycles are keyed by timestamp to ensure consistency across potentially overlapping executions.

By decoupling charging, income generation, and capacity import from the market, the system is able to react much more rapidly to demand changes. Capacity is relatively static on the order of minutes (emergency capacity changes can still be manually propagated in $O(m)$). Income and charge resolution indeed affect bidding power each cycle. But there is a feature of the market called *minimum affordable duration* that ensures that the 5 minutes frequency of processing income and charges is more than enough to make bids fluctuate quickly *only because of demand fluctuations*. Minimum affordable duration is a measure we introduced to ensure market stability and prevent abuse. It enforces that a team can bid an amount only if the burn rate of credits at that bid is sustainable for the next 120 minutes. Therefore, income and charges not being processed for the next 5 minutes will not affect the bidding power of any team.

Replayable Market. The core market clearing logic is encapsulated as a stateless, pure function, `RunAuction`. All function inputs and outputs are persisted alongside auxiliary system data. Isolating the auction logic from the runtime environment enables deterministic offline simulation and replay of historical iterations using the exact same RPC handlers. This architecture has proven indispensable for reproducing production incidents, iterating on mechanism design, and verifying the correctness of changes.

Deployment and Verification. The monolithic binary architecture complicates standard canary deployment strategies. To compensate, we rely heavily on offline simulation and deterministic replay. Furthermore, although the binary is deployed globally, the market is logically sharded by resource type. This allows us to gate new features or configuration changes incrementally per resource type, enabling granular rollouts despite the unified deployment artifact.

To prevent regressions and ensure high-level correctness, we enforce a suite of invariant checks on every change. These checks leverage the market's replayability to compare test outputs and key metrics against historical baselines.

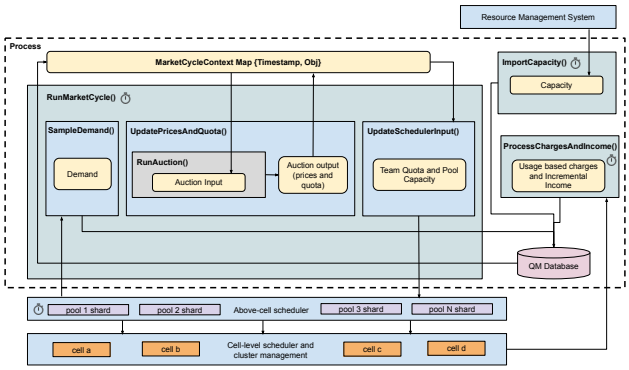

Figure 3: Architecture and components of the Quota Marketplace

Spatial Flexibility and Global Quota The system provides a location abstraction allowing users to submit *spatially flexible* workloads (i.e., workloads that can run in any cell). We

initially considered sharding the market by both resource type and cell. However, our analysis revealed that supply at the cell level is highly fragmented; running independent cell-level auctions yields "thin" markets with highly volatile pricing and unstable scheduling outcomes (smaller cells averaged $\sim$3% poorer occupancy than larger ones). To maximize market liquidity, we aggregate demand and supply into a single *Global Cell* abstraction, run a global market per resource type, and allocate global quota.

This abstraction introduces a trade-off between market stability and placement granularity. Global quota guarantees that capacity exists *somewhere* in the fleet, but not necessarily where to a specific workload's is location constrained. Consequently, in roughly about 10% of the cases, we observe cell-level contention despite being allocated sufficient quota in the global market. We accept this reduction in theoretical market efficiency as a necessary cost to ensure price stability and a usable experience for engineers.

Scheduler Interaction and Sharded Pool Scheduling. QM began operating as a naive asynchronous coordinator atop a hierarchical scheduler. It published quota and capacity updates, which the *Above-Cell Scheduler* consumed to place logical workloads in some cell, followed by the *Cell-Level Scheduler* which performed physical bin-packing of the workload in the chosen cell. Because these layers operated asynchronously, state conflicts were inevitable. We deliberately chose this loosely coupled design over deep integration to accelerate the initial deployment and isolate the market logic from the critical path of the scheduler kernel. While this introduces consistency challenges, it allowed us to iterate on the market mechanism without destabilizing the underlying cluster management stack.

Relatedly, due to legacy constraints, the above-cell scheduler made separate scheduling decisions for each pool. This forced the QM system to physically move capacity between pools so that the above-cell scheduler can realize the quota allocated by the market. This operational lag between the market (which allocates quota immediately) and the resource manager (which moves capacity slowly), compounded mismatches between workload constraints (e.g. global quota vs. location constraints discussed earlier) and available supply.

We very recently mitigated these issues by moving up the above-cell scheduling logic into the market system and thereby unifying scheduling across pools. This removes the asynchrony between the market and the scheduler and removes the expressivity limitations imposed by the quota interface. This change allows the market to define the inevitable contended cell queuing behavior described in the section above. Importantly, it also paves the way for the market to have a variety of workload-level signals, which it didn't have earlier. This architectural shift has major current and future benefits, but comes with a tradeoff: it trades off increased failure domain risk (centralization).

Market Cycle Latency Improvements. The latency of the market cycle determines the system's control loop frequency and its ability to react to demand spikes. Through optimizations in the auction algorithm and RPC handling, we reduced the p50 market cycle latency from 100s to under 30s. End-to-end scheduling latency acts as a "tax" on the system, resulting in a measurable 1.3% occupancy wastage across the fleet. As another significant benefit of the architectural shift discussed in the preceding paragraph, we were able to reduce the end-to-end latency to approximately 30s. This recovers some of the occupancy wastage and improves engineering velocity by reducing the time between workload submission and feedback.

Volatility and Churn. Because QM adjusts quotas dynamically based on price fluctuations, it naturally incurs somewhat higher preemption rates than static systems. To prevent high-frequency volatility, as previously mentioned, we enforce that teams must demonstrate sufficient credit balance to sustain a bid for a minimum duration. This smoothing mechanism ensures that bids do not oscillate with the granular income and charge cycles. We treat market stability not merely as an optimization but as a critical usability requirement; users rely on stable price signals to interpret scarcity effectively. Beyond this, there are a host of other scheduling algorithm features designed to mitigate scheduling churn.

Workload Boundaries and Cube Aware Scheduling. While the market models demand as a scalar fluid, physical ML workloads are discrete and topological (e.g., a 64-chip request often requires a specific $4 \times 4 \times 4$ cube, corresponding to 16 interconnected machines). The cell-level scheduler handles the physical bin-packing and defragmentation of these shapes. QM is currently *topology-oblivious*: it assigns aggregate quota without guaranteeing that the free chips form a contiguous cube. This abstraction gap inevitably leads to defragmentation-based preemptions where quota exists but geometry does not, and today it arises roughly in about 1% of the cases. For the initial deployment, we accepted this inefficiency to avoid the complexity of solving a multi-dimensional knapsack problem in the market loop. Future iterations aim to incorporate topology-aware pricing to bridge this gap.

Auxiliary Resource Requirements. QM employs a *principal resource pricing* model: it explicitly prices only ML accelerators, while auxiliary resources (CPU, RAM, disk, network) are allocated proportionally to the accelerator quota. This design is grounded in the observation that accelerators are the dominant bottleneck resource for ML training at Google. Further, this design choice avoids a combinatorial marketplace, and presents users with a single-dimensional price signal, significantly reducing the cognitive load required to participate in the market. While combinatorial auctions could theoretically offer higher allocative efficiency, we prioritize the operability of a simpler pricing model.

3 Deployment Metrics and Takeaways

In this section, we quantify the gains unlocked by the deployment of Quota Marketplace, Google-wide. There are many dimensions along which we discuss improvements. For some cases, the comparison we present is with the conventional static pools. In other cases, when there are entirely new opportunities unlocked by the Quota Marketplace, we discuss them with metrics.

Occupancy & Company-Prioritized Occupancy. In the Introduction, we described how QM would increase both company-prioritized occupancy and overall occupancy. Here, we quantify these increases. Figures 4 and 5 illustrate this increase by showing occupancy fractions of prioritized and opportunistic allocations of the same, very popular, resource type in two different pools: Quota Marketplace and conventional, respectively. Both pools are comparable in their sizes with hundreds of thousands of chips each. The difference in occupancies is stark. The average overall occupancy (i.e., prioritized + opportunistic) in the conventional pool is at 75%, and the same quantity in the Quota Marketplace pool is at 93%. This marks a ∼24% increase in overall occupancy. Also, average opportunistic occupancy in the Quota Marketplace pool is at a small 5.67%, as opposed to 33.5% in the conventional pool. This fully validates our expectation that the market-based system would substantially eliminate opportunistic occupancy, and what remains of it would be small, arising from some system inefficiencies.

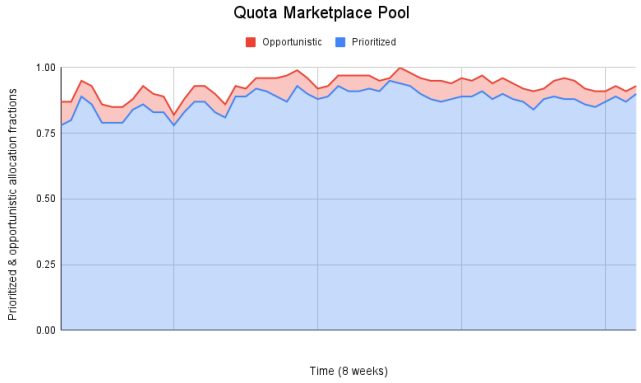

Figure 4: Occupancy fractions of company-prioritized and opportunistic allocations in the Quota Marketplace pool for a popular resource type.

Time Varying Supply. The available pool of compute resources often experiences significant fluctuations driven by evolving business priorities and supply chain dynamics. Common events include supply reductions via clawbacks for reprioritization, temporary capacity injections, reallocation of resources across different geographical locations or accelerator

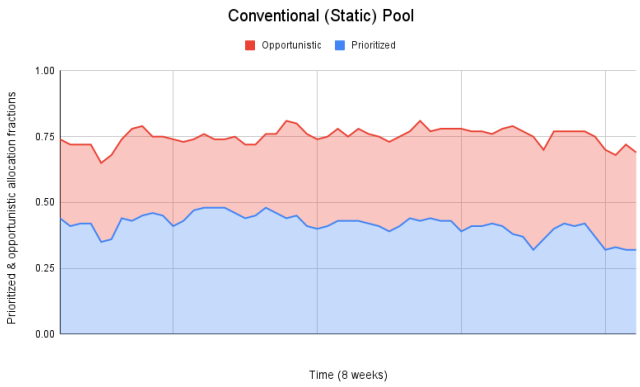

Figure 5: Occupancy fractions of company-prioritized and opportunistic allocations in the conventional (static) pool for the same popular resource type as in Figure 4.

types, and changes to anticipated delivery timelines for new hardware. These frequent supply adjustments pose a challenge to traditional resource allocation systems, often resulting in slower user adaptation and, consequently, suboptimal fleet utilization. Figure 6 shows that supply variations over time are substantial, and are not just a theoretical worst-case situation to reason about. While the figure captures shifts in accelerator types, note that supply fluctuations extend beyond this. For instance, even within a single accelerator type, numerous changes in geographical location (among the 3-digit number of data centers) can occur.

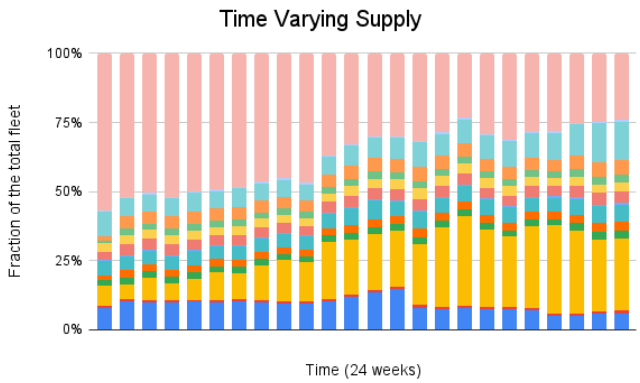

Figure 6: The total fleet managed by Quota Marketplace broken down by resource type over a period of 24 weeks.

Minting Supply from Transient Resources. As discussed in the Introduction, historically, in order to maintain allocation speed, various processes had to rely on substantial amounts of readily available buffer resources, that were underutilized and unprioritized in the meantime. Since the Quota Marketplace allows clawbacks in a matter of minutes, this enabled

the addition of a large fraction of these buffer resources to Quota Marketplace, resulting in additional minted supply. We club multiple such buffer sources into an umbrella category named "serving buffer". Likewise, new capacity keeps arriving on a daily basis, even though the promised delivery date of these chips could be several days or weeks down the line. This is because fulfilment of a large consignment necessarily has to happen in batches, slowly building up to the deadline where the entire consignment is due. On the other hand, even if one were to allocate these chips that arrived ahead of time to the business units that are due to receive them later, the business units cannot be charged back ahead of their scheduled start date. Therefore, these soon-to-be assigned chips can neither be charged back for, nor be put to other high priority uses (given that clawbacks are time-consuming in traditional pools). Such temporarily available resources tend to be underutilized and unprioritized in traditional systems, but they can be readily utilized by the Quota Marketplace. We call the supply that the Quota Marketplace receives from such sources as the "holding pool". Figures 7 and 8 serve to illustrate the magnitude of bonus capacities unlocked by the Quota Marketplace from serving buffer and the holding pool. The bonus capacity unlocked by the Quota Marketplace consistently is in the order of hundreds of thousands of chips, reflecting the substantial volume of reclaimed resources integrated into the marketplace. Note that given the 8-year period over which demand has been growing tenfold annually, and correspondingly companies have been heavily investing in these chips, these holding pools are inevitably substantial. Thus, a crucial contribution of the Quota Marketplace is its ability to effectively harness large quantities of transiently available resources, improving overall system utilization.

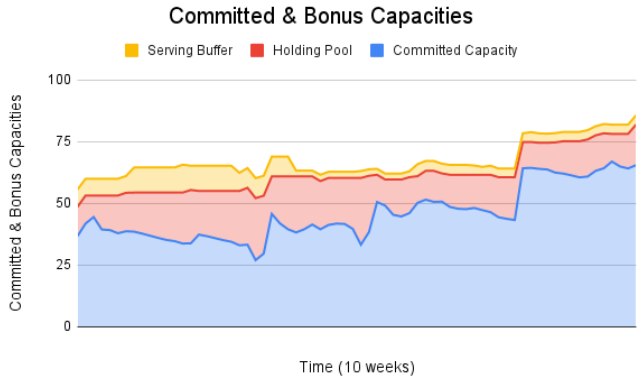

Figure 7: Over the period of 10 weeks, we see the bonus capacities that the Quota Marketplace has made available from different sources (y-axis is normalized). The total bonus is substantial, and remains consistently so.

Incentives in Action: Occupancy. The operational dynamics of the Quota Marketplace periodically offer empirical

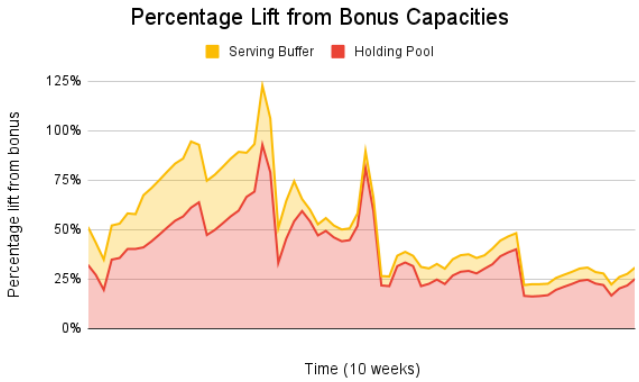

Figure 8: Another way to visualize Figure 7: over the same period of 10 weeks as in Figure 7, the percentage lift in capacities offered by the two different sources. The lowest point in this 10 weeks period is about 25%.

insights into user responses to its incentive structures. A key example arises during the regular deployment of new accelerator hardware batches to specific geographic locations or cells. By measuring the time lag between the introduction of this new supply and the corresponding rise in resource occupancy, we can quantify the market's efficiency in absorbing new capacity. We conducted a comparative analysis focusing on this phenomenon. As shown in Figures 9 and 10, two resource pools received simultaneous additions of new accelerators: one operating under the Quota Marketplace framework and a control pool managed via traditional static allocation. Within the Quota Marketplace pool, occupancy levels rapidly tracked the increase in available supply, while in the conventional pool, occupancy substantially lagged supply. Significantly, this swift uptake in the Quota Marketplace pool occurred organically, without requiring broad organizational announcements or specific notifications regarding the new hardware's availability or location. Users, guided predominantly by the price signals within the marketplace, efficiently discovered and migrated towards these newly-introduced and lower-priced resources.

Incentives in Action: Demand Shaping. The introduction of a new resource type, that is a partial substitute to a pre-existing resource type, provides another opportunity to obtain useful insights into user responses to incentives. Initially available at very low prices due to lack of demand, this new resource type requires users to adapt their workflows for compatibility. Despite the existence of this friction, the price of this new resource type rapidly increases to almost catch up with the pre-existing resource type. This price convergence occurs organically through user responses to price signals and peer communication via chat and email about the existence of a very low-priced alternative, rather than management directives or mandates. This behavior confirms that the Quota Market-

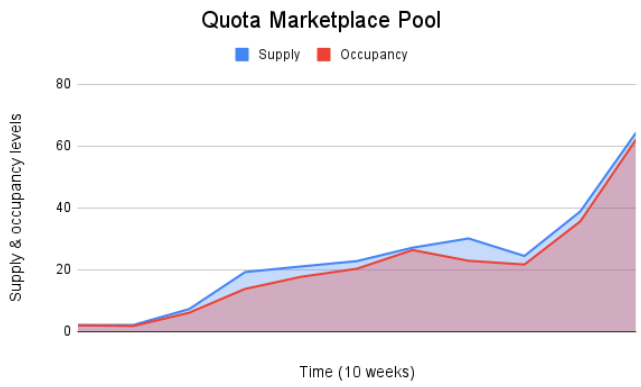

Figure 9: Over a 10-week period when a new resource type was introduced, we see how occupancy closely tracks supply, even during substantial supply spikes (y-axis is normalized).

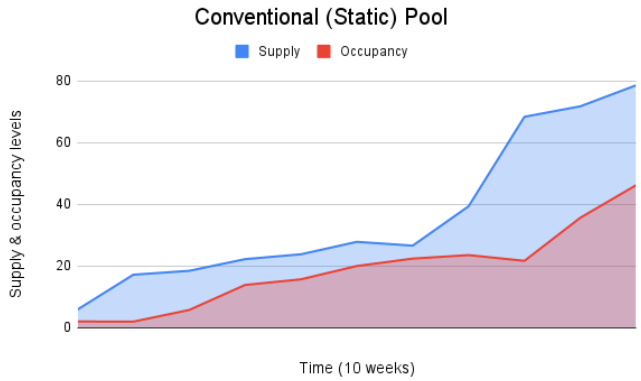

Figure 10: Over the same 10-week period as in Figure 9, when the same new resource type was introduced in the conventional static pool, we see how occupancy substantially lags behind supply (y-axis is normalized as in Figure 9).

place effectively shapes demand through pricing mechanisms, i.e., it indeed makes demand flow towards less-congested resource types.

Tackling Highly Non-trivial Tasks. Another important benefit of the QM and the flexibility that it provides is that it makes it feasible to tackle highly non-trivial large-scale tasks that would have previously required multiple quarters to complete. Such tasks can now be completed much faster (in a matter of weeks) due to the unprecedented acceleration that the Quota Marketplace is able to provide by reprioritizing portions of its massive fleet. Note that even such massive reprioritizations need not severely impact any particular business unit, or team, as their impact is seamlessly amortized across the whole market through price increases.

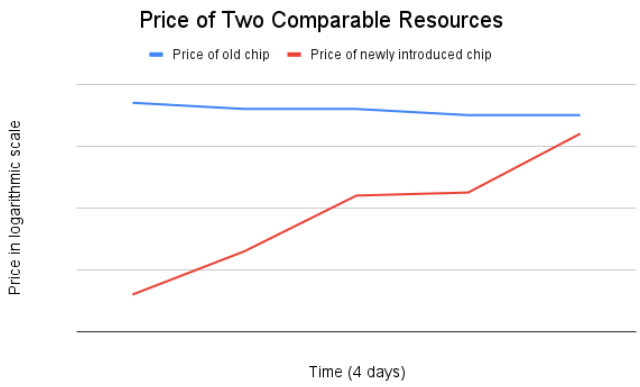

Figure 11: When a new resource type is introduced in the market, it starts at a low price, but the price grows exponentially (y-axis is in logarithmic scale) to catch up with that of a comparable pre-existing resource type.

4 Theoretical Analysis

We now formally prove that the market-based mechanism achieves efficiency and fairness guarantees, and we provide examples exhibiting how previously proposed solutions, like Karma, fail to achieve the same. We exhibit this separation in a simple model with a fixed shared supply of a single resource and ignore pool-specific supply. Due to space limitations, most of our proofs are deferred to Appendix A.

Model. A set N of n agents (teams) compete over s units of a single resource, and our goal is to design a fair and efficient mechanism that determines how these units are allocated over time. Specifically, given some time horizon of $T \geq 1$ rounds, the mechanism decides how many units each agent is allocated in each round $t \in [T]$ (where $[T] = \{1, 2, \ldots, T\}$). An allocation $x \in \mathbb{N}^{n \times T}$ determines the number of units $x_t[i]$ that each agent i will receive in each round $t \in [T]$ (for simplicity, we assume units are divisible, so $x_t[i] \in \mathbb{R}$). For an allocation to be feasible, it needs to allocate no more than s units in each round, i.e., $\sum_{i \in N} x_t[i] \leq s$ for all $t \in [T]$.

At each round t, each agent i demands $d_t[i] \geq 0$ units and has some value $v_t[i] \geq 0$ for each of these units. Therefore, i's value for receiving $x_t[i]$ units in round t, denoted $v_t[i](x_t[i])$, is equal to $\min\{x_t[i], d_t[i]\} \cdot v_t[i]$, and the overall value of i in allocation x is $v_i(x) = \sum_{t \in [T]} v_t[i](x_t[i])$. This strictly generalizes the class of valuations used in the Karma paper [26], which correspond to the special case where $v_t[i] = 1$ for all i and t, i.e., all the agent values are uniform over time. Another interesting intermediate class that we consider are bi-valued agent preferences, which are the mild generalization of uniform values where each agent's values can take one of two values, e.g., either HIGH or LOW.

Pareto Efficiency and Max-min Fairness. An allocation x is Pareto-dominated by allocation x' if $v_i(x') \geq v_i(x)$ for every agent i and $v_i(x') > v_i(x)$ for at least one agent i. An allocation is *Pareto efficient* if it is not Pareto-dominated by any other feasible allocation. If $w_i > 0$ captures the relative weight, or significance, of each agent $i \in N$ (often referred to as the agent's "fair share"), then the (weighted) *max-min fair* allocation assigns to each agent i a fraction $\frac{w_i}{\sum_{j \in N} w_j}$ of the $T \cdot s$ available units. We call an allocation x α-*fair* if the total number of units allocated to each agent i is at least

$$\alpha \cdot \frac{w_i}{\sum_{j \in N} w_j} \cdot T \cdot s.$$

Market-Based Mechanism. Without loss of generality, we assume agent weights are normalized so that $\sum_{i \in N} w_i = s$, and the market-based mechanism starts by allotting a budget of $T \cdot w_i$ credits to each agent i. Then, at the beginning of each round t, each agent i reports the number $d_t[i]$ of units they request, along with a limit price $\bar{p}_t[i]$ (the maximum amount they would be willing to pay per unit), and amount of budget $b_t[i]$ that they are willing to spend in that round. Given this information and some price p_t, the mechanism can compute the demand of each agent i at round t as

$$D_t[i](p_t) = \begin{cases} 0 & \text{if } p_t > \bar{p}_t[i] \\ \min\{b_t[i]/p_t,\ d_t[i]\} & \text{otherwise.} \end{cases}$$

The total demand at round t for a price p_t is then equal to $D_t^*(p_t) = \sum_{i \in N} D_t[i](p_t)$, and the market-clearing price is the maximum price that ensures all units are allocated, i.e., the price p_t that satisfies $D_t^*(p_t) \geq s$ and $D_t^*(p_t + \varepsilon) < s$ for any $\varepsilon > 0$. The mechanism computes this market clearing price and allocates to each agent i a total of $D_t[i](p_t)$ units (if $D_t^*(p_t) > s$, the requests that would remain at price $p_t + \varepsilon$ are satisfied first, and a tie-breaking rule is used for the rest). The mechanism then subtracts $p_t \cdot x_t[i]$ credits from the total budget of each bidder i and proceeds to the next round.

We make the common "large market" assumption that no single agent can significantly affect prices, so they behave as price-takers, and since these are very scarce resources, the number of units requested at each round t is at least s, i.e., $\sum_{i \in N} d_t[i] \geq s$. We also assume that agents can estimate their demands and the prices for future rounds, and they choose how much to spend in each round t accordingly.

Chip-Hour Mechanisms. To overcome the limitations of traditional approaches that allocate chips in a static fashion (i.e., each agent has a fixed number of chips in every round), Chip-Hour mechanisms allocate "hours" of chip access to the agents, and then provide them with some flexibility regarding when to request these hours. In each round t, each agent i requests $d_t[i]$ units and, based on what fraction of their chip-hours they have used, and the overall demand, the Chip-Hour mechanism decides how many chips to assign. A prominent example is the Karma system of Vuppalapati et al. [26], which strictly prioritizes agents who have used less of their chip-hours so far, aiming to optimize max-min fairness. Some aspects of this system are similar to the market-based mechanism: agents are bootstrapped with some credits and they also earn an income of such credits (in proportion to their chip-hours); they then spend these credits to gain access to resources. However, there is a crucial difference: the "price" of every resource in the Karma system is fixed over time, so spending one credit always buys the user access to the same amount of resource. As we show in this section, this limitation restricts the agents' ability to optimize their allocation and it can lead to unfair and inefficient outcomes.

4.1 Limitations of Chip-Hour Mechanisms

To exhibit some limitations of Chip-Hour mechanisms, we first consider the class of uniform valuations (i.e., $v_t[i] = 1$ for all i and t), which was the focus of Vuppalapati et al. [26] in their analysis of Karma. For uniform valuations, they were able to achieve significant improvements over prior work which assumed that agent requests are static over time (i.e., $d_t[i] = d_{t'}[i]$ for any $t, t' \in [T]$). Specifically, they showed that Karma is Pareto efficient for uniform valuations and achieves a "myopic" notion of fairness: at any round t, given the resource allocation choices made in previous rounds (which may be unfair but cannot be changed anymore), the allocation at round t aims to optimize max-min fairness.

We first exhibit that moving beyond this myopic notion of fairness and aiming for a global notion like max-min fairness is, in fact, impossible, not just for Karma, but for any Chip-Hour mechanism. This is in contrast to the market-based mechanism which leverages the agents foresight regarding their future demand to move beyond myopic fairness notions and achieve (approximate) max-min fairness even in settings with general heterogeneous valuations (Theorem 4).

Theorem 1. *Chip-Hour mechanisms cannot guarantee* α*-fairness for* $\alpha > 1/n$*, even for uniform-value instances.*

Proof. Consider a simple instance with n agents of equal significance $w_i = 1$, $s = n$ units, and $T = n$ rounds. Agent 1 requests $d_1[1] = s$ units in round 1 and $d_t[1] = 0$ for all subsequent rounds $t > 1$. All other agents request s units in every round. The max-min fair solution for this instance would allocate all the s units in the first round to agent 1 and split the units of the remaining rounds equally among the other agents, allocating $s = n$ units to every i. On the other hand, given this instance, and lacking any foresight regarding the drop in future demand from agent 1, any Chip-Hour mechanism would distribute the units in the first round equally among the agents (since all agents have equal w_i and, hence, equal chip-hours). This yields a single unit ($s/n = 1$) for agent 1, leading to an outcome that is only $1/n$-fair.

In comparison, consider the outcome of the market-based mechanism facing this instance. Since agent 1 does not need any units after the first round, she is willing to spend all of her s credits in the first round. This leads to unit price of at least 1 for the first round. If any other agent i also spent some of their budget on the first round, then at least one round $t > 1$ would have a unit price that is strictly less than 1 (this is because the budget spent on subsequent rounds would be strictly less than $(n-1)s$, while the number of available units in subsequent rounds is $(n-1)s$). Therefore, this would not be a market equilibrium since agent i would prefer to spend on round t rather than round 1. As a result, in the market equilibrium every agent receives an equal number of units, leading to the max-min allocation, i.e., 1-fairness. □

We now show that for the slightly more general class of bi-valued preferences, Chip-Hour mechanisms are unable to guarantee Pareto efficiency too. In fact, moving beyond uniform valuations introduces incentives for the agents to manipulate these mechanisms and strategically misreport their demands. Our next result shows that their Pareto efficiency is violated, regardless of whether the users behave truthfully or strategically. This is in contrast to the market-based mechanism which achieves Pareto efficiency even for the general class of heterogeneous valuations (Theorem 3).

Theorem 2. *Chip-Hour mechanisms violate Pareto efficiency even for bi-valued instances, irrespective of whether the agents behave truthfully or strategically.*

4.2 Efficiency & Fairness of Markets

In contrast to Chip-Hour mechanisms, the market mechanism always guarantees Pareto efficiency, even for instances where the agents have general heterogeneous values.

Theorem 3 (Pareto Efficiency)**.** *The market mechanism achieves Pareto efficiency for general heterogeneous valuations, irrespective of how much the prices may vary.*

Apart from Pareto efficiency, we also show that the allocations induced by the market mechanism are (approximately) fair. Specifically, one of the things that we observed though the deployment of the market mechanism is that although the prices of the units can vary significantly over time, the average price that each agent pays per unit in the long run does not vary as much. One way to interpret this is that there is no reason why any one agent's requests may be strongly correlated with higher prices. If we let $\tilde{p}$ denote the average price per unit across the T rounds and let $f_i \cdot \tilde{p}$ be the average price paid by agent i over this time horizon, then we can bound the fairness of the induced allocation using the f_i values. Specifically, the resulting allocation is $\min_{i \in N} \frac{1}{f_i}$-fair, converging to max-min fairness as the f_i values converge to 1. Note that this is in stark contrast to Chip-Hour mechanisms which cannot even achieve better than $1/n$-fairness when $f_i = 1$ (see the instance used in the proof of Theorem 1).

Theorem 4 (Fairness)**.** *Let $\tilde{p}$ be the average price of a resource over time. If the average price paid by some agent i is at most $f_i \cdot \tilde{p}$, then the resulting allocation is $\min_{i \in N} \frac{1}{f_i}$-fair, even for general heterogeneous valuations.*

5 Discussions and Future Directions

While the system is deployed in Google to serve thousands of users and manage resources at scale, there remain significant improvements to be explored in maximizing efficiency, flexibility, and user experience. We outline here some unresolved challenges, and opportunities being currently explored.

Shaping User Behavior. Users were shown to respond to market prices which opens the opportunity to use prices as a vehicle for driving other organizational goals. One example is carbon-efficiency: prices can be adjusted to incentivize scheduling in more carbon-efficient datacenters or use more carbon-efficient configurations. Similarly, the market can be changed to provide discounts (or penalties) guiding towards desired behavior. For example, workloads that are well configured to make good use of the hardware, don't crash, save checkpoints can be rewarded. These mechanisms can also be used to drive adoption for workload improvements that require additional user effort or opt-in.

Currently, our system simply balances supply and demand without taking many other factors into account, but the existence of prices creates the possibility of shaping the behavior of users using economics rather than mandates.

Reducing Failure Blast Radius. Centralized resource allocation with the QM improves efficiency but also creates a single point of failure. One way to reduce the impact of a bad rollout or bug in the code is to shard the system into multiple deployments, each managing a subsection of the fleet. There are many ways to consider sharding which offer tradeoffs in efficiency and user experience. One approach is to thin out the necessary global component while transferring as much logic as possible to sharded replicas. We can also imagine separating parts the system by location or resource type.

Potential for Gaming. Our system operates within Google, where users and teams prioritize their own resource needs but are policy constrained to not intentionally disrupt others. We now briefly discuss a few potential gaming strategies in general adversarial environments. Appendix B discusses their removal at the cost of increased complexity for users.

Gaming: Currency Conversion. When designing QM, we made the conscious decision of letting each business unit mint their own currency. All the business-unit-local credits get converted to a global currency when the market clears. The local-to-global currency exchange rate is a function of

both the number of credits minted by that business unit, and the market weight assigned to that business unit by the company. This freedom to mint credits has ergonomic benefits: for example, credits minted per hour, can be maintained in proportion to the number of engineers in the team. However, this freedom also comes with an ability to game the system. Consider a scenario where a team mints a lot of credits per hour for a while, accumulates a substantial number of credits in its savings, and then dramatically reduces the rate at which it mints credits per hour. The newly minted credits are worth much more because the currency's value had significantly risen. But if the system were to value the accumulated old credits also at the same level as the new credits, the team would have successfully managed to mint credits out of thin air. If we value these credits differently, we introduce complexity. We discuss a few possible solutions and the tradeoffs they present in appendix B, and a good middle-ground.

Gaming: Adversarially Depleting Other Teams' Credits. Teams bid for demanded resources, but are only charged credits for jobs that run. A bad actor could launch a job which is unlikely to schedule and is set to immediately fail if it does. For example, this job may require all the resources of a specific type in a specific location to start. The bad actor is thus able to inflate prices for all other market participants without paying any credits to do so. We discuss a few solution approaches and the tradeoffs they present in appendix B.

6 Related Work

Systems literature on resource allocation mechanisms is rich and vast. Here, we focus on a few related streams of work. To the best of our knowledge, ours is the first work that (a) guarantees Pareto efficiency and (approximate) max-min fairness in the presence of dynamic demand with heterogeneous values, and (b) has designed, implemented, and deployed a market-based mechanism for system resources at this scale.

Market-based mechanisms for pricing computer resources is an old idea [4, 6, 23]. However, pricing for shared resource allocation was not a first-order concern in time-shared systems, leading to this research being short-lived. There have been other works that took a market approach to resource allocation [24, 27]. Two decades ago, when [21] described why the time was right to revisit market-based solution for systems resource allocation, they cite the demand-supply gap as the primary reason. This has never been any more true than it is today. Therefore, research on market-based ideas for resource allocation is indeed timely. Documented experiences of markets allocating resources in a wide variety of settings are valuable, as they serve as catalysts for wide-spread adoption of this powerful tool. With this motivation, we go over how we addressed some of the markets-systems integration challenges that were raised in [21].

Allocation Policy Must be Explicit. The main challenge identified is that of landing on an allocation policy that all the users can agree on: whether to maximize allocation efficiency, or to favor jobs from under-represented users etc. In the environment we operate in (a large company) all players are in agreement that they want to maximize the value to the company. Disagreements about what is more valuable can be resolved top-down following the organizational structure – which mirrors the way credits are distributed.

Calculating and Expressing Valuation. Despite the significant influence of bidding interfaces on user perception of market mechanisms, this area remains under-researched. Our system allows users to express workload value via parameters specifying job credits. While finer-grained controls are possible, the system must balance expressivity with interface simplicity, as Shneidman et al. [21] note that ease of use often surpasses the importance of complex features.

Well-Defined Currency. Shneidman et al. [21] also note that virtual currencies have a lot of issues, particularly that they are not exchangeable outside the system. While our credits too cannot be used for buying anything outside the system, we note that business units (not individual teams) are charged back for the market power they are assigned. I.e., business units pay in real dollars for getting credits, and indeed they could have used those dollars towards headcount, other equipment etc. Therefore, credits in QM have a tangible dollar value. Designing a good currency also includes creating mechanisms to control inflation and volatility in prices. QM has guardrails like bid upper bounds to ensure that teams are unable to hoard credits and flood the market with credits.

Pricing-Based Resource Allocation. Spot-instance marketplace and virtual machine auctions [3, 7, 9, 29, 31, 32] are examples of pricing-based resource allocation. Nevertheless, fair resource allocation is not their goal, and even in rare cases where fairness was the goal [28], it is qualitatively different from the long-term fairness that we focus on [26]. Beyond resource allocation, other places where credits have been used in game-theoretic contexts include [5, 8, 18, 30].

Max-min Fairness and Generalizations. Being able to satisfy Pareto-efficiency and fairness has inspired a lot of work on this topic [10, 12–16, 19, 20, 22], including generalizations to multiple resources [10–12]. As described earlier, the efficiency guarantees of these mechanisms crucially rely on the demand being static; the recent Karma mechanism addresses this exact problem [26]. In this paper, we further this line of work by including heterogeneous values for demand.

A Proofs omitted from Section 4

In this section we provide all the proofs that were omitted from the main body of the paper due to space limitations.

Theorem 2. *Chip-Hour mechanisms violate Pareto efficiency even for bi-valued instances, irrespective of whether the agents behave truthfully or strategically.*

Proof. Note that Chip-Hour mechanisms ask each agent i to report their $d_t[i]$ demand. We first consider the case where the agents truthfully report this value in each round, and we then also consider the case where the agents may strategically misreport this value (e.g., by reducing the $d_t[i]$ in rounds where their value is LOW, aiming to save their credits for subsequent rounds of HIGH value). For this proof we normalize the HIGH value to 1 and the LOW value to some $\varepsilon \in (0,1)$.

Truthful Reporting. To verify the lack of Pareto efficiency for the case where the agents truthfully report their demand, $d_t[i]$, consider the following simple instance involving just two agents and two rounds. In this instance, we have $d_t[i] = 2$ for both agents and rounds, but the values of agent 1 are 1 for the first round and some arbitrarily small ε for the second, while the values of agent 2 are ε for the first round and 1 for the second. In other words, agent 1 strongly prefers the units of the first round while agent 2 strongly prefers those of the second round. However, since Chip-Hour mechanisms do not elicit the agents' values (implicitly assuming that they are uniform over time), the two agents look identical, and the outcome would equally split the two units of each round among the two agents, leading to an overall value of $(1+\varepsilon)$ for each. To verify that this is not Pareto efficient, note that if we were to give agent 1 both of the first-round units and give agent 2 the second-round units, then both agents would have a value of 2 instead, leading to an almost 100% increase in both values.

Strategic Reporting. It is natural to assume that an agent facing a mechanism that disregards the intensity of their demand (as in the instance above), the agent may choose to strategically misreport their $d_t[i]$ requests, aiming to maximize their value (e.g., by submitting no requests during rounds of lower value). We now show that even if agents report strategically aiming to optimize their allocation with respect to their underlying values, Chip-Hour mechanisms still fail to achieve Pareto efficiency. We prove this using small instances with two agents, two units, and two rounds. In all instances that we consider, both agents request both units of the second round, so the Chip-Hour mechanism's decision regarding how to allocate those two units is purely a function of the units they were allocated in the previous round (or, equivalently, a function of their remaining budget). We prove that irrespective of how the mechanism uses this information, there exists an instance for which the resulting outcome will be Pareto inefficient.
