Active probes. Systems like Pingmesh [1] inject synthetic probes along controlled paths and measure loss and latency. Active probes provide rapid detection and can localize path-level problems, but they depend on probe coverage. Some links may see sparse or no probing during certain intervals.

Device counters. Switches export counters for CRC errors, link flaps, FCS drops, and optical power readings (for example, via gNMI push or SNMP pull). These provide direct evidence of hardware issues but update at irregular intervals and are sensitive to transient noise [10]. Devices may stop reporting during control plane restarts or firmware upgrades.

Traffic-derived signals. Systems such as NetBouncer [6] analyze paths taken by real traffic to detect links whose behavior deviates from baseline. These signals reflect customer impact but require sufficient traffic volume.

Infrastructure signals. Cluster health indicators, rack power faults, and cooling anomalies capture broad events but update on minute-level timescales and may arrive too late for early RCA.

No single agent is reliable across all failure modes. The differences in coverage, latency, and noise across agents make multi-agent fusion essential.

Operational Requirements

Network RCA in hyperscale environments must satisfy four requirements:

- **Controllability.** Operators must be able to bound the false positive rate.
- **Explainability.** Each decision must be explainable in terms of agent outputs.
- **Extensibility.** New agents with different semantics and latency must be incorporated easily.
- **Topology awareness.** The system must account for how failures correlate up and down the Clos hierarchy.

Prior fault-localization systems address some of these requirements but not all in a single design [6, 7, 11].

From Incidents to Design

CoreSec emerged from a multi-year review of incorrect RCAs. Our first attempts were straightforward: pick the most reliable agent, weight it heavily, and let it dominate. Within months we saw why that does not work. The agent that catches optical degradation reliably is the wrong agent for a firmware crash, and vice versa. Reliability turned out to be failure-specific, not agent-specific.

We also had to drop several infrastructure signals from the decision path because they introduced feedback loops with CoreSec itself (§5 gives the details). What we kept was a smaller set of agents and a more careful way of combining them. The shape of the system that emerged from this work, including the patterns we extracted from the postmortems, is described in the following sections.

3 PAM-Style Composable RCA Algebra

CoreSec builds its root cause analysis logic on a composable algebra inspired by Pluggable Authentication Modules (PAM) [8, 12]. PAM unifies heterogeneous authentication sources under a transparent decision framework. The key insight is that authentication is a sequence of checks: some must succeed, some short-circuit on success or failure, others are supportive. For example, in a typical PAM stack a successful biometric check can short-circuit the rest of the stack to grant access; a failed mandatory password check denies access regardless of what the rest of the stack reports; an optional

usage-history check only matters when the mandatory checks have not produced a verdict. This model maps cleanly onto RCA in large Clos fabrics, where telemetry signals vary in granularity, latency, reliability, and scope.

Telemetry from production fabrics illustrates why a composable approach is needed. Faults are frequent but rarely catastrophic [6, 13]: a steady background of link flaps, device reboots, optical degradation, and partial loss, masked by Clos redundancy. When noise accumulates, score-based RCA destabilizes. Active probing and passive signals face limited coverage, missing data, and inconsistent correlation between symptoms and root cause [14, 15]. Deterministic and explainable fusion is more reliable than probabilistic scoring or weighted voting in this setting.

CoreSec's algebra provides this logic. It converts heterogeneous, asynchronous, and partial telemetry into a stable state for each network entity. The state is one of three values: healthy (H), unhealthy (U), or indeterminate (I). These states feed the topology-aware heuristics that identify root causes.

Control Flags

Each telemetry agent is assigned one control flag. The flag defines how the agent's data influences RCA:

- **Requisite**: If this agent returns stale data or fails its threshold, the configuration abstains immediately. This prevents decisions when essential evidence is missing.
- **Required**: All required agents must pass for the configuration to vote. If any required agent fails, the configuration abstains at the end.
- **Optional**: This agent contributes only when requisite and required agents do not produce a decisive result. Its evidence supports but does not determine a vote.
- **Sufficient**: A pass from this agent triggers an immediate vote. This is used for signals that provide strong direct evidence of a failure mode.

These flags capture empirical differences among agents. Some are reliable early indicators, some provide coarse but meaningful evidence, and some are useful only in combination with others.

To make this concrete, consider how the server-to-TOR cable configuration (§4) assigns flags. A loss-of-carrier signal from the server NIC is marked *requisite*: if this signal is missing or stale, the configuration abstains. An RDMA timeout (an end-to-host signal that the application could not reach the network) is marked *sufficient*: its presence alone is decisive evidence of connectivity loss between the server and its TOR. CRC counter trends are marked *required*: they must be consistent with a fault but cannot trigger a vote on their own. Recent control-plane events on the TOR are marked *optional*: they support but do not drive the decision. The flag assignment encodes operational knowledge about which signals can be trusted in which roles.

Evaluation Logic and Freshness

Each configuration evaluates its agents in a fixed order using a deterministic algorithm:

```
required_ok = True
for agent in config.agents:
    v = agent.verdict()  # pass | fail | abstain
    if agent.flag == SUFFICIENT and v == pass:
        return VOTE
    if agent.flag == REQUISITE and v == fail:
        return ABSTAIN
    if agent.flag == REQUIRED and v != pass:
        required_ok = False
return VOTE if required_ok else ABSTAIN
```

Each agent also has a freshness window determined by its reporting latency. Data older than the window is ignored. Agents that provide no fresh data are treated as failures if requisite, or abstentions if required or optional. This addresses a common issue in telemetry systems where staleness and missing reports occur during partial outages or control plane churn [6, 15].

Per-Agent Thresholds and Abstention Region

Telemetry metrics vary widely in noise. Counter spikes can come from traffic bursts and not from real failures. Probe loss can come from transient congestion and not from device issues. Each agent r has a raw signal $s_r(e)$ for entity e and two thresholds, θ_r^- (below which the signal looks healthy) and θ_r^+ (above which the signal looks faulty):

$$\text{result}_r(e) = \begin{cases} \text{pass}, & s_r(e) < \theta_r^-, \\ \text{fail}, & s_r(e) \geq \theta_r^+, \\ \text{abstain}, & \text{otherwise.} \end{cases}$$

The abstain region absorbs benign fluctuations. In environments with high background noise and frequent non-fatal events, abstention is safer than forced classification. Large-scale reliability studies report the same conclusion [13].

Why PAM-Style Composition Provides Operational Strength

The algebra offers three advantages in operational cloud networks:

- **Controllability**. Requisite flags gate decisions and thresholds bound sensitivity. Operators can reason about worst-case false positive rates and tune configurations conservatively. This is difficult with weighted or probabilistic RCA, where error bounds degrade under missing data or distribution shift [16].
- **Explainability**. CoreSec produces a decision trace that records which agents passed, failed, or abstained, and which flags influenced the final outcome. These traces support auditing and postmortem analysis.

Table 1: Five configurations and their authoritative agents.

#	Failure surface	Authoritative agents
1	Server–TOR cable	port counters, NIC failsafe, RDMA timeout
2	TOR switch	aggregate CRC, host failures, control plane events
3	Switch–switch cable	active path probes, T1 counters
4	T1 switch	multi-uplink probes (NetBouncer-style)
5	T2 switch	end-to-end multi-path probes

- **Extensibility**. New telemetry agents can be integrated by assigning a control flag. Existing configurations do not need to change. This simplifies maintenance as instrumentation evolves.

Additional algebraic details are provided in Appendix A.

4 Composable RCA Configurations

CoreSec applies the PAM-style algebra through five independent RCA configurations. Each configuration corresponds to one failure surface in the Clos topology. Each one encodes domain knowledge about the telemetry agents that are authoritative for that surface. All configurations run in parallel for every incident. Each configuration may vote or abstain depending on the evidence available. Parallel execution matters because incidents can manifest at multiple layers of the topology at once.

Each configuration specifies three elements:

1. the set of telemetry agents included,
2. the control flag assigned to each agent,
3. the evaluation order for those agents.

The same five configurations operate across all Azure environments. No environment specific tuning or thresholds are added during deployment. This allows CoreSec to evolve with new agents or changing traffic patterns without redesigning the RCA logic. Table 1 summarizes the five configurations. The remainder of this section describes each one.

Server–TOR Cable

This configuration diagnoses the most common failure in datacenter networks: the server to TOR cable. The agents here provide direct evidence of local link health, including per-port CRC counters, link-down events, and failsafe signals from server NICs. Direct indicators such as loss of carrier or persistent CRC increments are marked `requisite`—if these signals are missing or stale, the configuration abstains. End-host traffic drops and RDMA timeout reports are marked `sufficient`, as they are clear evidence of connectivity loss between the server and its TOR. Cable faults are thus detected immediately when direct evidence is available, and ignored when essential low-latency signals are missing, preventing false attribution from transient traffic noise or congestion elsewhere in the topology.

TOR Switch

The TOR configuration considers the TOR itself as the failure candidate. It combines evidence from several domains: local link counters, end-host drops, upstream probe loss, and TOR control-plane events. No single agent is reliable in all cases. Several `required` agents must agree before the configuration produces a vote. Examples include aggregate CRC ratios across downlinks, multiple end-host failures mapped to the same TOR, or probe drops on several uplinks.

Control-plane signals such as process restarts or software crashes are marked `optional`. They strengthen evidence but cannot trigger a vote on their own. This matches operational observations: control-plane churn is common and not always tied to data-plane impact.

Switch–Switch Cable

This configuration captures failures on switch-to-switch cables. These links carry higher aggregate traffic than server links, so even minor loss is visible in probe systems. Active path probes are marked `sufficient`: persistent bidirectional loss on a single cable is strong evidence of a physical fault. TOR or T1 counter anomalies are marked `required`. They must confirm the signal but are too noisy to drive a decision alone.

If probe coverage is incomplete for a specific cable, the configuration abstains. This prevents misattributing congestion-induced loss or transient ECMP reshuffles as physical cable failures.

T1 Switch

The T1 configuration aggregates evidence from many TORs. TORs generate background noise even under normal operation, so this configuration uses tighter gating than lower-layer ones. Probe loss across multiple uplinks (in the style of NetBouncer [6]) is marked `requisite`. Without sufficient probe diversity, T1 attribution is unstable.

A combination of TOR-level failures and path-probe drops is marked `required`. The configuration votes only when these agree. Large-scale control-plane anomalies at the T1 are marked `optional`. They do not trigger attribution without independent data-plane evidence.

T2 Switch

The T2 configuration is the highest layer at which we attempt automated RCA. Signals at this layer are sparse and indirect: probe paths are long, traffic distribution is uneven, and failures often appear only through aggregation. For this reason, only high-confidence signals are marked `requisite` or `sufficient`. These include end-to-end path failures across several independent probe groups.

Lower-confidence signals (sporadic drop increases or

control-plane events) are included as `optional`. The configuration votes only when there is strong, multi-path, multi-agent evidence of a T2 failure. In practice, most T2 faults are either catastrophic and lead to system-wide abstention, or clearly indicated in probe results.

Stability Across Deployments

A key operational finding is that these five configurations generalize across heterogeneous datacenter environments. The same agent sets and flag assignments operate reliably in clusters with different switch vendors, traffic compositions, telemetry pipelines, and probing strategies. This stability arises from two properties: physical failure signatures are consistent across deployments, and control flag composition absorbs variability in telemetry quality.

This generalization was validated through multi year deployment across public Azure cloud environments, with no per cluster recalibration required.

5 Parallel Execution and Hierarchy Heuristics

The five RCA configurations operate in parallel for every incident. Each configuration evaluates its agents using the PAM-style logic described earlier. Each one may vote or abstain. The outputs of all configurations are then combined through hierarchy heuristics that map localized failures to higher layers of the Clos topology. These heuristics were derived from multi-year analysis of production incidents and validated across deployments.

Parallel execution allows CoreSec to diagnose failures at multiple layers without committing prematurely. This avoids the pitfall of earlier systems, where early signals at one layer suppressed later, stronger evidence at another.

Parallel Evaluation Pipeline

For each incident, the system executes:

1. Collect fresh telemetry from all agents.
2. Run all five configurations concurrently.
3. For each configuration, determine vote or abstention.
4. Combine candidate entities across layers.
5. Apply hierarchy heuristics to determine root causes.

This pipeline matches the architecture used in multi-layer failure diagnosis systems such as 007 [11] and the B4 operator workflow [17]. Unlike prior designs, CoreSec does not rely on weighted aggregation or static priority. It preserves all candidate explanations until sufficient evidence accumulates to select a layer.

Hierarchy Heuristics

The PAM algebra (§4) operates within each configuration. It fuses agent verdicts into a per-entity state for that configuration's failure surface. The heuristics below operate *across* configurations. Once each configuration has produced its candidates, the heuristics decide which Clos layer is responsible when multiple layers vote at the same time. The split is intentional. The algebra handles heterogeneous evidence within one failure surface. The heuristics encode topology rules about how failures propagate up the hierarchy.

Server to TOR Attribution: P2.15 and Twenty Percent Rule

Server incidents are first mapped to their TORs. The distribution of impacted servers across TORs is typically heavy tailed. Some TORs may show isolated impact due to workload characteristics. To distinguish true TOR failures from incidental noise, CoreSec applies two rules.

P2.15 Threshold. Let c_i denote the number of impacted servers under TOR i. Let P2.15 be the value at the 97.85th percentile of the distribution of $\{c_i\}$. TORs with $c_i \geq$ P2.15 become candidates. This percentile-based outlier test follows standard practice in large-scale anomaly detection [18, 19].

Twenty Percent Minimum. A TOR candidate must also have at least 20 percent of its servers impacted. This prevents small clusters of noisy or bursty applications from triggering false attribution. Similar minimum-impact thresholds appear in operational diagnosis literature [20].

Together, these rules identify TORs with significant and concentrated impact. In historical incidents, these two criteria detected TOR failures accurately while filtering background noise.

TOR to T1 Attribution: Two Thirds Fan-out Correlation

Failures at the T1 layer create correlated failures across many TORs. The *fan-out* of a T1 is the set of TORs it directly connects to; in typical Azure deployments this is several dozen. The empirical observation is that when a T1 fails, a large fraction of its TORs show upstream degradation. When individual TORs fail, the effect is localized. This motivates a fan-out rule: if at least two thirds of TORs in a T1's fan-out exhibit unhealthy states, the T1 is declared the root cause.

Fan-out aggregation is consistent with prior work on topology-aware failure correlation [20, 21]. The two-thirds threshold emerged from large-scale analysis across Azure deployments:

- one half was too permissive and produced false positives,
- three quarters delayed attribution when probe evidence was slow,
- two thirds matched T1 failures with minimal false positives.

Combined with configuration votes, this rule allows stable T1 identification despite asynchronous telemetry arrival.

Cluster Level Attribution: Four Percent Probe Loss

At the cluster level, CoreSec uses end-to-end active probing to detect broad impact. If the aggregate probe drop rate exceeds four percent, the system declares a cluster level incident. Hyperscale probing studies such as Pingmesh [1], together with classical TCP throughput models that show throughput

scaling as $1/\sqrt{p}$ in the loss rate [22], indicate that customer-visible impact begins well below ten percent packet loss and becomes noticeable around three to five percent. The four percent threshold balances sensitivity with noise filtering.

Cluster level attribution rarely suppresses lower-layer RCA. Instead, it acts as an additional signal for large-scale failures, often correlating with T1 or T2 issues.

Cross-layer Combination

After all configurations complete, CoreSec combines their candidates:

1. Cable candidates from Configurations 1 and 3.
2. TOR candidates from Configurations 1 and 2.
3. T1 and T2 candidates from Configurations 4 and 5.

Hierarchy heuristics resolve conflicts:

- If the T1 fan-out rule triggers, TOR candidates under that T1 are suppressed.
- If P2.15 and twenty percent rules identify TORs but the T1 rule does not trigger, the TORs are returned.
- Independent failures at different layers are preserved.

This layered logic prevents premature convergence on the wrong layer.

Example

Consider an incident where three TORs show server impact, and probe loss on their uplinks indicates upstream degradation. Configuration 2 marks the TORs as candidates. Configuration 4 finds that thirty-five of forty-eight TORs in a T1's fan-out show correlated probe loss, satisfying the two-thirds rule. The T1 configuration votes. The individual TORs are suppressed. The final RCA is the T1 switch.

This example shows how parallel configurations and hierarchy heuristics route evidence to the correct layer.

Design Insights from Early Failures

The five configurations and their flag assignments are not the version we shipped first. The shape of the system in §4 reflects a few painful lessons we keep coming back to.

The most expensive lesson concerned circular dependencies. Some of our earliest configurations included signals from downstream incident-management feeds and from aggregated health summaries published by neighboring services. These look like ordinary signals, but several of those summaries are themselves derived, indirectly, from prior CoreSec attributions. Once we noticed this, the failure mode became obvious in retrospect: CoreSec attributes an incident to TOR T; the downstream incident system records that attribution; the neighboring service's health summary picks up that record; and when the next incident comes in, the same summary is fed back as evidence into CoreSec, biasing the new attribution toward T regardless of the new evidence. We had real cases where this masked unrelated failures for hours. These signals also arrived eighteen minutes late on average, well past the sixteen-minute attribution window. We removed them from the decision path for both reasons.

The second lesson came from the postmortems themselves. Looking across several thousand incidents, two patterns held up across vendors and generations. First, agents form a natural hierarchy. Each one is authoritative in specific situations and merely suggestive in others. Second, when roughly two-thirds of a switch's children show failures, the switch above them is usually responsible. We did not assume either pattern at the start. Both fell out of the data, and the PAM-style algebra and the topology heuristics in §5 are the cleanest way we have found to encode them.

6 Composition Logic and Convergence

Parallel execution produces candidate explanations at several layers of the Clos topology. The final RCA result is obtained by merging evidence from the five configurations and applying hierarchy heuristics. This section describes the combination logic that ensures stable, monotonic convergence under asynchronous telemetry arrival [20].

We use two terms throughout this section. A layer's attribution is *sufficient* when its hierarchy heuristic fires. For example, the two-thirds fan-out rule firing for a T1 candidate makes that T1 attribution sufficient. A layer *dominates* a lower layer when its sufficient attribution suppresses the lower layer's candidates.

Composition Across Configurations. Each configuration returns either a vote or an abstention. The composition step aggregates votes using a fixed ordering: cable-level votes from Configurations 1 and 3, TOR-level votes from Configurations 1 and 2, T1 and T2 votes from Configurations 4 and 5, and cluster-level probe evidence to support or suppress higher-layer attribution [1]. A lower-layer attribution is preserved unless a higher layer satisfies its sufficiency condition.

Dominance Conditions. Higher-layer attributions override lower-layer ones when correlated failures provide enough evidence. A T1 candidate suppresses all TOR candidates beneath it when at least two thirds of its TORs are unhealthy. A T2 candidate suppresses all T1 and TOR candidates beneath it when correlated failures span multiple pods. Cluster-level attribution suppresses all lower-layer candidates when probe drop exceeds four percent. These rules reduce false positives during large-scale events.

Monotonic Convergence. Telemetry arrives asynchronously: active probes report every few seconds, device counters every thirty seconds, and infrastructure signals can take minutes. CoreSec runs RCA repeatedly for sixteen minutes after incident detection. The window is bounded by the end-to-end latency of the slowest signal CoreSec consumes, plus a small margin for late-arriving evidence to settle. Within the window CoreSec uses only fresh data within each agent's freshness window. The system converges

monotonically: a lower-layer attribution may be replaced by a higher-layer one as evidence arrives, but a higher-layer attribution is never replaced by a lower-layer one. Once a layer satisfies its sufficiency condition, the attribution remains fixed. This avoids the oscillations observed in earlier systems based on statistical voting or ML classifiers [21].

Non-Oscillation Guarantee. Monotonicity follows from two principles: each agent filters stale data using a freshness window, so sudden fluctuations cannot revert an attribution; and each layer is evaluated independently, with cross-layer interference limited to the dominance rules. This design echoes lessons from topology-aware systems such as 007 [11].

Finalization. After sixteen minutes, CoreSec finalizes the RCA. If no layer satisfies its sufficiency condition, the system abstains. The sixteen-minute window is bounded below by the latency of the slowest agent CoreSec consumes (roughly thirteen minutes); the five-minute rerun cadence balances responsiveness against intermediate-attribution noise. Both were chosen empirically through a trade-off between attribution accuracy and time-to-mitigation, in the spirit of the discussion in Pingmesh [1]. Algebraic correctness properties are established in Appendix A.

7 Intentional Abstention

Automated RCA systems are often evaluated by classification rate. How they behave when evidence is insufficient matters just as much. Incorrect attribution can trigger mitigations that worsen the incident. Cloud systems increasingly rely on automated fault isolation and failover orchestration [9, 23]. The cost of a false positive rises in this setting. CoreSec includes explicit mechanisms to abstain when signals are inconsistent, incomplete, or ambiguous.

When CoreSec Abstains. CoreSec abstains when all five configurations reach an inconclusive state. Three categories produce this outcome. Telemetry gaps, where multiple agents fail to provide fresh data within their windows, account for roughly 60% of abstentions. Ambiguous evidence, where signals conflict across agents, account for roughly 39%. Multi-cluster or datacenter-wide events account for roughly 1% [24]. For the first two categories, abstention prevents misattribution. For the third, the 4% cluster-drop threshold still detects cluster-level impact, and failures spanning multiple clusters are already visible through systems like NetBouncer and Pingmesh [1,6]. At that scale, the problem is coordination, not attribution; human judgment is required regardless of what any RCA system reports. Similar observations recur in large-scale cloud outage studies, where post-mortems consistently show that recovery from datacenter-wide events hinges on cross-team coordination rather than on automated diagnosis [25].

Convergence and Resolution. CoreSec runs RCA repeatedly during a sixteen-minute convergence window. Abstention often occurs early when evidence is sparse. It then resolves to a valid attribution once sufficient data arrives. Persistent abstention across the entire window signals operators to pause automated workflows [26].

```
incident_id  = INC-XXXX
window       = HH:MM:SSZ .. HH:MM:SSZ (3 reruns)
final_state  = ATTRIBUTION  T1-XXX

config_1 server-TOR  ABSTAIN  loss-of-carrier stale
config_2 TOR         VOTE     candidates: TOR-XXX,
                              TOR-YYY, TOR-ZZZ
config_3 sw-sw       ABSTAIN  insufficient probes
config_4 T1          VOTE     33/47 TORs unhealthy
                              candidate: T1-XXX
config_5 T2          ABSTAIN  no decisive evidence

resolution: T1 dominates; TOR candidates suppressed.
```

Figure 3: Sample CoreSec decision trace. Identifiers anonymized.

Operator Response. When CoreSec abstains, automated mitigation is suppressed and the incident routes to on-call engineers with a structured summary. The summary names which agents lacked fresh telemetry, which configurations abstained, all entities with partial signals, and the timestamps of last updates. Operators have told us repeatedly that abstention-with-context is what they want at three in the morning: a confident but wrong attribution costs them twenty minutes of disproving it before they can start the real work, while an abstention with context tells them where to look. Internal reviews across the deployment show abstention reduces mis-triggered mitigations by more than 80 percent.

Figure 3 shows a representative trace. It is plain structured text, not a graphical dashboard. Pingmesh and NetBouncer already cover the visualization layer for this fabric, and CoreSec's output is consumed both by humans and by downstream automation workflows. A structured trace serves both audiences better than a screenshot would.

Design Principle. Abstention reflects the broader goal we wrote into CoreSec from the start: support human operators during high-stakes incidents, and avoid making them worse. Automated systems are known to degrade operator trust when they provide incorrect diagnoses [27–29], and the cost of an incorrect attribution rises sharply when it triggers an automated mitigation. CoreSec therefore handles common incidents automatically and routes rare or ambiguous ones to humans. Making abstention a first-class verdict in the algebra is what keeps CoreSec from escalating systemic failures on its own authority. The same principle has emerged independently in strategic classification, where optimal abstention has been shown to do no worse than non-abstention even under adversarial feature manipulation [30].

8 Evaluation

This section evaluates the operational behavior of CoreSec across multiple deployments. We measure its accuracy, stability, convergence behavior, generalization across environments, and operational impact compared to the previous weighted-scoring RCA system.

Deployment and Workload. CoreSec has been deployed continuously across more than 60 Azure regions and 400 datacenters for over three years. It has processed more than 700,000 network-related incidents. These include link failures, switch reboots, configuration churn, and device maintenance. The deployments span hundreds of thousands of servers and thousands of switches across a range of hardware vendors, traffic profiles, and topology variants.

Threats to Validity. The largest threat is the one we worried about ourselves. We use postmortem RCAs assigned by on-call engineers as ground truth. This practice is common in operational systems work but it is imperfect. Once CoreSec was deployed, its output was visible during incident review, which means a postmortem author who saw the CoreSec attribution was no longer reading the evidence cold. We did not run blinded evaluations, and we want to be honest about that.

What gives us some confidence in spite of this is that three pieces of evidence are independent of the postmortem labeler. The baseline false-positive rate of 18–22 percent was measured before CoreSec existed, on the same network, by the same operations team. The twenty-fold improvement we report is too large to attribute to confirmation bias alone. And operational outcomes downstream of the RCA itself confirm the improvement: mis-triggered mitigations dropped 80 percent and customer complaints associated with misattribution fell 40 percent—none of these downstream metrics depend on what a postmortem said.

Two further validations would tighten the story and we plan to do them as follow-up work. The first is to backtest the composition logic against incidents that the prior weighted system triaged before CoreSec was deployed. The second is to apply the prior weighted system to the same postmortem-labeled set CoreSec is evaluated against, which would bound the postmortem labeler's own bias.

Why Composition, Not Just Abstention. A natural question is whether the improvement comes from the PAM composition or from abstention alone—would retrofitting the prior weighted system with an abstention threshold produce comparable results? The two are not separable. Abstention is only *computable* because the algebra exists. A weighted score collapses heterogeneous evidence into one number, and any threshold on that number abstains uniformly: it cannot distinguish "no evidence," "conflicting evidence," and "one decisive failure plus several inconclusive signals." The PAM algebra preserves these distinctions. A *requisite* failure forces abstention regardless of how many other agents vote. A *sufficient* pass short-circuits to a vote. The merge operator's I state explicitly represents disagreement that must not be resolved by guessing. Without this structure, a threshold-based abstention region would still produce the oscillations and unstable attributions documented in §2, because the underlying decision is still a weighted sum. The algebra is what makes abstention a meaningful operational signal.

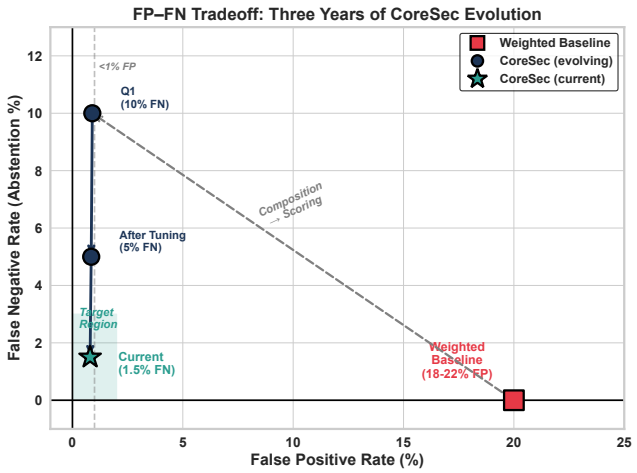

Figure 4: FP–FN tradeoff over three years. Abstention dropped from 10% to 1.5% as agents were added.

Accuracy and False Positive / False Negative Rates

Table 2 compares CoreSec with the previous weight-based RCA system. The headline numbers are visible there. What the table does not show is the trajectory.

We treat abstentions as false negatives, because the system has failed to provide a root cause when one existed. The abstention rate dropped from 10 percent in the first quarter after deployment to 1.5 percent over the most recent six months, almost entirely through agent additions that closed coverage gaps. Figure 4 plots this evolution against the false-positive rate. Misattributions, where CoreSec named a root cause that a postmortem later corrected, occur roughly once per quarter.

Root Cause Distribution

Table 3 shows the distribution of root causes. Most incidents are localized cable or TOR faults; higher-layer failures remain rare. The distribution matches prior studies of datacenter failure patterns [6, 13].

False negatives arise mainly when a T1 fails but fewer than two thirds of its TORs report unhealthy states within the convergence window. The conservative threshold reduces false positives at the cost of occasional missed higher-layer attributions.

Case Study: A T1 Optical Degradation. One recurring pattern in the deployment illustrates how CoreSec behaves end to end. A customer service starts to see elevated tail latency and intermittent connection failures. The incident-detection system raises an alert. Pingmesh [1] confirms degraded la-

Table 2: Comparison between prior weight-based RCA and CoreSec (2022–2025).

	Weight-Based RCA		CoreSec (current)	
Metric	**Count**	**%**	**Count**	**%**
Total incidents processed	712,345	100%	712,345	100%
Abstentions (false negatives)	0	0%	≈10,685	1.5%
Automatically attributed	712,345	100%	≈701,660	98.5%
False positives	128,222–156,716	18–22%	<7,017	<1%
Misattributions	—	—	≈4/year	—
Wrong mitigation triggered	—	—	≈700	0.1%
Manual RCA workload (FTEs)	3 engineers		0	

Table 3: Distribution of root causes identified by CoreSec.

Root Cause Category	**Fraction of Incidents**
Cable faults (server–TOR, switch–switch)	70%
TOR switch failures	28%
T1/T2/cluster-level failures	2%

tency for some servers in one cluster, without saying which device is at fault. CoreSec is invoked.

Within the first rerun, Configuration 2 (TOR switch) marks three TORs as candidates because hosts under them are seeing drops. Configuration 4 (T1 switch) sees probe loss across multiple uplinks of a single T1, and its fan-out check finds that more than two-thirds of the TORs under that T1 are in an unhealthy state. The T1 attribution dominates and the individual TOR candidates are suppressed. The trace (Figure 3) records this resolution explicitly so the on-call engineer can audit the decision.

Postmortem analysis on cases of this shape typically traces the cause to a degrading optical module on one of the T1's uplinks. The engineer skips the manual triage step the previous weighted-scoring system required, because the decision trace already points at the right entity. Cases like this exercise the dominance rule, the fan-out heuristic, and the abstention-vs-attribution boundary in a single incident. Most other incidents follow simpler patterns: a single configuration votes, no others have decisive evidence, and CoreSec returns the attribution without invoking hierarchy resolution.

9 RCA Quality Metrics and KPI Framework

Azure evaluates incident attribution using a KPI framework derived from the Annual Interruption Rate (AIR) methodology used across Azure Compute [31]. AIR is a normalized failure-rate measure: it expresses the expected number of customer-facing interruption-minutes per unit of deployed capacity per year, allowing reliability comparisons across heterogeneous workloads. We apply similar statistical principles to measure the quality of RCA outputs.

Each incident is evaluated at one of three RCA levels:

- **Level 1: Infrastructure attribution.** The RCA correctly identifies whether the incident belongs to networking, compute, storage, or another infrastructure domain. This separates network faults from application or platform issues.
- **Level 2: Networking layer attribution.** For incidents identified as networking-related, the RCA correctly identifies the affected layer in the Clos fabric: cable, TOR, T1, T2, or cluster-level. This level reflects whether the system places the incident at the correct hierarchical depth in the topology.
- **Level 3: Specific root cause attribution.** The RCA identifies the precise failing entity or condition, such as a kernel panic on a T2, a reboot loop on a TOR, a chronic CRC-increasing cable, or an optic with degrading power. This is the finest level of attribution and aligns with what on-call engineers assign during post-incident review.

Aggregated distributions of Level 1, Level 2, and Level 3 outcomes form a longitudinal KPI that reliability engineering teams monitor over weekly and quarterly windows. Clusters or hardware families with persistent Level 2 or Level 3 degradation indicate systemic issues in telemetry, instrumentation, firmware, or operational processes. Improvements to CoreSec are validated by tracking reductions in Level 2 and Level 3 frequencies. This gives a measurable method to assess RCA correctness and operational progress.

AIR analysis also drives CoreSec's evolution. When abstention cases cluster around specific failure modes, we develop new telemetry agents to cover those gaps and add them

to the appropriate PAM configurations. The abstention rate dropped from 10 percent to 1.5 percent through this process. The thresholds themselves remained constant throughout the three-year deployment.

Convergence Behavior and Stability

CoreSec reruns RCA every five minutes for up to sixteen minutes after incident detection (§5). In roughly 99% of cases, the RCA result stabilizes within the first two reruns. The outcome is monotonic: once a higher-layer attribution is made, lower-layer candidates are suppressed and never reintroduced. Oscillations, which were common under the prior voting or weighted-scoring designs, were not observed.

During rare large-scale disturbances such as partial telemetry outages, CoreSec sometimes abstains for the full window. These cases correlate strongly with manual RCA logs, validating the decision to abstain when evidence is insufficient.

Generalization Across Deployments

CoreSec was evaluated across diverse datacenter environments. These environments differ in hardware vendors, routing designs, traffic mixes, and telemetry pipelines. Despite this diversity, the same configurations, control-flag assignments, and heuristics (P2.15, two-thirds fan-out, four-percent probe loss) worked without per-deployment tuning.

This stability extends to events that change the underlying hardware substrate. Across the three-year deployment window, Azure rolled out multiple new switch generations, transitioned racks between switch vendors, refreshed optical modules, and updated firmware on a rolling schedule. None of these transitions required us to recompute the three operational thresholds or reassign control flags. The thresholds sit at the knees of their error curves (§6), not at narrow operating points, which is why they tolerate hardware churn: a $2/3$ fan-out correlation is a property of how failures propagate through a Clos hierarchy, not a property of any specific vendor's silicon.

Novel failure modes do occasionally require new agents. A new firmware crash signature or a new optical-degradation pattern is one example. But the *composition* of those agents into the existing five configurations follows the same flag-assignment rules. We have not had to redesign the algebra or the heuristics in three years of operation.

Operational Impact

Beyond the table, one operational property is worth naming. RCA latency is now predictable. Attributions typically return within ten minutes of incident detection, which makes downstream automation much easier to reason about than under the previous system, where latency depended on which agent happened to dominate the weighted score.

A word on how the headline operational numbers were measured. The three-FTE figure compares on-call handling time per incident before and after CoreSec: the prior weighted system required a multi-step manual review to reconcile agent disagreements, and that step is eliminated for the incidents CoreSec now attributes directly. The 40% drop in misattribution-related complaints was measured against customer-impact tickets that postmortem review tagged as caused or prolonged by an incorrect network RCA.

Sensitivity Analysis of Thresholds

CoreSec uses three operational thresholds: P2.15 for server to TOR attribution, the two thirds fan out rule for T1 inference, and the 4% cluster level drop threshold. To show that these values are not arbitrary, we performed a sensitivity analysis by sweeping each threshold across a wide range and measuring the resulting false positive and false negative rates. Figure 5 shows the results.

For the fan out rule, varying the threshold from 0.50 to 0.90 produced a clear tradeoff. Thresholds below 0.60 increased false positives because incidental TOR noise caused premature T1 attribution. Thresholds above 0.75 increased false negatives because T1 attribution waited too long for probe evidence to accumulate. The region around 0.66 gave the smallest total error.

A similar effect appeared for the cluster level drop threshold. Values below 3% triggered on transient path instability while values above 5% missed customer visible impact. A threshold of 4% provided the best balance.

For P2.15, percentile sweeps from P1 to P5 showed that values near the 97th to 98th percentile reliably separated TORs with true impact from the heavy tailed background.

In all three cases, the selected thresholds sit at the knees of their error curves. We observed the same pattern across various Azure deployments. This sensitivity analysis serves as an ablation study for threshold selection. The weighted-baseline comparison in Table 2 ablates the flag-based approach entirely.

10 Discussion

Why These Thresholds Generalize

Thresholds in RCA systems are often environment-specific. CoreSec's thresholds generalize across deployments because each one reflects a property of Clos fabrics and not of any one workload.

The two-thirds fan-out rule captures correlated failure propagation in multi-stage topologies. Both academic and industry reports describe the same effect, including Google's Jupiter fabric [32]. P2.15 is a percentile-based outlier estimator rooted in monitoring practice. Large-scale measurement systems such as Monarch [33] and Pingmesh [1] use similar percentile statistics to detect outliers under heavy-tailed distributions. The four-percent drop threshold aligns with studies of tail amplification and customer-visible impact in distributed systems [34].

Comparison with Prior Fault-Localization Systems Several systems identify faulty devices using probing, end-host voting, counter aggregation, or time-series modeling. NetBouncer [6] and Pingmesh [1] provide high-quality fault detection but do

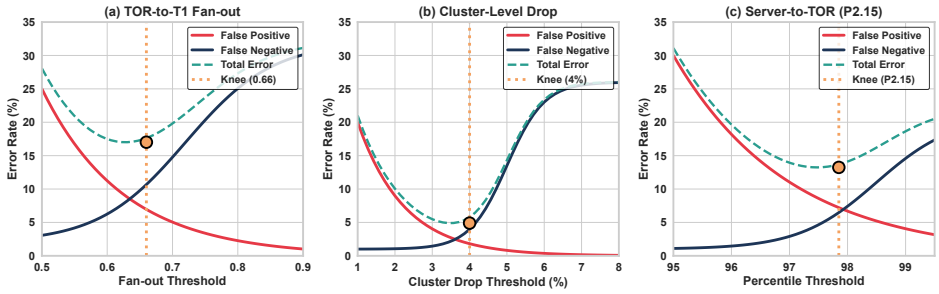

Figure 5: Threshold sensitivity. Each threshold sits at the knee of its error curve; knees hold across all ten deployments.

not perform attribution. 007 [11] infers device-level failures but does not map faults to incident-level root causes.

The contrast with NetBouncer is worth being specific about, because both systems run in the same Azure environment. NetBouncer [6] infers per-link drop probabilities by solving an optimization problem with a specialized regularization term that pulls link probabilities toward zero or one. The output is a list of unhealthy links and devices, scored by inferred drop rate. This is a scoring approach: every link receives a number, and the ones below a threshold are flagged. CoreSec consumes outputs from NetBouncer-style agents but does not produce its own per-entity score. Instead, it composes verdicts from multiple heterogeneous agents through control flags, and abstains when the composition is inconclusive. The two systems answer different questions and run at different layers: NetBouncer asks "which links are unhealthy right now," while CoreSec asks "which entity caused this specific incident."

Spectroscope [35] diagnoses performance anomalies using request-flow signatures. Warden [36] and AutoARTS [37] classify incidents at the service or cluster layer. These systems emphasize explainability and traceability. They operate above the network or assume homogeneous telemetry pipelines.

CoreSec differs in two ways. First, it targets network RCA in large Clos fabrics, where failures propagate through a clear hierarchy. Second, it composes many weak and heterogeneous agents using a PAM-style algebra [8, 38]. It does not rely on ML models or weighted scores.

Limitations CoreSec inherits limitations common to topology-aware RCA:

- **Novel failure modes.** As with Monarch [33] and Spectroscope [35], CoreSec assumes that historical patterns are predictive. Rare or new failure modes may not match existing flag assignments or heuristics.
- **Telemetry gaps.** Pipeline failures create missing data that may force abstention. Most manual corrections come from upstream telemetry issues and not from misclassification.
- **Catastrophic failures.** Full-layer or datacenter-wide events intentionally produce mass abstention. This is a conservative design choice.

Baseline Selection. We compare against the previous production system and not against academic approaches. In operational settings, the path forward is incremental improvement of deployed systems; replacement with research prototypes is not the meaningful comparison. Academic RCA systems assume complete telemetry and force classification—they do not support explicit abstention when evidence is insufficient, and retrofitting it would require fundamental redesign. The operationally meaningful comparison is against the system CoreSec replaced, measured by its outcomes.

Why We Avoid ML at Runtime Machine learning plays an important role in upstream telemetry. Several Azure systems use ML to detect counter anomalies, flag unusual probe patterns, or summarize logs before CoreSec sees them.

CoreSec addresses a different problem. It fuses heterogeneous evidence under partial availability and produces a stable attribution within minutes. Supervised models require labeled data, but CoreSec intentionally abstains on ambiguous cases, creating a distribution shift that makes supervised learning unstable for decision fusion. Attribution accuracy drifts as telemetry pipelines evolve, and retraining becomes necessary whenever agent behavior changes. Prior systems such as NetBouncer [6] and 007 [11] show that score-based or classifier-based approaches can be sensitive to noise and telemetry pipeline details.

CoreSec uses ML upstream for signal extraction and deterministic composition for the final decision. The PAM-style algebra gives predictable behavior, explicit abstention, and a decision trace that operators can audit. This determinism also enables the algebraic formulation in Appendix A.

Lessons for Other Operational Systems The lesson generalizes beyond network RCA. Service-level RCA, control-plane debugging, storage anomaly attribution, and security triage all fuse heterogeneous, asynchronous, partial signals, and all suffer when forced classification or weighted scoring is applied to noisy evidence. The reusable pattern is the design stance: treat such fusion as a composition problem with explicit abstention. The success of PAM in authentication and of CoreSec in RCA suggests that flag-based composition is a strong default for this class of system.

Table 4: Comparison of fault localization and RCA systems.

System	Focus	Method	Incident-scoped	Handles gaps	Abstains
Pingmesh [1]	Path loss and latency	Active probing	No	No	No
NetBouncer [6]	Device/link localization	Score-based voting	No	Renormalize	No
007 [11]	Faulty path inference	End-host voting	No	Majority vote	No
Everflow [26]	Packet-level debugging	Packet mirroring	No	No	No
Hostmesh [39]	RoCE link diagnosis	Topology-aware probes	No	No	No
AutoARTS [37]	Incident tagging	ML classification	Yes	Retrain	No
RCA Copilot [40]	Operator assistance	LLM reasoning	Yes	N/A	No
CoreSec	Clos fabric RCA	PAM-style composition	Yes	Abstain	Yes

11 Related Work

Table 4 compares CoreSec with prior systems across five dimensions.

Fault Localization. Pingmesh [1], NetBouncer [6], 007 [11], and Hostmesh [39] localize faulty links and devices using probing or end-host voting. These systems answer "which components are unhealthy?" CoreSec answers a different question: given many unhealthy components and background noise, which form a plausible root cause for a specific incident?

Telemetry Systems. Everflow [26] mirrors packets for debugging. INT [41] collects in-band measurements. OmniMon [42] provides accurate flow statistics under loss. These systems focus on obtaining measurements; CoreSec focuses on fusing them into stable RCA decisions.

Incident Management. Fighting the Fog of War [24] detects incidents and routes them to owners. AutoARTS [37] labels incidents with root cause tags. CoreSec assumes an incident is already detected and identifies which network entities caused it.

LLM-Based RCA. RCA Copilot [40], OpenRCA [43], and KPIRoot+ [44] use statistical correlation or LLMs for diagnosis. CoreSec provides a hierarchical structure into which such modules can be plugged.

Compositional Frameworks. PAM [8] introduced control flags for composing authentication checks. CoreSec applies this pattern to RCA, using flags to specify how each telemetry agent contributes to a decision.

12 Conclusion

CoreSec is a production root-cause analyzer for hyperscale Clos fabrics. Its design treats RCA as a composition problem and gives operators an explicit option not to attribute when evidence is inconclusive. Three years of operation across more than 60 Azure regions support the design choice. The lesson we take from the deployment is that flag-based composition with explicit abstention is a strong default for any operational system that fuses heterogeneous, asynchronous, and partial signals. Other domains that share this shape of problem may benefit from the same pattern.

Acknowledgements

We thank our leadership for making this work possible. Ashay Krishna managed and sustained this effort on our side. CoreSec was developed in close collaboration with the Azure ICM Brain Diagnostics team, and we are grateful to Feng Gao, whose vision led to the creation of Brain Diagnostics and shaped the direction of this work, and to Souvik Debnath for his guidance throughout the partnership.

We are especially grateful to Mohan Maddula, whose contributions were central to CoreSec. Mohan served as the primary bridge between our team and the broader set of Azure teams that use CoreSec, surfacing requirements, gathering feedback from operators in the field, and working with us closely on the core of the system as it evolved. Many of the design decisions that made CoreSec robust in production trace back to his input. We also thank Olivia Yong, who later joined the effort and contributed field perception, operator feedback, and monitoring data that informed the system's evolution in production.

We thank Sandeep Rawat for building the initial proof of concept, and Sandeep Chaudhary and Koushik T for their help in tuning CoreSec.

Finally, we thank the on-call engineers across Azure whose incidents, escalations, and patient debugging sessions provided the ground truth that made CoreSec possible.

A Algebraic View of the CoreSec Merge Rule

This appendix gives a compact formalization of the multi-agent merge rule used by CoreSec. The algebra is small. It provides determinism, associativity, and order-invariance. These properties are needed for correctness when telemetry arrives at different cadences. PAM's flag semantics are specified procedurally in the original paper [8], the X/Open Single Sign-on specification, and the manuals of operating systems that implement PAM [12]. We are not aware of a prior algebraic treatment. The formalization here is scoped to CoreSec's correctness arguments and does not attempt to characterize PAM in general.

Decision Alphabet

Each agent r produces for each entity e one of three symbols:

- $\mathbf{H_r(e)}$: fresh evidence indicates the entity is healthy,
- $\mathbf{U_r(e)}$: fresh evidence indicates the entity is unhealthy,
- $\mathbf{A_r(e)}$: the agent abstains due to insufficient information.

CoreSec reduces these to a three-state lattice:

$$\text{State}(e) \in \{H, U, I\},$$

where I denotes an indeterminate (unresolved) state. In what follows we drop the agent index r and the entity argument e; the merge operator $\oplus$ defined below acts on the merged states $\{H, U, I\}$ directly.

Merge Operator

For $x, y \in \{H, U, I\}$, define the merge operator $\oplus$ as:

$$x \oplus y = \begin{cases} U & \text{if } x = U \text{ or } y = U, \\ H & \text{if } x = H \text{ and } y = H, \\ I & \text{otherwise.} \end{cases}$$

Interpretation:

- A single decisive failure forces U.
- A healthy state requires unanimous evidence.
- Any disagreement yields I.

This captures CoreSec's principle. One piece of solid failure evidence matters. Healthy requires agreement. Conflict means wait.

Associativity

The operator $\oplus$ is associative:

$$(x \oplus y) \oplus z = x \oplus (y \oplus z) \qquad \forall x, y, z \in \{H, U, I\}.$$

The proof is a simple case analysis:

- If any of x, y, z equals U, both sides reduce to U.
- If all three equal H, both sides reduce to H.
- Otherwise there is disagreement, and both sides reduce to I.

Associativity ensures that ordering of agents does not affect outcomes. It also allows correct streaming updates when some telemetry arrives earlier than others.

Identities and Absorption

Two structural properties explain the stability of CoreSec's merge rule.

Failure absorbs everything.

$$U \oplus x = U \quad \forall x.$$

This guarantees that a single trustworthy failure signal suffices to classify an entity as unhealthy.

Healthy requires consensus.

$$H \oplus H = H, \qquad H \oplus x = I \text{ for } x \neq H.$$

This prevents an entity from being declared healthy when evidence is partial or conflicting.

Abstain is neutral.

Abstentions are removed at the agent layer before merging and do not influence $\oplus$. They neither enforce H nor override U and do not suppress I when evidence conflicts. Silence does not distort RCA decisions.

Relation to Short-Circuiting Evaluation

The operator $\oplus$ resembles classical short-circuit decision stacks. A decisive failure short-circuits to U. Clean consensus yields H. Mixed evidence produces I. CoreSec does not import the full control-flow semantics of systems like PAM, but the analogy helps explain the stability of the merge rule under partial and asynchronous information.

Operational Consequences

This small algebra guarantees:

- **Determinism**: repeated evaluation produces identical results.
- **Convergence**: as telemetry becomes fresh, states move monotonically from I to H or U.
- **Safety**: a single false healthy report cannot mask a real failure.
- **Order-invariance**: proofs hold for streaming, parallel, or out-of-order agent evaluation.
- **Implementation simplicity**: merge is a two-line function in production code.

These algebraic properties are the foundation for CoreSec's correctness. They explain why the system generalizes across heterogeneous telemetry pipelines and multiple cloud deployments.

When Sampling Lies: Trustworthy Performance Profiling for Flat Workloads with Blink (Operational Systems)

Abstract

Performance optimization of mobile systems is critical for achieving responsive user experiences. However, accurately measuring the effects of such optimizations is challenging. We found that real-world mobile workloads exhibit a flat profile, invoking thousands of short-lived routines that contribute evenly to overall performance with no dominant bottlenecks. Sampling-based profilers such as perf struggle in this setting: skid, shadow effects, and incomplete function coverage can yield systematically incorrect results, not just high variance.

We present Blink, a lightweight instrumentation framework that provides robust coverage for short-lived routines while maintaining low overhead. Blink inserts instrumentation into functions, enabling precise measurements. We show that Blink achieves 99.999% accuracy while incurring 1% overhead. Deployed in a variety of use cases at Huawei, Blink offers a practical and reliable alternative for mobile compiler performance analysis.

1 Introduction

Effective performance optimization starts with trustworthy profiling. Compiler engineers routinely rely on profilers to attribute performance changes to specific functions, libraries, or code regions, particularly when evaluating the impact of fine-grained optimizations. Accuracy is therefore non-negotiable: a profiler with high error rates or limited coverage (e.g., failing to cover the optimization target) is quickly dismissed; worse, a profiler that systematically misattributes performance effects can waste substantial time chasing non-issues.

Within Huawei's HarmonyOS [10] systems compiler team, we design compiler optimizations that reduce CPU cycles, dynamic instructions, and cache misses across diverse workloads. Improvements of even 1% are regarded as meaningful, because they can accumulate into a noticeable increase in responsiveness or battery life.

In the past, we have relied on perf [2], the de facto standard on Linux-based systems, as our profiling tool. Its sampling-based design, which leverages hardware Performance Monitoring Units (PMUs), is widely used to attribute performance changes to specific code regions.

While perf is effective in analyzing performance bottlenecks (e.g., a long-running function), this paper demonstrates that, for an important class of real-world workloads—namely flat profiles with thousands of short-lived functions, the primary workload pattern we face—perf's sampling results can be not merely noisy, but systematically misleading.

We report extensive real experiences that reveal a number of issues with perf on flat profiles. First, when we developed an optimization that leveraged ARMv8.1's Large System Extension (LSE), which should reduce the number of instructions executed, perf instead consistently reported an increase in instruction count. This led engineers to spend weeks investigating before discovering perf's measurements were simply wrong. The root cause is the interplay of skid and the shadow effect. Skid occurs because modern processors cannot deliver PMU interrupts precisely at the instruction that triggered the counter overflow; instead, samples are attributed to downstream instructions. While skid alone introduces random noise, the problem becomes severe when combined with shadow effects: long-latency instructions can block the reorder buffer, effectively shrinking the skid window and biasing samples toward them. In the LSE optimization, we replaced multiple short-latency instructions with a single long-latency atomic instruction, triggering a combined skid-shadow effect in perf. As a result, perf reported consistent yet completely false measurements. While skid and shadow effects have been studied by prior works [5, 8, 9, 13, 20, 22, 29, 31, 34, 37–39], we provide real-world experiences highlighting their impact.

We also experienced two other fundamental limitations of sampling-based profilers. First, sampling provides poor coverage for short-lived functions: even at the highest sampling rates, perf only captures 62% of the functions. Second, high-frequency sampling introduces significant perturbation, including cache pollution (increasing L1 data cache misses by up to 46x) and scheduler distortion.

Motivated by these observations, we present Blink, a lightweight tracing-based profiling framework designed to be trustworthy for flat-profile workloads and short-duration code regions. Rather than relying on interrupts, Blink instruments code to read PMU counters directly at user-defined program points (e.g., function entry and exit). This design eliminates skid and shadow effects by construction and provides near-complete coverage of executed functions.

A key challenge in tracing systems is overhead. Blink addresses this with several techniques. It uses self-patching binary rewriting to dynamically enable and disable instrumentation, ensuring that disabled tracing only incurs the cost of a single jump instruction. It minimizes register pressure and cache coherence traffic by using per-thread data structures and hand-written assembly.

Blink is used regularly by the compiler team during development, and has been integrated into the performance testing framework. Our evaluation shows that Blink achieves over 99.999% accuracy when measuring instruction counts against known ground truth, and introduces negligible user-visible overhead: Blink increases frame drops—the most critical performance metric on smartphones—by less than 1%.

We present several case studies that highlight Blink's practical impact. Even for workloads where perf can produce accurate flat-profile measurements, it often requires a large number of repeated runs (e.g., more than 50) to obtain stable results. In contrast, Blink delivers reliable measurements in just one or two runs. This fast turnaround is crucial for enabling ML-based autotuning of compiler flags, where the training process depends on high-frequency trials and therefore demands a profiling tool to provide rapid feedback. Engineers have also used Blink to diagnose long-standing frame rendering anomalies that were previously impossible to analyze with perf due to their short-lived nature.

2 Experience with Perf

Huawei compiler engineers heavily relied on perf to assess the impact of their optimizations, specifically using it in sampling mode (`record` option). [1] This allows them to attribute low-level performance shifts to specific code regions (modules, libraries, and functions), as optimizations often affect only these localized areas. All our observations and results concerning perf are from its use in sampling mode.

Unfortunately, through painful lessons the compiler engineers have learned that perf's output cannot be trusted due to its inaccuracy in our workload. This is a terrifying reality because we have spent months chasing non-issues–trying to understand why an optimization appeared to fail, only to discover that perf's results were misleading. Worse, a poorly designed optimization that actually degrades performance could mistakenly be deployed to production. Next, we will describe several cases showing how perf's unreliable results have complicated engineers' development process.

2.1 Experimental Setup

Our experiments were conducted on a Huawei Mate 60 Pro smartphone running OpenHarmony OS version 0324. It uses Huawei HiSilicon KIRIN 9000S SoC, which has a total of 8 CPU cores: four "big" (more powerful) cores: one 2.62 GHz Cortex-A710 and three 2.15 GHz Cortex-A710, and four "little" (less powerful) 1.53 GHz Cortex-A510 cores. The phone has 12 GB 3200 MHz RAM. To measure the performance change of compiler optimizations, the compiler team uses a test suite that mimics real-life user interaction through automated clicks and swipes in representative applications.

The Large Picture View in the Camera app (C/LPV) test is prioritized by developers within this suite. This test involves a series of swipes to browse pictures, and its results are more consistent run-to-run because it does not rely on an internet connection. Some of our experiments were run only on the C/LPV test, while others were run on the entire test suite.

The primary optimization target is the system's frame rendering process, `render_service`. Rendering performance is one of the most critical concerns for smartphones because (1) it is one of the most resource-demanding tasks, and (2) it directly influences user experience, as the rendering frame rate reflects the visual smoothness [36]. Unless otherwise specified, all results in this paper are from profiling `render_service`, and we report the average of 10 runs.

2.2 Skid and Shadow Effect on LSEO

We describe a case where misleading output from perf led to weeks of wasted engineering effort pursuing a non-issue. The problem arose after compiler engineers implemented Large System Extension Optimization (LSEO), an optimization designed to reduce instructions for atomic increment/decrement operations, as explained in Listing 1. [2]

To confirm LSEO's effectiveness, the engineers enabled it for a single library, `librender`, and used perf to profile its dynamic instruction counts. However, this supposedly quick sanity check turned into a lengthy investigation: perf *consistently* reports a 6%, or 90 million, *increase* in instruction count for `librender` post-LSEO. Despite the percentage fluctuating, the trend—an instruction increase—was always reported across different runs.

Trusting this contradictory result, the engineers engaged in an extensive "bug hunt", including (1) manually examining `librender`'s binary instruction sequences to verify correct optimizations were applied (we wrote static binary analysis

[1] At Huawei we use *Hiperf*, which is a fork of Linux perf adapted for OpenHarmony. We believe, however, that all the findings in this paper generally apply to Linux perf as they are fundamentally rooted in its design.

[2] In addition to reduced instructions, other benefits of the optimization include (1) no branch prediction cost, (2) less cache coherence traffic and contentions, (3) better forward progress and scalability, and (4) simpler code.

Listing 1 Two versions of ARM instruction sequences for atomically decrementing a value. **Lines 1-6 are before LSEO**: `ldaxr` (Load-Acquire Exclusive) loads the value stored at memory address in `x8` into `x9`, and sets up an exclusive monitor on that address. `sub` decrements the value in `x9` by 1, storing the result in `x10`. `stlxr` (Store-Release Exclusive) attempts to *conditionally* store `x10` back to `[x8]`. The store succeeds only if the exclusive monitor is still valid (i.e., no one else has written to `[x8]` since the `ldaxr`). `w11` indicates whether the store was successful or not. `cbnz` then checks the value of `w11`, and branches back to `retry` if it is non-zero (i.e., store failed). This sequence repeats until the store is successful. **Lines 8-10 are after LSEO**. ARM's Large System Extensions (LSE), introduced in ARMv8.1-A, added an atomic add instruction `ldaddal`. Now we can implement the same atomic decrement logic by using only two instructions, without the need for a retry loop.

```
1  // before lse optimization
2  retry:
3      ldaxr x9, [x8]
4      sub x10, x9, #1
5      stlxr w11, x10, [x8]
6      cbnz w11, goto retry // retry if failed
7
8  // after lse optimization
9      mov x9, #-1
10     ldaddal x9, x8, [x8] // atomic add
```

and found a total of 4,006 static instances of atomic decrement); (2) verifying that the change only affected the atomic decrement; (3) confirming that LSEO was only applied to `librender` and no other libraries (by only swapping the library binary file and flashing the phone to the same state beforehand); and (4) brainstorming extensively on any possible side effects that could increase the instruction count. Only after these steps, combined with the observation that perf's non-sampling mode [3] indeed reported a 13M (.4%) decrease in total instruction count *for the entire process*, we concluded that perf's sampling result was inaccurate.

The root cause is the combined effect of skid and shadow effect. Perf implements sampling by configuring the Performance Monitoring Unit (PMU) counter to overflow at a user-specified frequency (default 4kHz). A PMU counter overflow triggers an interrupt, allowing perf to collect profiling information within the interrupt handler.

Skid refers to the imprecision between the instruction that actually causes the PMU counter to overflow and the Instruction Pointer (IP) recorded when the interrupt is handled. ARM-compatible processors cannot deliver the interrupt precisely at the triggering instruction [8]. Instead, the interrupt is delivered a few instructions later, so the recorded IP often corresponds to a nearby downstream instruction.

If skid were the only factor, it would introduce only random noise. For a consistent skid window (e.g., 100 instructions), the sampled IP would be, on average, 100 instructions after the event's source. With a large sample size, this noise should not lead to an incorrect statistical conclusion. However, when skid is compounded with *shadow effect*, the result could be *consistently wrong*.

The *shadow effect* occurs because long-latency instructions remain in the processor's in-flight instruction buffer (e.g., the reorder buffer) for extended periods [8]. Perf samples the instruction at the head of this buffer (the next one to retire). Since instructions retire in program order, a long-latency instruction at the head blocks all subsequent instructions from retiring, effectively shortening the skid window and significantly biasing the sampled IP toward long-latency instructions.

This is the case for the LSEO. The atomic add instruction `ldaddal` in the LSEO code is a long-latency instruction because it must gain exclusive ownership of the cache line during the entirety of the operation, often implementing the same retry mechanism as underlying micro-operations.

Figure 1 shows this result. It plots the instruction count measured by perf for the top 8 libraries in the `render_service` process. Here we run perf at its default 4kHz sampling rate. [4] Notably, while `librender` reported 30.9M increase in instruction count post-LSEO, two *unchanged* libraries–`librender_server` and `ld-musl`–reported a combined decrease of 38.7M. Analysis of the sample call stacks confirms that functions in `librender_server` and `ld-musl` call functions in `librender`. The observed change is attributed to a shadow effect from `ldaddal`: prior to LSEO, instructions frequently "skidded" from `librender` into `librender_server` and `ld-musl` at function return. After LSEO, samples that previously skidded past `librender` are now captured at `ldaddal`.

Skid effect can be almost entirely eliminated by CPUs that support *precise event delivery* [8]. Examples include Intel Precise Event-Based Sampling (PEBS) [21] and AMD Instruction-Based Sampling (IBS) [14]. They record the exact IP that caused a PMU counter to overflow.

ARM introduced an optional Statistical Profiling Extension (SPE) [28] starting with v8.2 to mitigate skid. Unlike interrupt-driven sampling, SPE periodically samples and records microarchitectural states. However, the HiSilicon Kirin 9000S cores currently lack support for SPE.

Crucially, even with SPE, our specific issue remains unresolved. This is because SPE does not support sampling based on instruction count (i.e., one sample every N retired instructions) [1]. Implementing instruction count sampling would be costly, as it requires complex and potentially disruptive deep hooks into the pipeline. Instead, SPE sampling is based on micro-operations [1]. Consequently, a single, long-running

[3] perf stat measures hardware and software performance counters over the entire duration of a program

[4] Note that a higher sampling rate on perf does not address the skid and shadow effect.

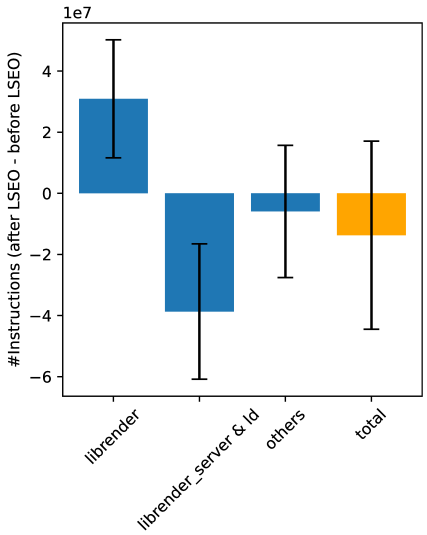

Figure 1: Difference in mean dynamic instruction count (y-axis) after and before LSEO for `librender`, the combination of `librender_server` and `ld-musl`, other libraries, and total for the entire process. Total for the entire process is computed with perf stat, whereas the others are computed using perf record (sampling). Shown in error bars is the geometric sum of the 2 standard deviations.

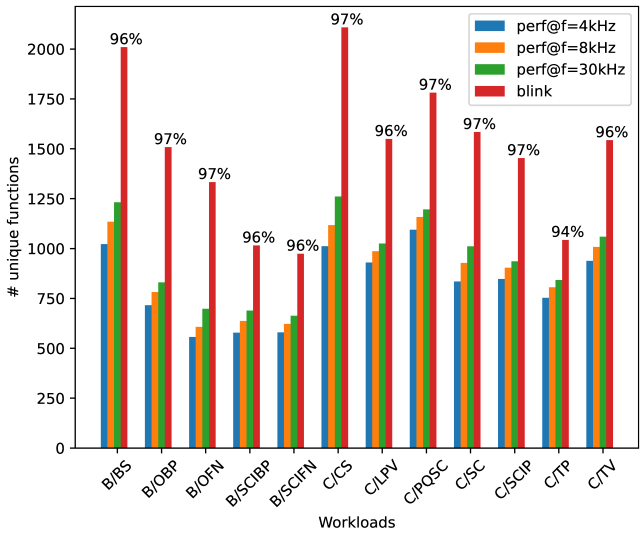

Figure 2: Unique functions covered by perf record at different sampling frequencies and Blink. Blink's coverage is reported on top of each workload.

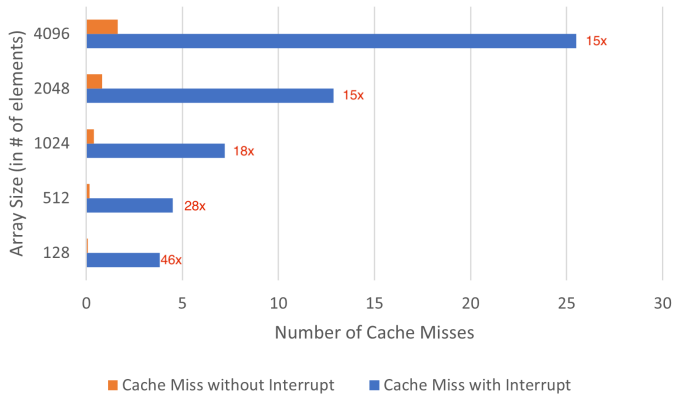

Figure 3: Cache misses of one `read_random()` invocation with and without timer interrupts.

instruction that involves many micro-operations will be sampled more frequently, resulting in a similar issue. In contrast, Intel PEBS and AMD IBS would resolve our issue because they support instruction count sampling.

Precise instruction count can also be obtained with Intel's Last Branch Record (LBR), which records all taken branch addresses. Unfortunately, our phones do not have this hardware support. In addition, this approach is limited to a buffer size. More importantly, LBR can only provide instruction counts, but engineers are often interested in other PMU events.

2.3 Low Coverage and Disturbance

Perf's sampling inherently limits the coverage. Figure 2 illustrates the coverage of unique functions across our 12-test suite. We tested various sampling rates for perf, ranging from 4kHz up to 30kHz.

At 4kHz, perf can only capture 54% of the functions on average. Even at 30kHz, coverage is still limited to 62%. While this is acceptable when profiling for performance bottlenecks, it poses a major obstacle when analyzing a flat profile or profiling functions with very short execution times, which is the case for the rendering workload where the execution time is often equally split across thousands of different short-lived functions. In contrast, Blink achieves a coverage of 96%.

Sampling at a higher frequency is often impractical. We ran an experiment where we increased the sampling rate from 4 kHz to 40 kHz. While we expected a 10x increase in the number of samples, we only observed about a 7x increase. This is because perf monitors its CPU usage and dynamically adjusts the actual sampling frequency to remain below a certain threshold (25% by default).

Furthermore, a high sampling rate can also significantly perturb performance. This can cause some frame rendering to take longer, missing deadlines and causing UI jank. We also observed that the increased CPU demand from the higher sampling frequency can cause threads typically scheduled on a little core to compete for a time slice on a big core. This shift completely alters the scheduling dynamics and, consequently, the entire system's performance characteristics.

2.4 Cache Pollution

Perf's sampling mechanism—interrupts—could introduce perturbation by polluting processor caches. We designed an experiment using a function `read_random()` that reads from an array randomly. Each element is cache line aligned (64 bytes). We ensured the array elements were resident in the L1 data cache before the function invocation. We read randomly because, for sequential reads, the hardware prefetcher would eliminate the cache misses.

Directly using perf sampling was not feasible as it utilizes the same registers needed to measure L1-Dcache misses. To simulate the effect of a sampling interrupt, we register a 4 kHz timer, which triggers hardware interrupts that invoke a signal handler. When the signal is received, the handler invokes `read_random()` to read the array one time, and we record the number of cache misses. `read_random()` is invoked a total of X times where X is the number of timer interrupts. In comparison, for the baseline (without interrupt), we invoke `read_random()` X times and compute the average cache misses for each invocation.

Figure 3 shows that, across different array sizes, the interrupts led to a dramatic increase in L1 D-cache misses, ranging from 15x to 46x. Such cache misses can alter the timing of loads and stores, potentially perturbing sensitive workloads. For instance, in the pre-optimized LSE snippet in Listing 1, sampling interrupts can increase load/store latency on the sampled CPU. Consequently, a CPU not sampled by perf is more likely to win the contention, thereby increasing the number of retry attempts on the sampled CPU.

3 Blink: A Trustworthy Tracing Tool

We design and implement Blink, an efficient and *trustworthy* performance profiler. Blink is a tracing-based profiler: it injects code snippets that read PMU counters before and after the code block being profiled, and records the counter values in a memory buffer that is later flushed to a trace file. By relying on tracing instead of interrupt-based sampling, it avoids the skid and shadow effects, and achieves full function coverage as users can trace any code region.

By default, Blink traces every function by inserting paired trace points at their entry and exit. It is also general: it can be used to trace any arbitrary code blocks. Developers may provide a list of functions to exclude from tracing.

Using Blink involves three steps: (1) Compile-time instrumentation: Target binary is compiled with appropriate flags to enable instrumentation at function entry and exit. (2) Execution and data collection: Each time an instrumented function is executed, Blink records a pair of tuples—`<tpID, PMU value>`—one at entry and one at exit, where `tpID` is a unique tracepoint ID. (3) Post-processing: The trace files are analyzed to compute the difference between the entry and exit PMU readings and to produce per-function summaries. Blink also generates flamegraphs [19], a feature used by engineers.

Blink can operate in two modes: sampling or always-on. In sampling mode, after N samples are collected within a thread for a particular function, the instrumented tracing code will self-disable its tracing via a carefully designed binary rewriting mechanism. A control thread will then periodically re-enable the tracing.

Next, we explain the design and implementation details.

3.1 Lightweight Tracing

We carefully designed our tracing logic to ensure its high efficiency. Crucially, because users expect zero overhead when tracing is disabled, we design a self-binary-rewriting mechanism to enable and disable tracing. We further optimize the tracing overhead by minimizing the use of shared variables and synchronization, and by using hand-written assembly to tightly control register usage.

An important concept in Blink is a *trace point*–a static code location to be instrumented. For each traced function, the trace points include its entry block and all its exit blocks (a function may have multiple exit blocks). Blink assigns a unique ID to each function and to each of its trace points.

Listing 2 shows the instruction sequence embedded at each trace point. It saves the required registers to the stack before calling the `tracing` function that performs the actual PMU reads. Specifically, lines 3-5 save registers `x0`, `x1`, `x8`, `x16`, `x29` and `x30`. This is much less than the full caller-saved set (`x0-x15, x29, x30`) specified by the AArch64 ABI. This is safe because these are the only registers used by `tracing`.

Lines 7-10 store the two arguments to be passed into `tracing`, namely `fn` and `tpID`, into `x0` and `x1`. Lines 12-14 store the address of `tracing` to `x16` before branching to it, effectively calling `tracing` with `fn` and `tpID` as arguments. Lines 16-18 restore the registers after `tracing` returns.

The first `nop` instruction is the target for binary rewriting. To disable tracing, we overwrite this instruction to a jump (i.e., an unconditional branch) to skip the following 13 instructions (`b +13`). As a result, when tracing is disabled, the only added overhead is a single jump instruction—there is no need to check for a flag and execute a conditional branch.

Listing 3 shows `tracing` logic (shown in C but implemented in assembly). It takes two arguments: a pointer to a structure `FData` and `tpID`, the trace point ID. Each function has a `FData` structure that stores its function ID `fID`.

We first obtain a pointer `tls` to the thread-local storage (TLS). The TLS region stores an array of counters (`tls->counters`), one for each function, and the buffer to store the profiling information (`tls->buf`).

Lines 5-11 in Listing 3 disable the tracing at the current trace point if its counter exceeds $2N$. Specifically, we obtain the IP of the `nop` instruction shown in Listing 2 in the caller, which is located at 11 instructions above the return address,

Listing 2 Instructions inlined at each trace point.

```
nop  // if disabled, rewritten to b +13

stp x0, x1, [sp,-16]!      // save args
stp  x8, x16 [sp,-16]!     // save scratch/x16
stp x29,x30,[sp,-16]!      // save FP/LR

adrp x0, fn:HI
add  x0, x0, fn:LO      // fn arg0
mov  w1, tpID:LO
movk  w1, tpID:HI LSL 16    // tpID arg1

adrp x16, tracing:HI
add  x16, x16, tracing:LO
blr  x16                   // call tracing

ldp x29,x30,[sp],#16       // restore FP/LR
ldp x8, x16,[sp],#16
ldp x0, x1, [sp],#16       // restore args
```

Listing 3 The function body of `tracing` that is invoked to collect PMU counters.

```
void tracing(FData* fn, int tpID){
  int fID = fn->fID;
  TLS* tls = emuTLS(); // thread-local storage
  // Disabling logic
  if (tls->counters[fID] >= 2*N || fn->disabled == true) {
    asm("mov %0, lr" : "=r"(ret)); // return addr
    *(ret - 11*4) = BRANCH_13; // rewrite with "b +13"
    tls->counter[fID] = 0 // reset
    fn->disabled=true;
    return;
  }

  asm("mrs %0," PMU_REGISTER :"=r"(pmu));
  record(tls->buf, tpID, pmu); // write to buf
  tls->counters[fID]++; // increment counter
  if(isfull(tls->buf))
     flush(tls->buf);  // flush
}
```

and rewrite it to an unconditional branch `b +13`, effectively skipping the compiler-injected snippet in Listing 2.

Lines 13-18 read the PMU counter value, store a tuple `<tpID, pmu>` into the per-thread buffer, and increment `tls->counters[fID]`. If the buffer is full, it will flush it to persistent storage.

The reason we compare the counter value to $2N$ instead of N is that trace points for a function are executed in pairs (i.e., the entry and exit of a function). Both share the same `FData`, hence the counter of this function `tls->counters[fID]` gets incremented twice per invocation. Consequently, each function invocation contributes two entries into the buffer. During post-processing, we pair these records and compute their difference to determine the performance of the function.

The reason that we are differentiating `fID` and `tpID` is that they represent two (subtle) distinct identities in the instrumentation. `fID`, stored in `FData`, uniquely identifies a function, whereas `tpID` uniquely identifies a trace point. A single function may have multiple trace points (i.e., multiple exit blocks), yet all of them correspond to the same `fID`. `fID` allows us to properly count the total number of function invocations, while `tpID` enables us to distinguish between entry and exit events during post-processing. This distinction becomes essential in cases such as recursion, where multiple nested invocations of the same function are active simultaneously; having `tpID` ensures we pair the correct entry and exit points.

This design minimizes variable sharing across threads, avoiding the need for synchronization and reducing cache-coherence traffic on shared variable read/write, which can be as costly as synchronization itself [12]. Both the buffer and the counters are stored per-thread. The only variable shared across threads in Listing 3 is `fn->disabled`, which indicates whether tracing is disabled for that function. Because multiple threads could be running this function, the `FData` is shared. However, this `disabled` flag is updated rarely, so the resulting cross-thread coherence overhead is negligible.

Enabling Tracing

Tracing is re-enabled periodically by a control thread waking up every T ms. It goes through every function's `FData` and examines the `disabled` flag. If a function's flag is set, the control thread enables tracing by rewriting the first instruction in Listing 2 from `b +13` back to `nop`. The address of this instruction is stored in the FData for each tracing function. If a function has n trace points, its FData contains n corresponding addresses. The control thread iterates over all these addresses and restores the initial instruction at each trace point, thereby re-enabling tracing for the entire function.

As a result of this design, for every thread Blink will collect at most N samples for every function for every T ms interval. This ensures high coverage on those rarely executed functions, yet the cap N keeps the tracing overhead bounded within each interval, regardless of how frequently a function executes. This design achieves a practical balance between limiting overhead and maintaining broad sampling coverage.

Blink has a feature to enable or disable tracing signals. Initially, all traces are disabled, and the control thread is only created when a signal is delivered. This feature is useful in practice because it allows developers to skip tracing the process startup phase.

3.2 Addressing Skid

Because modern superscalar CPUs execute instructions out of order, the PMU counter read instruction can be reordered. This can cause a similar skid effect. Blink supports an optional feature that adds an instruction fence (`ISB`) before every PMU read to enforce correct order. In practice, engineers only use this feature when measuring dynamic instruction count.

In addition, the injected instrumentation itself introduces a systematic measurement offset: instrumentation adds additional instructions that are inevitably captured in the measurement itself. This affects instruction count measurement. By manually counting the included instructions, we know this offset is 44 instructions, and we correct it in our post-processing.

3.3 Tree versus Self

The difference of the PMU counters between the entry and exit of a function would include the performance of all its callees (and their entire call chains). We refer to such measurements as the "tree" measurement. In contrast, a "self" measurement refers to only the function without any callees.

Blink supports both measurements. In theory, supporting "self" is straightforward because post-processing reconstructs callee relationships. By tracking entry and exit events, we can determine which functions are active at any point in time and subtract the PMU contributions of each callee from its caller, thereby isolating the caller's own ("self") cost.

In practice, however, not every function is instrumented. For any uninstrumented function, we would need to instrument immediately before and after its call instruction (`bl`) to subtract its contribution. For this feature Blink also allows developers to specify a list of call sites to exclude from instrumentation. This is used to skip a small number of very short helper functions that are invoked frequently and would otherwise cause a substantial slowdown if every call site were instrumented. (These short helper functions are not part of the system libraries we aim to trace and therefore are not included in our tree-based measurement.)

3.4 Other Implementation Details

Handling context switches and interrupts. The PMU counter on a CPU core increases monotonically, independent of context switches or interrupts. Therefore, when a thread is switched out, Blink must save its current PMU value and later restore it when the thread is switched back in. This save/restore logic is already handled by the kernel's perf subsystem in the same code path where the kernel saves and restores general-purpose registers. To leverage this capability, Blink makes a one-time `perf_event` system call at the first trace point executed by each thread.

Compiler integration. We cannot implement Blink's instrumentation as a compiler pass, because later optimization passes can modify the instrumented instructions. For example, instrumentation code might be reordered past the target; instrumentation might also cause functions that would otherwise be inlined to be no longer inlined because of the added instructions, hence the instrumented version may exhibit different performance behavior compared to the uninstrumented version.

To make sure the binaries are still comparable after instrumentation, we inject a placeholder at the Machine Intermediate Representation (MIR) stage, the last stage before IR becomes assembly. Naturally, MIR compilation passes execute after most major optimization passes. When MIR is lowered into assembly in the later stages, we replace the placeholder with actual assembly instructions.

Flush control. The per-thread buffer size is configurable. The default size is 10,000 records (i.e., `<tpID, PMU value>` tuples), which is determined experimentally such that we don't flush excessively, around once every 100ms. Each tuple is 16 bytes long, hence the buffer size is 160KB per thread.

Emulated TLS. For systems with native TLS support, a pointer to the Thread Control Block (TCB) is accessible using a system register (TPIDR_EL0 in ARMv8). Supporting this feature requires support from the linker, threading system libraries, and the architecture (providing a thread-specific system register).

Huawei's OpenHarmony currently does not support native Thread Local Storage (TLS). So we have to use emulated TLS (`emuTLS`) to obtain a pointer to a thread-local buffer. Emulated TLS is much slower than reading a register because it relies on POSIX thread API calls, specifically `pthread_get_specific` and `pthread_set_specific`, to emulate thread-local storage by using thread-specific keys to locate thread-specific data. In `tracing`, we made sure that `emuTLS` is only called once by reserving a register to save its return value.

Determining the PMU register. Unlike perf, Blink is designed to read the PMU counter values in the user space. However, `perf_event` does not specify which PMU counter it will use to record the event for user space programs, because in perf reading the PMU counter is done by the kernel module. On Huawei Mate phones, which provide eight PMU counters, we empirically found that the first five are reserved for kernel profiling. Blink therefore defaults to use PMU counter index 5 (`PMU_REGISTER` at line 11 of Listing 3 is a macro defined as `PMEVCNTR5`). For configurations where this counter is also reserved, we provide a script to detect the available PMU counters; users can then pass the appropriate index to Blink.

4 Evaluation

We aim to answer the following questions in our evaluation:

- *Correctness*: Can Blink profiles be trusted? How accurate are the PMU reads at function entry and exit?
- *Performance*: What is the performance overhead of Blink? Does Blink's overhead affect user-perceived metrics such as frame drops?
- *Utility*: How do developers use Blink? Does Blink's profiling data lead to more insights compared to perf?

Our experimental methodology follows the setup described in Section 2.1. Unless otherwise specified, we run Blink in

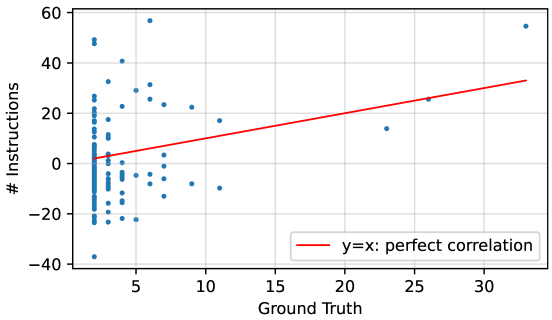

Figure 4: Per-function DIs: Blink *without* `ISB` vs. ground truth. Each point represents a unique function. Only 157 of the 1,112 static functions were invoked, so the figure contains 157 points.

sampling mode with $N = 30$ and $T = 400$ms, meaning that for every 400ms, each function running in each thread will collect at most 30 samples. We enable `ISB` and apply offset correction only when using Blink to measure dynamic instruction count; for all other PMU events we remove `ISB` and do not apply any post-processing correction.

4.1 Correctness Evaluation

To assess Blink's correctness, we compare Blink's reports against ground truth. Among the various PMU events, we use the **dynamic instructions (DIs)** event for comparison.

We selected 1,112 functions in `librender` that contain neither branches nor function calls. For such straight-line functions, DIs executed are known exactly. We use Blink to measure the DIs only for these functions via an include-list. We then ran the Camera large-picture-view workload `C/LPV` 100 times, and collected a combined total of approximately 177 million function invocations for the functions we selected. Among them, only *568 (less than .001%)* measurements showed any deviation from the ground truth. In all remaining records, Blink reported the exact instruction count as the ground truth, achieving an accuracy of $> 99.999\%$. These rare mismatches are likely due to infrequent counter glitches that occur when threads are interrupted.

Accuracy without `ISB`. Although engineers typically insert `ISB`s when measuring DIs, they often use Blink without `ISB`s when collecting other PMU events. Therefore, we evaluate Blink's accuracy in the absence of `ISB`s.

Figure 4 shows Blink's DI measurement without `ISB`s. The x-axis shows the ground truth instruction count of each function, while the y-axis shows the DI reported by Blink. Perfect accuracy corresponds to points lying on the red diagonal.

Across all functions, the mean error is -3.12 instructions, with a 95% confidence interval of $[-5.38, -0.86]$. This indicates that Blink's DI measurements without `ISB`s under-report the instruction counts by only a few instructions on average.

Jank	Baseline	Blink
Jank0	183.9 (65%)	186.8 (64%)
Jank1	68.5 (24%)	79.3 (27%)
Jank2	14.1 (5%)	14.5 (5%)
Jank3	14.1 (5%)	10.1 (3%)
Jank4	0.63 (0.2%)	0.38 (0.1%)
Jank5	1.75 (0.6%)	0.75 (0.3%)
Total Frames	283.0 (100%)	291.8 (100%)

Table 1: **Average jank breakdown for the gallery swipe workload.** Jank0 indicates the frame was rendered on time (higher is better); Jank$N$ ($N > 0$) represents N consecutive frames were delayed (lower is better). Higher Jank levels correspond to worse user experience.

4.2 Overhead and Perturbation

A profiling tool should not introduce overhead that causes user-perceived slowdown or perturbs application behavior. To evaluate this, we measure frame delays, also known as "jank". Table 1 reports the distribution of jank levels over 10 runs of `C/LPV`. We compare two configurations: the **Baseline**, which runs the workload without any instrumentation, and **Blink** configured *with* `ISB` enabled.

The jank distributions are similar in both configurations. Blink introduces only a 1% decrease in Jank 0 events (i.e., timely rendering), which is well within the acceptable margin (typically $< 2\%$). Interestingly, we also observe that some higher-level janks (e.g., multi-frame delays) shift to lower levels (e.g., single-frame delays) when running with Blink. This effect is likely due to workload fluctuations rather than a real performance improvement.

Micro-benchmark. We designed a simple micro-benchmark where we call a function 10 million times, and use Blink to trace it (without `ISB`). Each trace point executes an average of 140.9 instructions, and takes 38.7 cycles.

Memory overhead. We measure memory overhead using the peak resident-set high-watermark of `render_service`. We compared the Blink-instrumented runs against the uninstrumented baseline using the default buffer size (100k elements). When evaluated over 12 test workloads, the mean, median, and maximum overhead are 417.9 KB, 1,339.6 KB, and 5,666 KB, respectively. This overhead is dominated by the per-thread buffer allocation.

4.3 Use Cases and Experiences

Blink is available for all Huawei developers, but primarily used by the compiler engineers, who use it on flat-profile workloads to analyze short-lived functions. Blink has also been integrated into the performance testing framework so engineers can easily use Blink to debug any performance

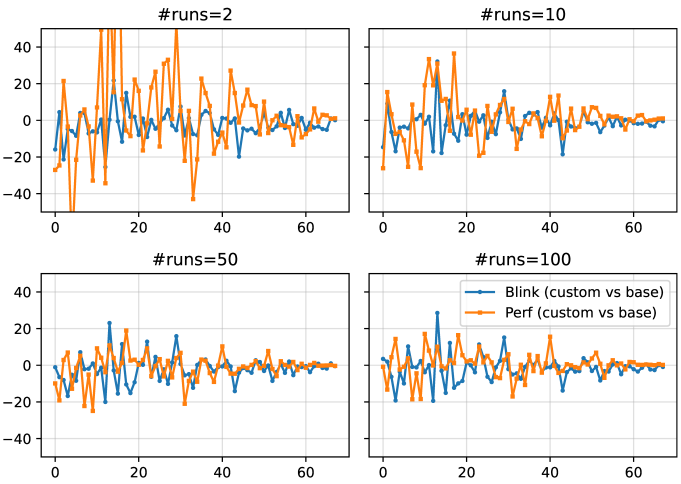

Figure 5: Comparison between perf and Blink. The x-axis lists functions (sorted by total cycle count), and the y-axis shows the percentage change in cycles when tuning from the `base` to `custom` compiler settings.

regressions. Next, we present four use cases where engineers find Blink particularly helpful.

4.3.1 Auto-tuning

One of the benefits of Blink is that it can collect trustworthy measurements with a small number of runs. Auto-tuning is such a use case, where we programmatically tune compiler flags, such as function inline threshold, in order to optimize the performance of a workload. These compiler adjustments can cause subtle and sometimes unpredictable performance shifts, so the tuning process must be guided and validated by reliable per-function profiles. The compiler team aims to train a machine learning model to automate these tuning decisions, which requires stable, fine-grained per-function data. Unfortunately, perf record is not suitable for this purpose due to its high variance across runs.

Figure 5 compares perf with Blink on 80 performance-critical functions in `librender` affected by a set of flags. The 'base' configuration uses the default compilation flags, whereas the 'custom' configuration modifies their values. [5] We measure per-function % cycle difference using both tools and repeat the workload between 2 and 100 times.

Perf exhibits substantial variance when only a few runs are available, stabilizing only after 50 or more repetitions. In contrast, Blink's results are stable after two runs.

This stability is critical for ML-based auto-tuning. The search space for compiler flags is large, and ML training requires evaluating many flag configurations. If each evaluation required 50+ repetitions (as with perf), the total cost would be prohibitive. With Blink, a workload generally needs to be run at most twice per trial, dramatically reducing training time and enabling exploration of a much larger configuration space.

[5] These flags are -inline-threshold, -intra-scc-cost-multiplier, -earlycse-mssa-optimization, -jump-threading-threshold, and -max-speculation-depth.

4.3.2 Frame Jank Investigation

Here we describe how engineers successfully triaged a long-standing performance bug using Blink. The `C/LPV` workload occasionally exhibited a frame that took significantly longer to render at the beginning of a swipe gesture.

We first provide some background on how frame rendering works on modern smartphones. A smartphone display refreshes at a fixed rate. On the Mate 60 Pro, the highest refresh rate is 120 Hz, meaning the screen renders a new frame every 8.33 ms. The display subsystem exposes this refresh rate via hardware VSync events. These events drive the system's software VSync callbacks, which are delivered to the foreground app to trigger frame rendering for the next display cycle. The app sends this frame to the system's rendering service to render it on the display. If the entire procedure takes longer than 8.33ms, the rendering is delayed; in severe cases several frames will be dropped, causing visible stutter.

Debugging with perf. Before Blink was available, engineers tried to debug this issue with perf. However, perf's sampling granularity is insufficient when rendering a frame only takes about 8.33ms. The highest sampling rate we can practically get from perf is between 30kHz and 40kHz—even if we set it to 100kHz, the maximum allowed sampling rate, it internally throttles due to overhead control. Even at 40kHz, we can only collect a few hundred samples per rendering window. When we compared the samples of a delayed frame with a healthy frame, the profiles looked completely different, with each function only sampled once or twice. We are essentially comparing two flat profiles that look very different. We concluded that profiling with perf is not suitable for short-duration tasks such as frame rendering.

Debugging with Blink. For this case, we used Blink to instrument functions in the rendering path and measure their cycle count. Tracing was enabled and disabled directly within the software VSync handler, giving us a clean trace for each frame-rendering interval. We further produced a differential flame graph [18] by comparing the healthy and delayed renderings. This analysis revealed a 10% increase in the execution time of the `execute` function in `libArk`. `libArk` is Huawei's managed-code runtime (supporting JavaScript, Java, and ArkTS), and `execute` is its main entry point. This clearly indicates that the slowdown lies in the application or in the libArk runtime, rather than in the system's rendering pipeline.

Unfortunately, Blink cannot trace the callees of `execute`, because they are JIT-generated code fragments produced by a library with a specialized compilation pipeline and non-standard ABI. Such code cannot be linked against static li-

	Avg. DIs	# Samples	Total DIs
Before LSEO	352.8	2,250	793,774
After LSEO	349.8	2,280	797,541

Table 2: Averaged DIs (dynamic instructions) per invocation of `update` before and after LSEO.

braries, while Blink's `tracing` function must be statically linked for instrumentation. As a result, callees such as `stub.an` (JIT-compiled JavaScript fragments) cannot be instrumented.

Nevertheless, Blink's findings were sufficient to triage the issue, and the bug was assigned to the Camera/Gallery app team and the libArk runtime team.

4.3.3 LSEO

Once Blink became available, one of the first cases engineers used it for was to confirm that LSEO indeed reduced instruction count. Specifically, we focus on the `update` function, which statically contains 26 LSEO opportunities, the most among all functions in the `librender` library. Interestingly, perf also reports the largest change for this function, claiming a 20% *increase* in DI after applying LSEO. This makes `update` an ideal case for evaluating LSEO's real effect and for contrasting perf's misleading measurement.

Table 2 presents the averaged DI for `update`, measured by Blink with `ISB` enabled. According to Blink, LSEO yields an average *reduction* of 3 instructions per invocation.

4.3.4 Test Suite Integration

We integrated Blink into Huawei's phone performance testing framework. Next we report results from the 12 tests in 2 applications (Camera and Browser).

As shown in Figure 2, a major advantage of Blink is its high function coverage: Blink is able to cover 96% of unique functions, whereas perf covers at most 62%. This is particularly valuable for compiler engineers, as optimization targets often lie in short-lived functions that appear flat or sparsely sampled under perf. Blink cannot cover all functions because some helper routines and stubs are generated by the compiler at link time, which occurs after the MIR stage where Blink inserts instrumentation.

Next we compare total cycle measurements from Blink and perf for all functions covered by both tools. For this experiment, Blink's tracing was configured to be always on.

Figure 6 shows the comparison of Blink and perf. Each data point represents a unique function covered by both tools. Its x- and y-axis coordinates are the measurements from perf and Blink, respectively. If the two measurements were identical, the point would lie on the red $y = x$ line. Data points above the perfect correlation are when Blink reports higher cycle count than perf, whereas those below are when Blink's measurements are lower.

Browser (B)

TP	1.23	3.05e5	0.9999
TV	1.11	3.24e6	0.9941

Table 3: Details of linear regression results

Table 3 provides detailed linear regression statistics. Slopes closer to 1 indicate greater similarity between perf and Blink.

Because the true cycle counts are unknown, we cannot determine which tool is strictly accurate. However, several observations are notable.

First, for functions with higher total cycle counts, the two tools tend to converge. The deviations from the $y = x$ line primarily occur for functions with small cycle counts. Given that perf's sampling design indicates that its accuracy is higher for long functions but lower for short functions, whereas Blink's tracing design should not be affected by function length, this result likely indicates that Blink's result is correct.

Second, the normalized standard deviation (NSD) results also show that Blink's result is more reliable than perf's. A positive NSD difference (i.e., yellow color) indicates perf has higher noise than Blink, whereas a negative value (i.e., blue) indicates the opposite. In 8 out of the 12 tests, perf demonstrated a higher standard deviation than Blink (as indicated by the NSD spectrum going to a higher positive value than the negative). There is only one test, B/OFN (Browser/Open-First-News), [6] where Blink showed higher noise than perf.

Finally, as shown in 9 of the 12 tests in Table 3, the y-intercept is positive, meaning that the regression line lies above the perfect-correlation line, indicating that Blink reports higher cycle counts than perf, which is expected because Blink's instrumentation introduces a fixed overhead of 38.7 cycles per collected tracing point, and we do not subtract this overhead during post-processing. Across all workloads, the R^2 values are high, indicating excellent fit quality.

5 Related Work

The problems associated with Event-Based Sampling (EBS)–including sampling skid and shadowing effect–have been extensively discussed in prior works [5, 8, 9, 13, 20, 22, 29, 31, 34, 37–39]. While these works provided valuable theoretical analysis, we describe experiences from real-world workloads to show the significance of these issues.

[6] This workload opens the first news article on m.baidu.com, and its fluctuations are affected by Wi-Fi quality

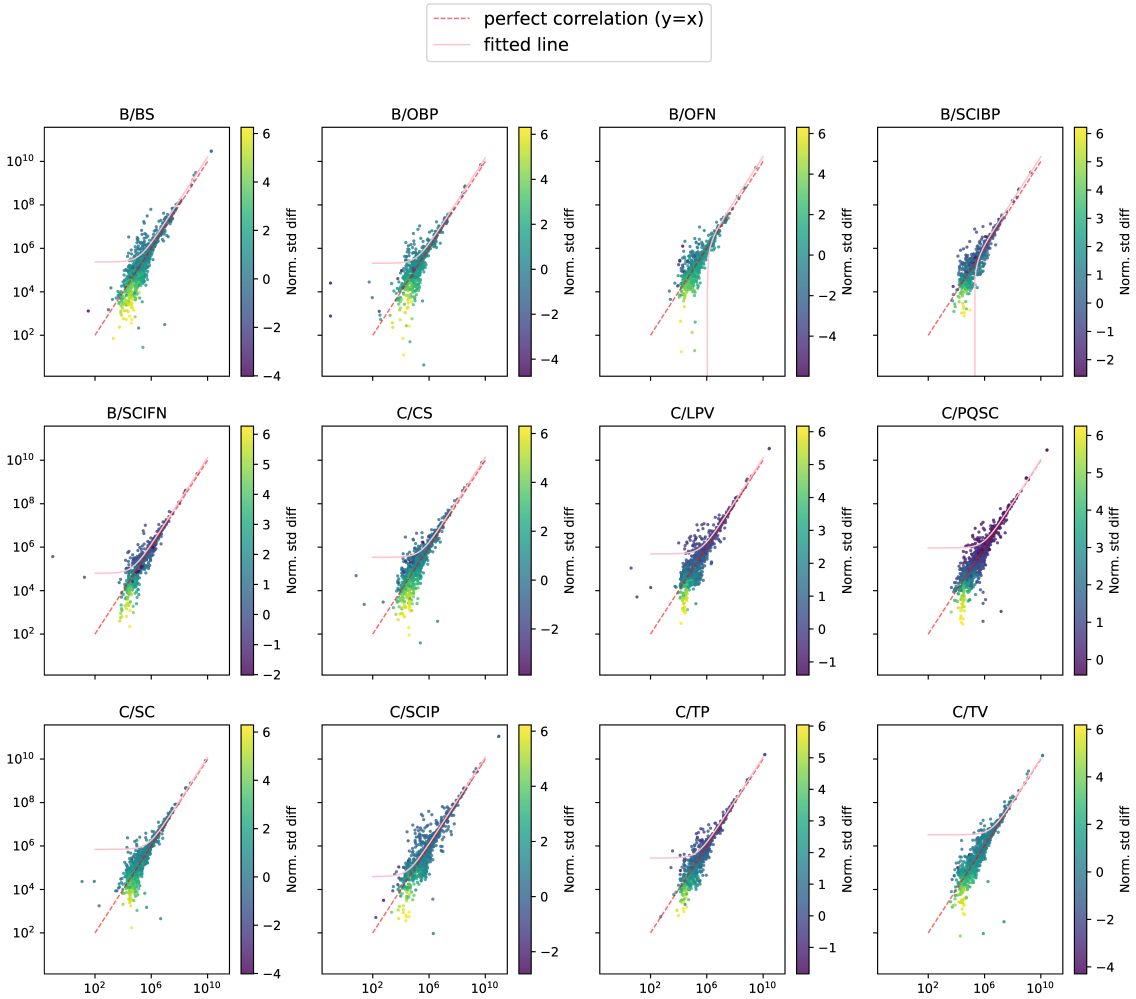

Figure 6: Log-log plot comparing total cycle count for perf (X-axis) and Blink (Y-axis). Linear regression in pink; perfect correlation line $y = x$ shown in red (dotted). Coloring represents the Normalized Standard Deviation difference based on 10 runs, $(std_{\text{perf}} - std_{\text{Blink}})/(0.5(avg_{\text{perf}} + avg_{\text{Blink}}))$. More yellow indicates that perf has higher standard deviation.

Some [5, 23, 26, 35, 37] enhance the accuracy of EBS by mathematically modeling the error due to skid and shadowing effects. For example, Xu et al. [37] quantify the value of skid in number of cycles and then use that to fix the sampled instruction distribution. These are orthogonal to Blink as both tackle the problem of EBS inaccuracy.

Many tracing profilers leverage compiler instrumentation. Compared to Blink, these approaches are often much simpler as they only support measuring execution time (rather than PMU events) and lack fine-grained sampling control. XRay [7] uses Clang/LLVM to insert instrumentation. While it also uses binary rewriting to disable or enable tracing, the mechanism is simpler than Blink's: it patches a no-op to a call to the tracing function, which takes no arguments because its tracing logic is minimal. Blink needs to pass in call-site-specific information as arguments to `tracing`, which requires a more sophisticated binary rewriting strategy. Moreover, XRay incurs 20%-40% overhead.

Hubble [24] is a function tracing tool for Android applications written in managed languages (Java and Kotlin). It records a time stamp and a function pointer at the entry and exit of every function. Compared to Blink, Hubble is much simpler—it is always-on and does not support PMU events, self-patching, or tracing native functions. However, Hubble is more efficient and lightweight than Blink and it is used on users' phones in production.

BOLT [30] is a binary optimizer to relocate functions after PGO (Profile-Guided Optimization) and LTO (link-time optimization) are performed. The authors argued that a sampling-based approach has low overhead and doesn't require recompilation, hence it should be preferred over tracing. However, we show a number of issues with sampling-based approach

in flat-profile workloads.

There are a number of other function call profilers. `gprof` [17] collects timing information through sampling and call graph information through tracing. GProfNG [27] extends `gprof` to work with PMU counters. However, GProfNG uses sampling instead of instrumentation. `strace` [3] and `ftrace` [33] allow users to profile system calls and kernel behavior.

There are a number of tracing tools designed to profile a large distributed cluster, including Project5 [4], MagPie [6], X-Trace [16], Dapper [32], Fay [15], ÜberTrace [11], and Pivot Tracing [25]. In comparison, Blink focuses on low-level profiling for smartphone workloads.

6 Limitations

Blink has several limitations. First, it is currently only used in testing and development environments, not on end-users' devices. A production-grade profiler would require far more comprehensive overhead evaluation to demonstrate that its *worst-case* overhead remains within 1–2% [24]. Further, Blink's self-patching mechanism requires access to a rooted and unlocked smartphone, which end-users do not have access to. Second, although Blink achieves 96% coverage across all functions—substantially higher than perf—a small subset of functions cannot be instrumented because they follow different ABIs. Third, Blink currently targets ARM64. Porting Blink to other architectures requires rewriting its hand-written ARM64 tracing instructions (Listing 2 and Listing 3) for other ISAs, which takes non-trivial effort. Finally, Blink's design is closely tied to instrumenting compiled binaries. As such, it cannot be used on interpreted and JIT-compiled languages. However, there exist other tools, like Hubble [24], that modify the runtime to trace managed languages.

7 Concluding Remarks

This paper first demonstrates that sampling-based profilers such as perf can produce systematically misleading results for flat-profile workloads with short-lived functions. Through real-world smartphone rendering workloads, we show how skid, shadow effects, limited coverage, and measurement perturbation can invalidate profiling results, leading engineers to chase non-issues or misjudge optimizations.

We present Blink, a lightweight tracing-based profiler that provides accurate and high-coverage PMU measurements with minimal overhead. Overall, we find that Blink is well-suited for profiling functions with low total hardware event counts, which constitute a large portion of Huawei's system libraries. These same functions are precisely the ones that sampling-based profilers struggle to capture reliably. Blink offers a practical solution for reliably evaluating compiler optimizations in environments where even small performance gains matter. Blink is available at https://github.com/Huawei-CPLLab/Blink.

8 Acknowledgements

We thank our reviewers and the shepherd for their insightful reviews and feedback. We also thank Henry Kao, Steven Huang, and all the other members of Huawei's BiSheng Mobile CPU team for their invaluable support in resolving technical challenges during the implementation of Blink. This research was supported by a contract between Huawei and YScope.

Abstract

Tree-of-Thought (ToT) reasoning structures Large Language Model (LLM) inference as a tree-based search, demonstrating strong potential for solving complex mathematical and programming tasks. However, its efficiency is constrained by the *reward dependency barrier*—a synchronization bottleneck caused by sequential reward-guided exploration that limits search parallelism and introduces substantial latency. Prior system optimizations, mainly designed for linear Chain-of-Thought (CoT) reasoning, cannot address these challenges, leaving the efficiency of ToT underexplored.

To enhance ToT reasoning efficiency, we observe that the reasoning paths can be explored speculatively to break the reward synchronization barrier. Therefore, in this paper, we propose SPEX and introduce three key techniques: (i) intra-query speculative path selection to predict and expand high-potential branches of ToT, (ii) inter-query budget allocation to balance speculative resource allocation across queries dynamically, and (iii) adaptive early termination to prune deep and redundant branches for a skewed search tree.

We implement SPEX on top of the SGLang framework and evaluate it across diverse ToT algorithms and LLMs. Extensive experiments show that SPEX achieves $1.2 \sim 3\times$ speedup for different ToT reasoning algorithms. Moreover, SPEX synergizes with token-level speculative decoding, achieving cumulative speedups of up to $4.1\times$. Ablation studies further confirm the contributions of each technique. Overall, SPEX represents a significant step toward efficient and scalable ToT reasoning, unlocking the parallelism required for high-performance inference-time scaling for LLMs.

1 Introduction

The recent success of Large Language Models (LLMs) has been driven by their ability to scale with inference-time compute budgets [3, 8, 26, 47, 50–52, 69]. Two main approaches have been constructed, including Chain-of-Thought (CoT) [13, 41, 59, 72] and Tree-of-Thought (ToT) [2, 11, 16, 19, 55, 66]. CoT prompts LLMs to reason over a coherent sequence of tokens (denoted as "thought") that serve as intermediate steps toward problem solving. ToT further generalizes CoT by maintaining a search tree and allowing LLMs to explore different branches of the tree adaptively, as in Figure 1 (a). To guide exploration, ToT often relies on a reward signal that evaluates existing reasoning branches and decides the next course of action, e.g., expanding existing branches or backtracking. Compared to CoT, ToT enables LLMs to perform complex reasoning and greatly enhance their problem-solving capabilities.

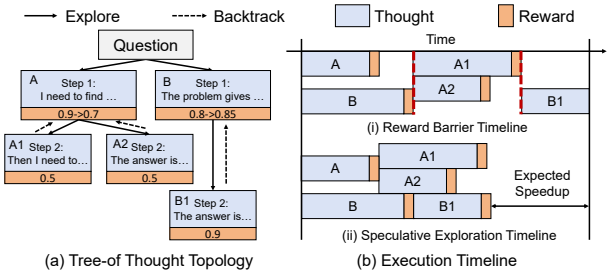

Figure 1: Illustration of ToT and Reward Barrier.

Prior ToT algorithms employ distinct exploration strategies driven by how reward signals guide the search. They can be categorized into two paradigms that impose different dependency patterns on the system [64]. **Breadth-First Search (BFS)** maintains a set of the most promising thoughts at each step, utilizing intermediate reward feedback to concurrently prioritize and expand branches at the current search frontier. In contrast, algorithms like MCTS [68] incorporate **Depth-First Search (DFS)**. The reward of all the nodes of a reasoning branch is iteratively updated via tree-search value propagation from leaf nodes. The search policy then leverages these refined rewards to revisit and expand prior nodes, enforcing a sequential dependency on previous iterations.

While ToT enhances reasoning capabilities and accuracy, it comes with increased latency overhead [10, 24, 30]. Many studies have explored strategies for efficient reasoning. On the algorithmic side, techniques like TrimR focus on reducing the length of thoughts for better reasoning efficiency [7, 9, 17, 24, 32, 35, 36, 45, 57, 70]. On the system side, serving frameworks such as vLLM [27] and SGLang [71] achieve significant efficiency improvement with PagedAttention and RadixAttention. However, these system optimizations are primarily designed for linear CoT reasoning and overlook the unique characteristics of ToT reasoning [29].

In this paper, we identify the critical performance bottleneck in ToT reasoning as the Reward Dependency Barrier as illustrated in Figure 1(b). In Breadth–First Search, the barrier imposes a synchronization overhead: expansion decision is gated by the aggregation of reward values of all concurrent thoughts. High variance in decoding lengths creates stragglers, forcing shorter branches to idle until the longest one completes. For Depth-First Search, the barrier imposes a sequential constraint: each new traversal must wait for the previous rollout outcome and tree-value update before deciding whether to continue or backtrack, enforcing a serialized execution flow. Consequently, both scenarios prevent the system from sustaining dense batch processing. This inefficiency limits parameter reuse and KV cache sharing, significantly degrading arithmetic intensity and shifting the workload to a memory-bound regime.

To break the barrier, we propose **SPEX** to enhance parallelism in ToT reasoning. By proactively generating subsequent thoughts for promising branches without waiting for the synchronization of reward values, SPEX allows the system to overlap the generation of future thoughts with the completion of current thoughts. It addresses three key challenges in speculative exploration: (i) How to accurately predict which branches to expand speculatively, (ii) How to efficiently allocate computational resources across queries with varying demands and reuse opportunities, and (iii) How to manage skewed tree structures, where a few disproportionately deep thought branches dominate overall inference latency and are difficult to explore speculatively.

To address these challenges, we identify three key insights that shape the design of SPEX. First, reward stability across iterations enables reliable prediction of high-potential branches, even in DFS. Second, shared computation opportunities, such as KV cache reuse and parameter sharing, can enhance speculative efficiency and resource utilization. Finally, in skewed tree structures, most correct solutions emerge at shallow depths, making it possible to terminate the deep branches early.

Motivated by these insights, SPEX introduces three key techniques: (i) **Intra-query speculative branch selection**, which leverages reward stability in DFS and score-based allocation in BFS to identify high-likelihood branches for speculative expansion. (ii) **Inter-query budget allocation**, which dynamically distributes speculative resources across queries based on predicted utility, KV cache reuse potential, and system constraints, ensuring balanced and efficient utilization. (iii) **Adaptive early termination**, which halts exploration in skewed trees once sufficient confidence is achieved, avoiding unnecessary computation in deep branches.

Finally, to unify speculative exploration across diverse ToT reasoning algorithms, we design SPEX as **a general producer–consumer execution framework** that integrates the three techniques. The framework decouples branch expansion (producer role) from control logic (consumer role), enabling concurrent progress on both primary and speculative branches while adapting to system resource conditions. Our contributions can be summarized as follows:

- We identify the reward dependency barrier as the principal bottleneck in ToT reasoning.
- We propose SPEX, a speculative exploration framework that breaks this barrier by proactively and speculatively exploring promising branches.
- We design three complementary techniques, i.e., intra-query speculative selection, inter-query budget allocation, and early termination strategy, to improve the effectiveness of speculation.
- We implement the **SPEX** on top of SGLang and demonstrate up to 3× speedup over prior-art ToT reasoning algorithms without compromising accuracy. SPEX is available at https://github.com/PKU-SEC-Lab/SPEX.

2 Background

2.1 Tree-of-Thought Reasoning

Recent research on inference scaling laws has shown that LLM performance improves with increased inference-time compute budget [3, 8, 20, 26, 42, 43, 50–52]. Chain-of-Thought (CoT) extends reasoning depth along a single trajectory, Tree-of-Thought (ToT) further expands reasoning breadth by exploring multiple solution paths in parallel [64].

Structurally, ToT frames reasoning as a search over a tree of discrete steps. In this framework, each step constitutes a coherent segment of thought, serving as the atomic unit of expansion. Accordingly, a node represents the partial solution state reached by applying a step, and a sequential trajectory of these states from the question to a final answer forms a reasoning path [60].

The search is guided by reward signals, derived either from a dedicated reward model [60] or through the reasoning model's intrinsic self-evaluation [18]. As illustrated in Figure 2, ToT algorithms can be categorized by their expansion and traversal strategies into BFS and DFS.

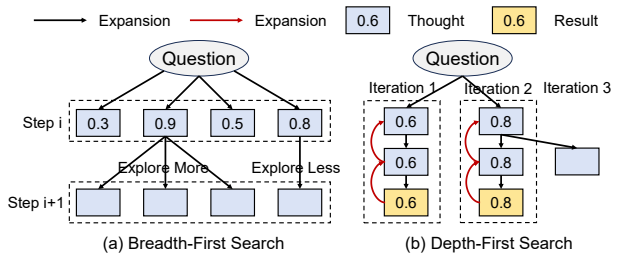

Figure 2: Classification of different ToT algorithms.

2.1.1 Breadth-First Search

Breadth-First Search maintains a collection of the most promising nodes at each step, optimizing the search frontier by utilizing intermediate feedback to concurrently prioritize and extend these branches [64]. A representative algorithm is REBASE [60] illustrated in Figure 2(a), which utilizes process rewards to guide this search. It employs a softmax-based mechanism to dynamically allocate expansion budgets. Formally, given a total sampling budget B_i at depth i, the expansion width W_j for a node n_j is calculated as:

$$W_j = \text{Round}\left(B_i \frac{\exp(R(n_j)/T_b)}{\sum_k \exp(R(n_k)/T_b)}\right)$$

where $R(N_j)$ denotes the reward score of node n_j, T_b is the balance temperature controlling the exploration-exploitation trade-off, and the summation index k iterates over all candidate nodes at the current depth i.

2.1.2 Depth-First Search

Depth-First Search explores the most promising path until a terminal state is reached, and then leverages updated value estimates to backtrack and revisit high-potential prior states for alternative exploration [64]. Thus, the next traversal is chosen only after the current rollout updates the tree state. Monte Carlo Tree Search (MCTS) is a representative algorithm for this category as illustrated in Figure 2(b) [5, 46, 56, 62]. It balances the trade-off between exploration and exploitation using the Upper Confidence Bound (UCB) metric to select the next action a^*:

$$a^* = \arg\max_a \left[Q(s,a) + c \cdot \sqrt{\frac{\log N(s)}{N(s,a)}}\right]$$

where $Q(s,a)$ represents the estimated value of taking action a in state s, $N(s)$ and $N(s,a)$ denote the visit counts for the state and the specific action, respectively, and c is the exploration constant. By updating these statistics after each traversal, the algorithm retrospectively adjusts its search focus. However, this iterative dependency typically enforces a sequential execution pattern, severely limiting parallelism.

Notably, DFS can operate in isolation or coexist with BFS. Pure DFS, such as RSTAR-MCTS [46], generates a single continuous chain per iteration, receiving a reward signal only upon reaching the final outcome. In contrast, REST-MCTS [68] adopts a hybrid strategy where each iteration functions as a step-wise BFS: at every depth, it expands multiple candidate nodes and utilizes immediate process rewards to select the single best child for the subsequent step.

2.2 Existing Optimizations for ToT Reasoning

Existing system optimizations for LLM inference are highly effective for single-path CoT reasoning, but few are specifically designed to support the tree-structured search process of ToT reasoning. This fundamental mismatch leaves current serving infrastructures unable to fully exploit the potential of multi-path search.

On the system side, a series of serving frameworks have substantially improved throughput and latency for linear decoding workloads. vLLM [27] introduces PageAttention, which decouples key-value caching from attention computation. SGLang [71] implements RadixAttention to reuse intermediate KV-cache memory across requests. FlashAttention and FlashDecoding utilize the online softmax to reduce memory usage [15]. FlashInfer integrates the above optimizations of attention into a unified block-sparse framework [65]. Together, these efforts demonstrate the effectiveness of system-level optimization for general LLM decoding.

On the algorithmic side, efficient reasoning methods primarily target token efficiency in CoT. Approaches reduce the number of generated tokens or adaptively adjust reasoning length based on task complexity [7, 9, 17, 35, 36, 57, 70]. ETS [23] goes beyond token-level analysis by providing a system-oriented perspective, showing that in memory-bound scenarios, KV cache access dominates inference costs. By optimizing KV reuse and access patterns, ETS connects algorithm design with system efficiency.

Despite these advances, existing methods share a fundamental limitation: they are tailored for linear CoT reasoning. While CoT-style optimizations leverage batching and prefix sharing across requests, they do not accommodate the irregular, tree-shaped exploration inherent to ToT reasoning.

3 Motivation and Challenge

Unlike CoT, ToT requires concurrent branch expansion, dynamic allocation of computational budgets, and synchronization based on reward signals. These characteristics introduce new system-level bottlenecks that current inference systems are not designed to handle.

In this section, we first present our key observation that the reward dependency barrier constitutes the primary bottleneck limiting ToT reasoning efficiency (§3.1). We then provide a quantitative analysis of how this barrier constrains system

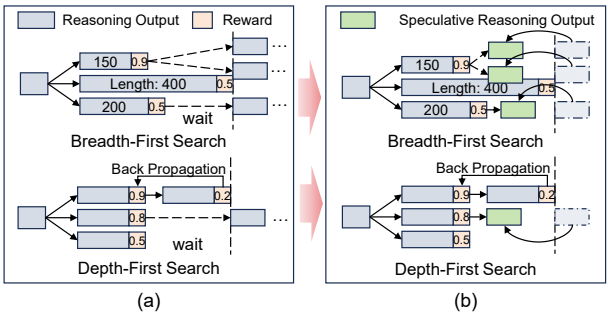

Figure 3: Example of (a) reward barrier and (b) our proposed speculative exploration.

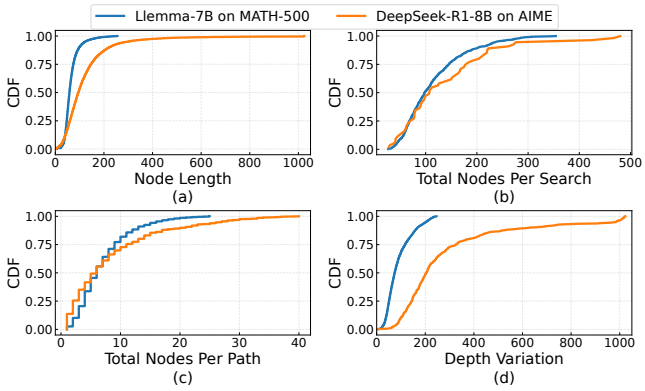

Figure 4: Cumulative Distribution Function (CDF) of reasoning characteristics for Llemma-7B [1] and DeepSeek-R1-8B. (a) Node Lengths; (b) Total Nodes Per Search; (c) Total Nodes Per Path; (d) Variation of Node Lengths at the same depth.

performance (§3.2), followed by our motivation: speculative branch exploration as a means to improve efficiency (§3.3). Finally, we discuss the challenges to perform speculative exploration in ToT reasoning (§3.4).

3.1 Observation on Reward Dependency Barrier

We observe that the reward dependency barrier is the principal performance bottleneck in ToT reasoning: At each stage of the search, the system must pause to await feedback from the reward model before determining the next action. The manifestation of this barrier varies depending on the underlying algorithmic paradigm and arises from two main sources.

1) Intrinsic Sequentiality in Depth-First Search. In DFS algorithm, the search advances along a single reasoning path, with progress contingent on receiving the reward signal. Only after obtaining this feedback can the system decide whether to backtrack and which alternative branch to explore next. This results in inherently sequential execution and severely limits opportunities for parallelism, as depicted in Figure 3(a).

2) Synchronization Bottlenecks in Breadth-First Search. In contrast, BFS algorithm can explore multiple candidate branches in parallel at a given search depth. However, its overall progress remains gated by synchronization points at each level: the system must aggregate reward signals across all branches before determining the expansion budget for each node at the next depth, as shown in Figure 3(a). This introduces critical synchronization overheads that limit parallelism, as faster branches are forced to idle until the global aggregation completes.

To quantify the reward barrier, we analyze the cumulative distribution of node lengths and their variation across search depths. We conduct this profiling on two representative workloads: Llemma-7B on MATH-500 and DeepSeek-R1-8B on the challenging AIME benchmark. Here, a node length is the number of tokens generated for one reasoning step. As shown in Figure 4(a), DFS typically involve a large number of sequential steps, with each step generating 50-100 tokens. Figure 4(b) and 4(c) further illustrate that the total number of nodes per search and the number of nodes along each path are both substantial, indicating that MCTS-style algorithms require traversing many nodes in series. Given that these methods often require hundreds of such steps, this results in significant cumulative latency. For BFS algorithm, Figure 4(d) quantifies the synchronization overhead by plotting the variation in node lengths at the same depth. The slow saturation of the CDF curves reveals a pronounced long-tail effect: while many branches finish early, the system is forced to idle for the slowest "straggler" branches to complete. This high variance, particularly evident in the DeepSeek workload, exacerbates resource underutilization at synchronization barriers.

Overall, this analysis highlights that both algorithmic paradigms are fundamentally constrained by the reward barrier: DFS methods suffer from high sequential latency due to deep search paths, while BFS methods are limited by stragglers and synchronization overhead.

3.2 System-Level Performance Analysis

To quantitatively illustrate how the reward dependency barrier limits system efficiency, we analyze the performance of ToT using the Roofline model. Two primary contributors dominate memory operations during inference: (i) model weight accesses and (ii) KV cache accesses. Both are significantly affected when parallelism is constrained, leading to repeated memory operations and inefficient resource utilization.

When batch sizes are small due to limited parallelism, the system must repeatedly load model weights for each reasoning step. Similarly, KV cache accesses become inefficient due to the lack of shared prefixes across reasoning paths. Without sufficient KV sharing, the system repeatedly reloads overlapping or identical context segments across different branches,

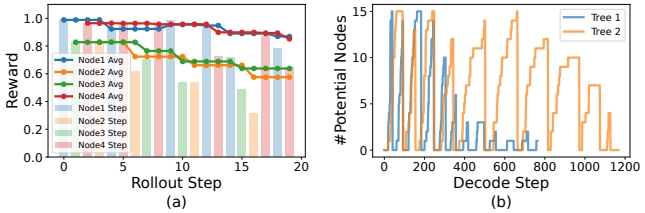

Figure 6: (a) Stability of MCTS node values across rollout steps. These estimates change as later rollouts update ancestor nodes. (b) Fluctuations in the number of potential speculative nodes for two queries at different decoding steps in REBASE.

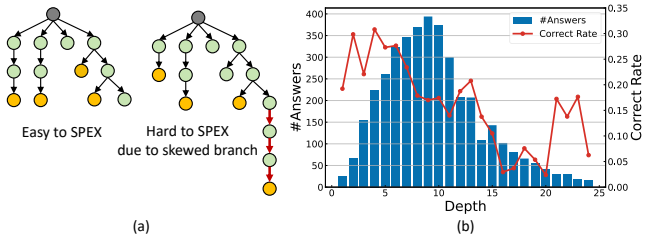

Figure 7: (a) SPEX struggles with skewed trees under the REBASE algorithm due to dominant deep branches. (b) Answer count and correct rate of different reasoning depths in skewed deep trees (depth > 10).

increasing memory bandwidth consumption. This repeated loading not only adds latency but also prevents tree-based optimizations like RadixAttention.

As shown in Figure 5(a), these repeated memory operations result in low arithmetic intensity (FLOPs/Byte), making memory access the primary bottleneck. DFS is inherently confined to the memory-bound region due to their strict sequentiality. While BFS starts with higher parallelism, it suffers from batch attrition. As illustrated in Figure 5(b), the early completion of shorter branches degrades the effective batch size, dynamically shifting the workload from compute-bound into memory-bound regime.

3.3 Motivation

While the reward barrier limits inter-branch concurrency, significant latent parallelism exists within the reasoning tree. By **speculatively exploring confident branches** before reward feedback arrives, we can break the reward barrier, reduce synchronization delays, and reuse shared prefixes.

This motivates **SPEX**, a speculative exploration framework that exploits potential parallelism to overcome sequential bottlenecks in ToT reasoning. Specifically, SPEX proactively and speculatively explores promising candidate branches based on predictive signals, as illustrated in Figure 3(b). This removes the blocking dependency on reward feedback, allowing the expansion process to continue without idling.

3.4 Challenges

However, directly applying speculative exploration is insufficient, as it faces the following challenges.

Challenge 1: Speculating Inaccuracy on Future-Needed Branches. Speculating on future-needed branches is straightforward in BFS, where candidate nodes are confined to the current depth. However, for DFS algorithms like MCTS, every node in the tree may be revisited, making it difficult to predict which branches will be required. This complexity increases the difficulty of efficiently allocating speculative computation to accelerate future exploration.

Challenge 2: Complex Speculative Budget Allocation across Multiple Queries. In multi-query scenarios, distributing speculative resources becomes more complex due to variations in the number of potential nodes per query and their probabilities of future relevance. As illustrated in Figure 6(b), the number of nodes available for speculative execution fluctuates significantly between queries. Additionally, these nodes may vary in their likelihood of being utilized, depending on the accuracy of predictions for each query. This variability, combined with limited system resources, requires dynamic allocation strategies that prioritize queries based on their search state, predicted utility, and overall system capacity to optimize throughput and responsiveness.

Challenge 3: Inefficient Resource Allocation under Skewed Tree Structures. For highly skewed trees, SPEX struggles to achieve significant acceleration, as shown in Figure 7(a). In such cases, the majority of computational resources are consumed by disproportionately deep branches, which are challenging to predict and explore speculatively. This reduces parallelism, increases latency from sequential exploration, and limits efficient resource allocation, particularly when dealing with long dominant branches.

4 The SPEX Design

This section presents the design of SPEX, a speculative exploration framework that breaks the reward dependency barrier

by increasing parallelism for ToT reasoning.

4.1 Overview

The key idea of SPEX is to speculatively explore confident branches before reward feedback arrives, as presented in §3.3. To address the challenges identified in speculative exploration (§3.4), SPEX leverages three core techniques, each motivated by key insights observed in ToT reasoning.

Insight 1: Reward Stability Enables Prediction. As shown in Figure 6(a), node value estimates in MCTS exhibit high stability across iterations, with reward values changing minimally as rollouts progress. A later rollout updates the value estimates and visit counts of its ancestor nodes, so a node's estimate may evolve over time. This is because each expansion step updates only one node's statistics, and rewards, averaged over multiple rollouts, evolve slowly while UCB variations are primarily influenced by visit counts. This stability allows reasonably accurate predictions of node behavior, facilitating speculative execution or pruning strategies to reduce sequential bottlenecks.

Based on the insight, we propose *an efficient intra-query speculative branch selection scheme*, which leverages reward stability in DFS and score-based allocation in BFS to identify high-likelihood branches for speculation (addressing Challenge 1).

Insight 2: Shared Computation Shapes Allocation. Efficient allocation of speculative resources requires evaluating the potential benefits of each query. The primary gains from speculative exploration arise from two forms of shared computation: (i) parameter loading reuse, where speculative branches share model weights with the primary branch, and (ii) KV cache reuse, where branches with overlapping prefixes reuse cached attention states. These benefits are influenced by factors such as the prediction accuracy of speculative branches and the proportion of the KV cache that can be reused. By quantifying these elements, the system can guide resource distribution to maximize the overall utility of speculation while minimizing waste on low-impact queries.

Based on the insight, we propose *an efficient inter-query budget allocation scheme*, which dynamically distributes speculative resources across queries based on predicted utility, KV cache reuse potential, and system constraints, ensuring balanced and efficient utilization (addressing Challenge 2).

Insight 3: Answer Depth Bias Favors Shallower Exploration. As illustrated in Figure 7(b), even for skewed deep trees, most answers are generated at shallower depths, where the correct rate is also higher. This indicates that early-stage exploration typically produces both more frequent and more accurate solutions, suggesting that deep exploration may often be unnecessary under majority vote [31] strategies.

Based on the insight, we propose *an adaptive early termination strategy*, which halts exploration in skewed trees once sufficient confidence is achieved, avoiding unnecessary computation in deep branches (addressing Challenge 3).

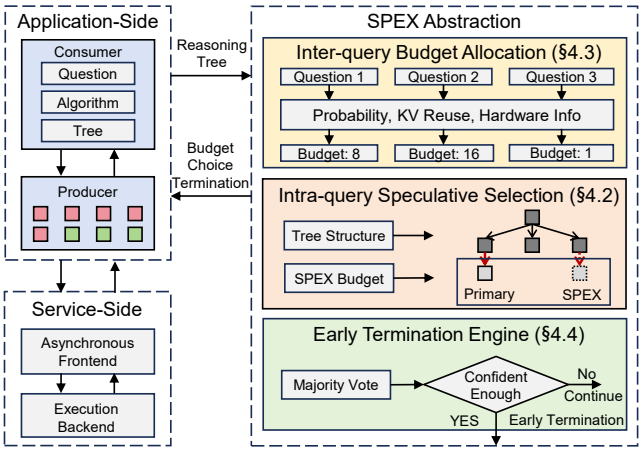

Figure 8: The architectural overview of SPEX.

Together, these three techniques define the SPEX workflow, as illustrated in Figure 8. First, given multiple queries, SPEX applies *the inter-query budget allocation scheme* to allocate speculative resources based on query probability, KV cache reuse potential, and hardware capabilities (§4.3). Next, for each query, SPEX employs *the intra-query speculative selection scheme* to predict and expand the most promising future branches for speculative exploration (§4.2). Finally, to handle skewed trees, SPEX integrates *the adaptive early termination strategy*, which halts exploration and returns answers when the system has gathered sufficient confidence (§4.4).

Finally, to unify speculative exploration across diverse ToT reasoning algorithms, we design SPEX as *a general producer–consumer execution framework* (§4.5) that integrates the three techniques.

4.2 Intra-query Speculative Selection

To improve efficiency within a single query, SPEX integrates speculative exploration into the node selection process, employing two complementary strategies: one tailored for DFS and the other for BFS algorithms.

1) Speculation for Depth-First Search. As shown in Insight 1, reward estimates of individual nodes in MCTS exhibit high stability across iterations, enabling accurate forecasting of future node selections without invoking the reward value.

SPEX leverages this property by *simulating* the next k primary selections under the current tree state. Here, simulation means applying the same UCB selection rule on a temporary tree state, using current value estimates, visit counts, and active speculation records, without invoking LLM generation or reward evaluation. After each simulated selection, the algorithm updates visit counts and UCB values before proceeding to the next simulated step, ensuring that subse-

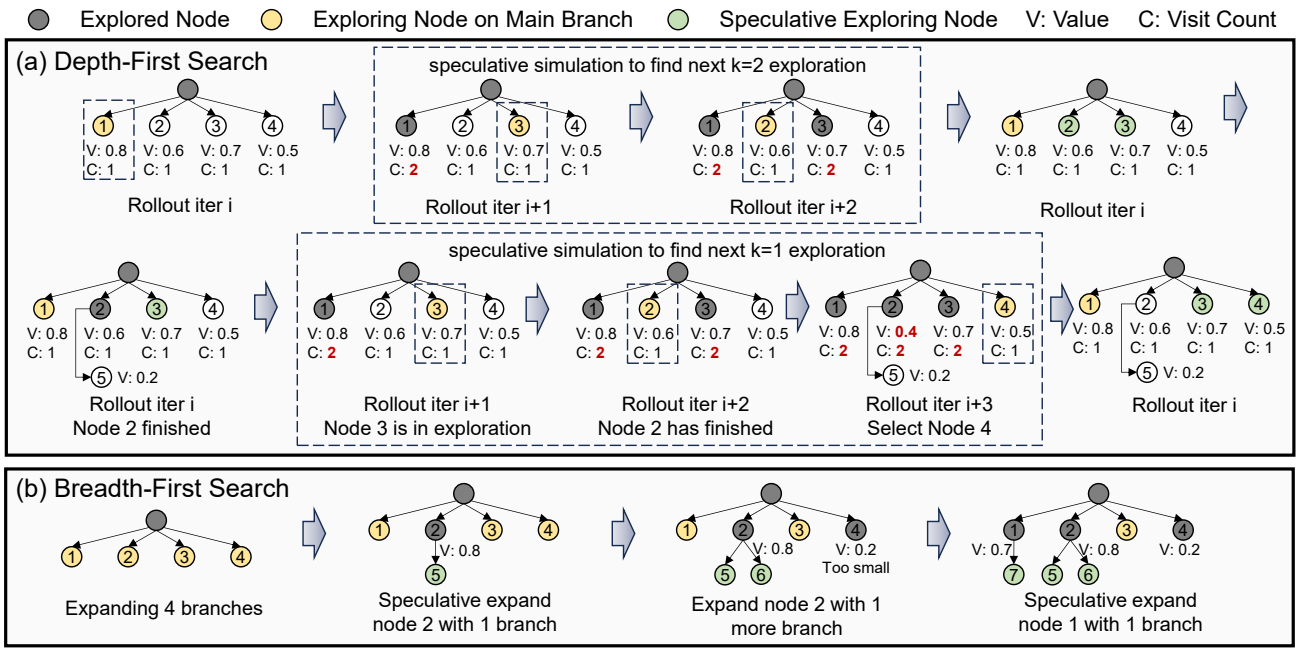

Figure 9: SPEX for (a) DFS and (b) BFS. (a) SPEX simulates the next k iterations, updating visit counts (C) and values (V) after each simulated choice, and skipping nodes already under or completed in speculation. (b) SPEX allocates speculative branches via softmax over reward scores, prioritizing high-value nodes to improve reuse and reduce stragglers.

quent predictions are conditioned on prior choices. It does not assume rewards are identical along a path; it relies on short-horizon stability of node value estimates. If the selected node is already under speculative expansion, it is skipped. If speculation for that node has been completed, the stored speculative reward is incorporated into the UCB update to refine the accuracy of future forecasts. This process focuses speculative computation on unoccupied, high-likelihood branches while reusing prior results to improve prediction accuracy.

Algorithm 1 presents the speculative selection procedure, and Figure 9(a) illustrates its execution. SPEX predicts the next UCB-based choices, skips nodes already under speculation, and integrates completed speculative results into value updates. As a result, the system keeps producers busy with reusable work while minimizing redundant expansions.

2) Speculation for Breadth-First Search. In BFS, speculative exploration targets the inefficiency caused by the long-tail variance in decoding lengths. Since shorter branches finish significantly earlier than the longest ones, they create valuable idle slots at the reward barrier. SPEX leverages this opportunity by proactively expanding these completed short nodes while the system waits for the stragglers.

As illustrated in Figure 9(b), the speculative budget matches the count of completed nodes. To distribute this budget, SPEX applies the expansion policy of the underlying BFS algorithm to these finished nodes. For instance, with REBASE, SPEX employs its reward-based softmax to determine the expansion width. By strictly adhering to this baseline policy, SPEX allocates more speculative children to higher-scoring nodes (e.g., node 2). This consistency ensures that speculative choices mirror the algorithm's intended search path, thereby maximizing prediction accuracy.

Algorithm 1 Speculation for ToT-DFS.

Input: Search tree *tree*, number of speculative branches k
Output: Ordered list of speculative nodes to expand

```
selected_nodes ← [ ]
for t ← 1 to k do
    node ← SimulateNext(tree)
    while node ∈ active_expansions or node ∈ completed_speculations do
        if node ∈ completed_speculations then
            UpdateUCBWithReward(node.reward)
        end if
        node ← SimulateNext(tree)
    end while
    selected_nodes.append(node)
    IncrementVisitCount(node)
    UpdateUCB(tree)
end for
return selected_nodes
```

Mis-speculation Handling. SPEX adopts distinct strategies for handling mis-speculation. For DFS, SPEX operates without explicit detection mechanisms. Since DFS explores paths iteratively, a prediction not selected in the current round

remains a valid candidate for future rollouts. In contrast, for BFS, SPEX implements strict verification. It detects misspeculation by cross-referencing predicted nodes with the actual expansion frontier. If a speculated node is not selected by the current frontier, SPEX immediately terminates the corresponding branch to prevent resource wastage.

4.3 Inter-query Budget Allocation

In multi-query serving, SPEX allocates speculative execution across queries to maximize overall throughput while respecting hardware limits and each query's parallel capacity.

We first determine the global speculative budget k_{total} using a roofline analysis. Achievable throughput is bounded by the intersection of the compute and memory ceilings; the corresponding batch concurrency is taken as k_{total}. This ensures that speculation moves execution toward the compute-bound regime without oversaturating on-chip memory bandwidth or degrading arithmetic intensity.

The acceleration of speculation arises from two primary forms of reuse: (i) *parameter reuse*, where speculative branches amortize model parameters with the primary branch, and (ii) *KV cache reuse*, where branches sharing long prefixes with the primary path reuse KV states in attention computation. Live nodes keep their prefix KV states in the serving cache when resident; a speculative child only needs to generate KV states after its fork point. Let S_w denote the model parameter size, and $S_{KV}(q)$ the amount of KV state in query q that can be reused by its speculative branches.

For each query q, we estimate its speculative utility as

$$score_q = C_q \times P_q \times (S_w + S_{KV}(q)), \tag{1}$$

where C_q is the exploitable parallel capacity within the query and P_q is the predicted hit rate of speculative branches. Concretely, C_q is the number of eligible speculative branches that query q can issue without duplicating active work.

The allocation of the global budget follows a softmax weighting over these scores:

$$k_q = \min\left(C_q,\ \left\lfloor k_{total} \cdot \frac{e^{\tau score_q}}{\sum_{q'} e^{\tau score_{q'}}} \right\rfloor\right), \tag{2}$$

where τ controls allocation sharpness. This strategy assigns more speculative capacity to queries with higher expected benefit while avoiding overspeculation beyond each query's intrinsic parallelism.

4.4 Early Termination for Skewed Trees

In highly skewed trees, SPEX faces significant challenges in achieving acceleration due to the disproportionate computational cost of exploring deep branches. However, as noted in Insight 3, most answers are generated at shallower depths, where the correctness rate is higher. This suggests that exhaustive exploration of deep branches is often unnecessary, especially when reliable solutions can already be inferred from earlier exploration stages.

To address this, we propose an *adaptive early termination strategy* that halts exploration once sufficient evidence has been gathered to confidently determine a result. This termination applies to the actual ToT search, not only to speculative branches. Specifically, during exploration, SPEX monitors the total number of generated answers n and the confidence scores of the top two hypotheses. The confidence scores are defined as:

$$\text{conf}_{1\text{st}} = \sum_{i \in 1\text{st}} w_i, \quad \text{conf}_{2\text{nd}} = \sum_{i \in 2\text{nd}} w_i, \tag{3}$$

where $\text{conf}_{1\text{st}}$ and $\text{conf}_{2\text{nd}}$ represent the total rewards belonging to the top 1 and top 2 answers, respectively.

Exploration terminates early if it satisfies the condition:

$$n \geq t \quad \text{and} \quad \text{conf}_{1\text{st}} - \text{conf}_{2\text{nd}} > \alpha \cdot \text{avg}(\text{w}_{2\text{nd}}), \tag{4}$$

where t is the minimum number of answers required, α is a scaling factor controlling the margin of confidence, and $\text{avg}(\text{w}_{2\text{nd}})$ is the average weight of answers belonging to the second-best hypothesis. In the experiments, α is set to 0.5. This ensures that exploration avoids unnecessary computation in deep branches when high-confidence solutions can already be determined from shallower exploration. Thus, any potential accuracy tradeoff stems from pruning these deep branches before full exploration.

4.5 General Producer–Consumer Framework

To unify speculative exploration across different ToT algorithms, we design SPEX as *a general producer–consumer execution framework*. It decouples branch expansion (producer role) from control logic (consumer role), enabling concurrent processing of both primary and speculative branches while dynamically adapting to system conditions.

Specifically, multiple producers execute explorations in parallel. A producer may be assigned to (i) a node along the *primary branch*—the branch that the underlying search algorithm $\mathcal{A}$ is currently committed to exploring—or (ii) a node from *speculative branches* predicted to have high utility. The centralized consumer loop monitors the completion of these expansions through a shared completion queue.

When a completed node belongs to the primary branch, the consumer immediately appends it to the search tree and triggers the next expansion step dictated by $\mathcal{A}$. Simultaneously, the consumer evaluates whether idle producers can be utilized for additional speculative expansions, thereby overlapping useful computation with reward model latency. The scheduler also favors speculative nodes with reusable prefixes, reducing extra KV-cache footprint. If the completed node originates from a speculative branch, it is appended to the speculative subtree. The system again inspects available resources and,

Algorithm 2 SPEX Producer-Consumer Framework

Input: Initial state s_0, search algorithm type $\mathcal{A}$
Output: Final state s_n

```
tree ← Tree structure with root s_0
request_queue, completion_queue ← []
Launch multiple ProducerWorker() instances
request_queue.put(s_0)
while search is not complete do
    (node, child) ← await completion_queue
    if tree.is_on_primary_branch (node, A) then
        tree.add_node(child)
        tree.expand(A)
    else
        tree.add_spec_node(child)
    end if
    while has_idle_producers() do
        spec_node ← tree.select_spec()
        request_queue.put(spec_node)
    end while
end while
Return tree.s_n

procedure ProducerWorker
    while not Terminate do
        node ← await request_queue
        new_child ← expand_node(node)
        completion_queue.put(node, new_child)
    end while
end procedure
```

if capacity permits, issues further speculative expansions to keep producer threads saturated.

Algorithm 2 outlines the execution flow. The design achieves three benefits. **1) Non-blocking Execution:** Primary branch progress is never stalled by speculative work. **2) Opportunistic Parallelism:** Idle resources are opportunistically exploited for parallel speculative exploration. **3) Algorithm-agnostic Unification:** The framework remains agnostic to the underlying reasoning algorithm, supporting different paradigms within a unified scheduling architecture.

5 Implementation

We implemented the **SPEX system** on top of SGLang [71], introducing several key modifications and components.

On the server side, we modified the SGLang front-end implementation. The original system was designed to handle batch requests that return results collectively. To enable finer-grained scheduling, we re-engineered the system to support asynchronous responses, allowing individual requests to return results independently.

On the application side, we utilized Python's coroutine framework to implement the coordinated operation of a **Producer-Consumer** model, which manages interactions with SGLang. All three core components of the SPEX system were implemented on the application side, ensuring seamless integration and efficient task execution.

Table 1: Configurations of evaluated algorithms. The configuration values denote the target number of generated answers.

Algorithm	Type	Configuration
REST-MCTS [68]	DFS+BFS	5, 10
RSTAR-MCTS [46]	DFS	5, 10
REBASE [60]	BFS	8, 16
ETS [23]	BFS	8, 16

6 Experimental Evaluation

6.1 Experimental Setup

Models. We evaluated SPEX across four models: Llemma-7B, Llemma-34B [1], DeepSeek-R1-Distill-Qwen-8B [20], and Qwen3-30B-A3B [53]. The Llemma suite was selected to ensure comparability with established ToT baselines, as these models are used in those evaluations [23, 60]. We employ its dedicated reward model for evaluation. Conversely, DeepSeek and Qwen were included to validate generalization to state-of-the-art models, where we derived reward signals directly from intrinsic log probabilities to serve as confidence proxies [18].

Hardware. We conducted experiments across different hardware setups to evaluate SPEX's performance under various scenarios. Specifically, we tested Llemma-7B and Deepseek-8B on NVIDIA A6000 GPUs, while Llemma-34B and Qwen3-30B-A3B were evaluated on NVIDIA A100 GPUs. These setups allowed us to analyze and compare performance across diverse compute environments.

Datasets. To ensure a fair comparison, we matched the dataset difficulty to the capabilities of each model. For the Llemma family, we utilized GSM8K [14] and MATH-500 [21, 34] following the experiment setup of REBASE and ETS, as more extreme challenges like AIME remain intractable for Llemma even with ToT. In contrast, for the state-of-the-art models (DeepSeek and Qwen), simpler tasks like MATH-500 can be easily solved without search. Therefore, we utilized high-difficulty benchmarks, including AIME 2024 [39], AIME 2025 [40], BRUMO [4], and HMMT-Feb25 [22] to demonstrate the performance of our framework.

Algorithms. As listed in Table 1, we evaluated SPEX on four representative ToT algorithms: REST-MCTS, RSTAR-MCTS, REBASE and ETS. Each algorithm was tested under two configurations, which represent the number of answers to generate; specifically, this corresponds to the rollout count for DFS methods and the initial search width for BFS methods. Here batch size denotes concurrent ToT queries, not individual

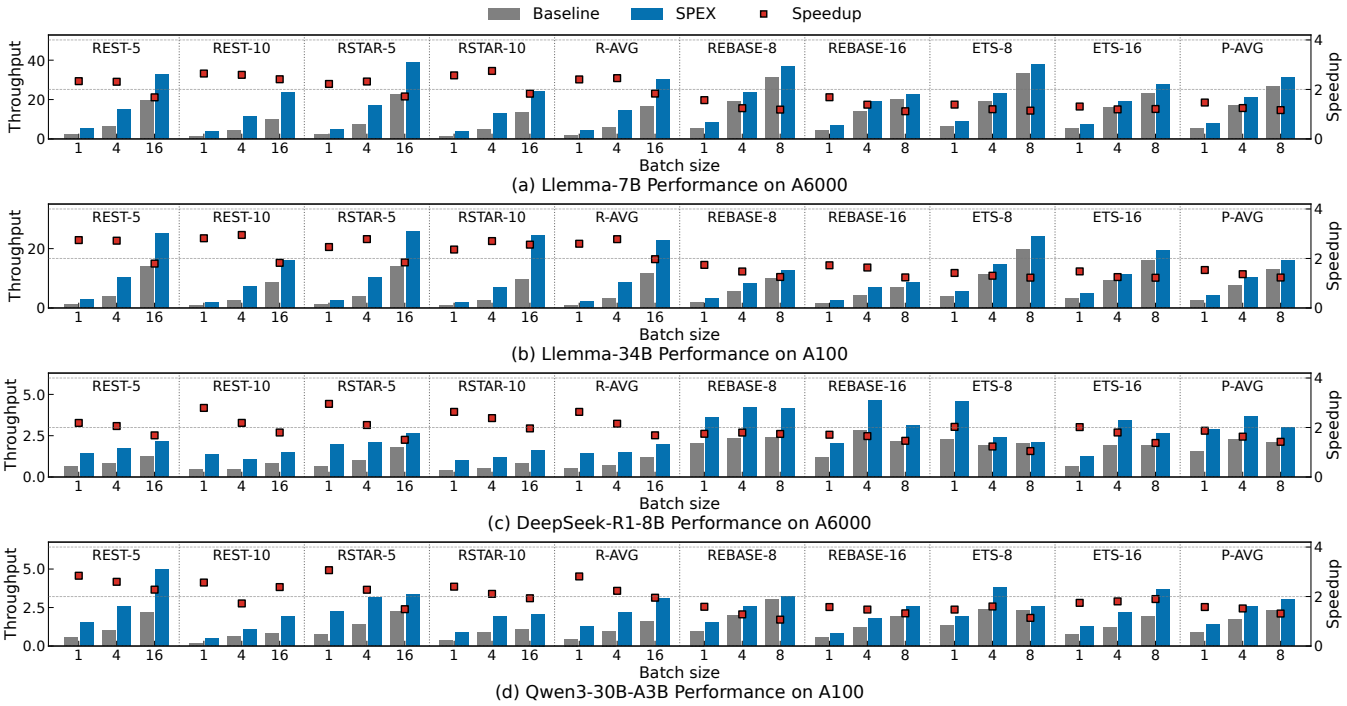

Figure 10: The speedup and throughput (finished questions per minute) for different ToT reasoning tasks.

branch-generation requests. For example, one REBASE-16 query already contains 16 requests, so BS=8 can expose up to 128 such requests before SPEX adds speculative branches.

6.2 End-to-End Performance

Figure 10 presents the throughput and speedup of SPEX compared to baseline across various algorithms, configurations, and batch sizes. The results demonstrate consistent performance improvements with SPEX under diverse settings. SPEX targets query throughput; extra speculative branches may slightly increase per-token latency, as analyzed in § 6.6.

On average, SPEX achieves a speedup of 1.8–3× for DFS and 1.2–1.9× for BFS. The greater acceleration for DFS stems from their inherently limited branch-level parallelism, where SPEX introduces more opportunities for optimization. In contrast, algorithms without DFS like REBASE already exhibit significant parallelism, leaving less room for further improvement. Among DFS algorithms, REST-MCTS achieves slightly higher speedup compared to RSTAR-MCTS, as the BFS creates more opportunities for SPEX optimization.

Impact of Batch Size: The speedup is particularly notable at smaller batch sizes. These batch sizes should be interpreted at the ToT-query level, not as the number of individual decoding sequences. For DFS algorithms, SPEX can achieve up to 3× acceleration at small batch sizes, and for BFS-only algorithms, the speedup reaches up to 1.7×. As the batch size increases, the system transitions from being memory-bound to compute-bound, reducing SPEX's relative benefits.

Impact of Configuration: DFS algorithms demonstrate higher speedup when generating more answers, as this increases the number of potential nodes. Conversely, for BFS-only algorithms, generating more answers results in lower speedup. This is because algorithms like REBASE expand branches proportional to the required answers, transitioning to a compute-bound regime.

6.3 Accuracy Evaluation

We report pass@1 accuracy and keep the same decoding settings, including sampling temperature, top-p, and token limits, for all methods. Table 2 demonstrates the accuracy evaluation across pure CoT, the ToT baseline, and SPEX. The results show that stepwise ToT provides a clear accuracy lift over pure CoT, and SPEX preserves this lift while improving throughput. The results indicate that early termination introduced by SPEX does not negatively impact accuracy. Any accuracy difference mainly comes from early termination changing the explored search space. For most configurations, SPEX can achieve slightly higher accuracy than the ToT baseline. This gain stems from our adaptive early termination technique. Deep, skewed branches tend to exhibit lower correctness. By terminating these branches early upon reaching high confidence, SPEX prevents low-quality tails from skewing the

Table 2: Accuracy evaluation.

majority vote.

6.4 Ablation Study

To evaluate the contribution of each key technique in SPEX, we conducted an ablation study as shown in Figure 11. Three techniques were analyzed: T1 (Intra-query Speculative Selection), T2 (Inter-query Budget Allocation), and T3 (Early Termination).

T1 demonstrates significant speedup by allowing speculative execution within queries to exploit parallelism, especially for smaller batch sizes. T2 becomes increasingly critical as batch size grows, ensuring efficient allocation of computational resources when the system transitions from memory-bound to compute-bound. T3 provides a stable speedup of around 1.2× across all configurations by identifying and terminating low-potential branches early.

The combination of all three techniques yields the highest overall performance, with notable improvements in both small-batch and large-batch scenarios.

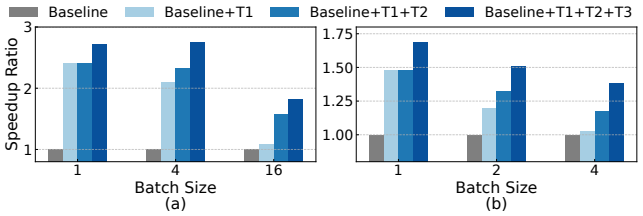

Figure 11: Ablation study of three techniques in SPEX for (a) RSTAR-10 and (b) REBASE-16. T1 represents Intra-query Speculative Selection, T2 represents Inter-query Budget Allocation and T3 represents Early Termination.

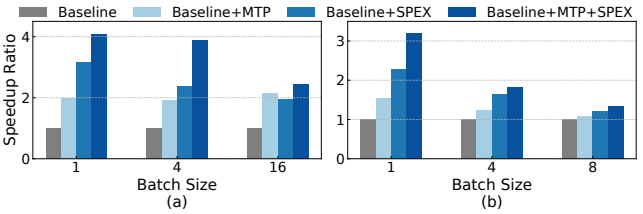

Figure 12: Orthogonality analysis of SPEX and MTP for (a) RSTAR-10 and (b) REBASE-8.

6.5 Compatibility with Speculative Decoding

To demonstrate that SPEX is orthogonal to token-level optimizations, we integrated it with the Multi-Token Prediction (MTP) module of DeepSeek-R1-8B. Since the performance of speculative decoding is highly sensitive to the token tree, we empirically tuned the token tree size based on the batch size. For RSTAR-10, which inherently has a smaller effective batch size due to sequential dependency, we maintained a token tree size of 16 across all settings. For REBASE-8, we adopted an adaptive configuration: a tree size of 16 for batch size (BS) 1, scaled down to 8 for BS=4, and 4 for BS=8, to mitigate compute contention.

Figure 12 illustrates the speedup breakdown. The results confirm that SPEX and MTP target distinct bottlenecks and can be effectively composed. The combination (**Baseline+MTP+SPEX**) consistently yields the highest throughput. Notably, for RSTAR-10 at BS=1, combining SPEX with MTP boosts the speedup from $\sim 2.0\times$ (MTP only) and $\sim 3.1\times$ (SPEX only) to a remarkably $\sim 4.1\times$. As the batch size increases, the system transitions from memory-bound to compute-bound. Consequently, the marginal gain from MTP diminishes. However, SPEX maintains robust acceleration even when token-level speculation saturates.

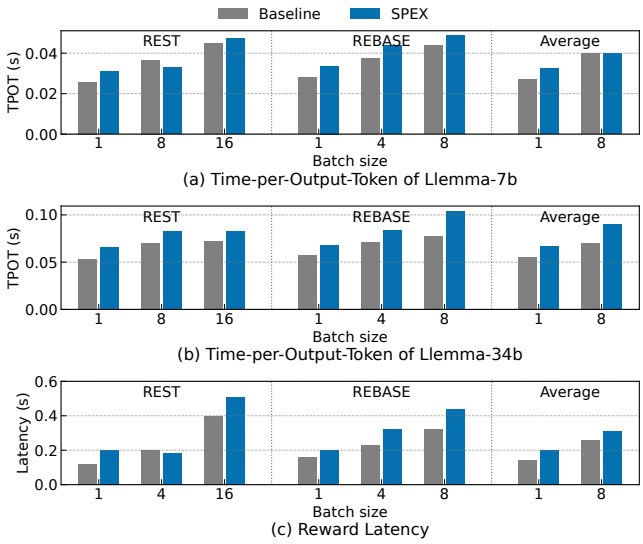

Figure 13: Overhead analysis of SPEX.

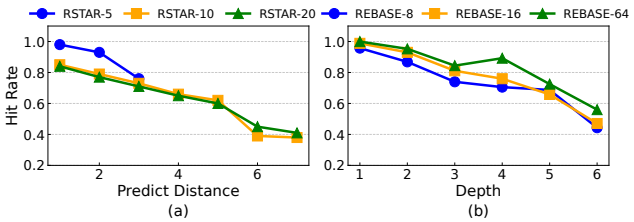

Figure 14: Prediction accuracy evaluation. (a) Hit rate of RSTAR-MCTS for predicting rollouts across different distances. (b) Hit rate of REBASE at varying depths.

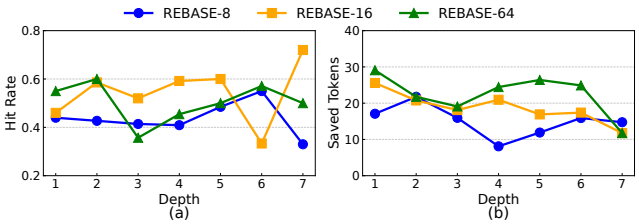

Figure 15: (a) Probability of speculative explorations reaching the critical path for REBASE configurations. (b) Tokens already generated speculatively before the critical path reaches.

6.6 Overhead analysis

As SPEX increases the number of parallel branches within each query, it introduces additional overhead that affects both the reasoning model's Time-per-Output-Token (TPOT) and the reward model's evaluation latency, particularly when the system approaches a compute-bound regime. Figure 13 illustrates these effects.

For the reasoning model's output speed, while SPEX raises the risk of pushing the system into an over-compute-bound state, the observed overhead remains controlled within 15%. This indicates that SPEX effectively balances the trade-off between batch size scaling and computational efficiency.

For the reward model's evaluation latency, the impact of SPEX is minimal. The average delay introduced by SPEX is less than 0.1 seconds, which is negligible compared to the reasoning model's overall processing time. This demonstrates that SPEX's design introduces only minor latency overhead for reward evaluation, ensuring it does not become a bottleneck in the reasoning pipeline.

6.7 Prediction Accuracy

Figure 14 evaluates the prediction accuracy of SPEX. In (a), the hit rate of RSTAR-MCTS decreases as the prediction distance increases, illustrating the challenge of maintaining accuracy in DFS algorithms when predicting further rollouts. In (b), the hit rate of REBASE decreases with increasing depth, as shallow layers contain more low-scoring nodes that are easier to identify, while deeper layers consist of nodes with closer scores, making differentiation more difficult. Therefore, we prefer to allocate SPEX resources evenly for DFS algorithms and prioritize shallow layers for BFS algorithms.

For DFS algorithms, prediction accuracy directly translates into speedup. However, for BFS-only algorithms like REBASE, only speculative expansions along the critical path lead to acceleration. As shown in Figure 15(a), the probability of speculative expansions reaching the critical path ranges from 40% to 60% across different depths. In Figure 15(b), the average number of tokens pre-generated before the critical path reaches them is approximately 20 per depth, highlighting the importance of accurate targeting for efficient performance.

7 Related Work

We categorize related work into three lines and position SPEX with respect to each.

Speculative Decoding. Speculative decoding is an effective method for accelerating memory-bound LLM inference. It uses a smaller draft model to predict future tokens, which are then verified by the main model [6, 28, 61]. Recent advancements have extended this technique to accelerate reasoning models [33, 44, 49, 63]. These techniques operate along a *single linear trajectory*, speculating on the next-token sequence of one reasoning path. In contrast, SPEX speculates over the *tree structure* of reasoning, predicting which branches will be needed before reward feedback is available. As we show in our evaluation, tree-level speculative exploration in SPEX is complementary to token-level speculative decoding and can be composed with it to yield cumulative speedups.

Speculative Tree Search and Speculative Execution. Speculation has also been applied to MCTS and other search procedures. Prior work on speculative MCTS [12, 25] targets AlphaZero-style game search, where the bottleneck is the cost of reward evaluation. These systems speculate on future rollouts to amortize network computation, assuming a compute-bound regime and relatively cheap tree traversal. Our setting is fundamentally different: ToT reasoning with LLMs is predominantly memory-bandwidth-bound due to autoregressive decoding and KV-cache access. SPEX is designed specifically for this regime: it breaks the reward dependency barrier for both Depth-First and Breadth-First Search, incorporates KV-cache reuse and parameter reuse into its scheduling decisions, and coordinates speculation across concurrent queries. More broadly, hardware-level speculative execution mechanisms (e.g., branch prediction, value prediction, and speculation for FSM parallelization [48]) motivate using prediction to unlock latent parallelism; SPEX instantiates this principle at the ToT algorithm and system level for LLM reasoning workloads.

Efficient Reasoning Algorithms. To improve reasoning efficiency, various algorithmic approaches focus on reducing the number of generated tokens. These methods include early exit [10, 17, 32, 67], CoT compression [7, 9, 24, 35, 57, 70], and adaptive reasoning [36–38, 45, 54, 58], which dynamically shorten or adjust reasoning paths based on task complexity or model confidence. These methods primarily optimize the *amount* of test-time compute. SPEX is orthogonal: given a target ToT algorithm and its compute budget, we focus on *how* to schedule and speculate over tree expansions to break the reward dependency barrier and improve hardware efficiency without changing the underlying reasoning algorithm.

8 Conclusion

We propose SPEX, a speculative exploration framework that breaks the reward dependency barrier in Tree-of-Thought reasoning. By introducing intra-query speculative branch selection, inter-query budget allocation, and adaptive early termination, SPEX significantly enhances parallelism and reduces latency. Comprehensive evaluations demonstrate up to 3× speedup for DFS and 1.7× speedup for BFS, all while preserving accuracy. SPEX provides an effective and scalable solution for optimizing ToT reasoning, bridging the gap between algorithmic innovation and system-level performance.

Abstract

Many developers and systems today rely on opaque software components. When executing, these components affect each other and the broader environment in which they execute. Some of these effects are expected and desired; others not so. This paper introduces semisolates, an abstraction and corresponding subsystem for controlling and manipulating the effects of opaque components. Available as an unprivileged, higher-order, language-agnostic command, `try` interposes on a component's execution to automatically capture and control its effects. Effect control includes introspection, optional application, effect stacking, and further manipulation—all driven by several real-world case studies. Today `try` is used in research and production applications across several organizations, mediating potentially undesired effects, maintaining full compatibility with real-world components, and incurring a modest performance overhead well within each case's acceptable levels.

1 Introduction

Modern software systems contain many intercommunicating components, including various subsystems, programs, commands, and packages [11, 44, 45, 93]. These components are often available in diverse programming languages, interact opaquely with the broader environment, and are developed by developers of varying skill and care. Even quick-and-dirty data-processing scripts pull together many polyglot components [44, 71] and simple update scripts or AI agents invoke other commands to complete their jobs [45, 93].

Unfortunately, the execution of these components—during *e.g.*, exploration or development—results in unpredictable and often-irreversible effects. These effects are a direct and necessary byproduct of the computation encoded by a component: executing `npm install` downloads and installs new software packages, directly altering several files and directories [1]. At times, effects are unintentional: naively running a `find -exec` as suggested by an LLM may result in deleting critical user files [52]. These and other cases (§2) hint at the necessity to control these effects during component execution.

Figure 1: Applying `try`. Execute a command in its own `try` semisolate to control its effects: inspect, selectively apply, revert, partially hide (all shown) or otherwise manipulate them—all within the *current* environment rather than a new isolated container.

This paper presents a new abstraction, the *semisolate* (§3), and corresponding implementation, `try` (§4), for controlling the effects of such opaque components. Semisolates offer the ability to execute a component in the current environment via an unprivileged, language-agnostic, higher-order command that allows its users to inspect and manipulate a completely unmodified component's externally observable behavior. But rather than focusing on the behavior encoded in standard streams, easily controllable by the usual pipe-and-filter patterns, `try` focuses on *side* effects such as filesystem modifications. And contrary to various forms of containment and virtualization [10, 54, 68], which create a new environment that fully isolates all effects, `try` allows the executing components to access the current environment in which they execute and enables effect manipulation directly in that environment; the term *semisolate* (from *semi-*, meaning "partially," and *isolate*) reflects this partial rather than complete isolation.

More specifically, `try` allows introspecting, selectively applying, stacking, and further manipulating a component's effects to the filesystem and the broader environment. To automatically capture these effects, `try` limits the component's view of the filesystem: it first sets up a *semisolate* to create a view of the filesystem and environment that retains partial isolation; it then executes the component inside the semisolate, collecting effects into a writable temporary directory; finally, either during its (streaming) execution or upon completion, the semisolate allows manipulating the collected effects by

*Equal contribution.

staging them, reverting them or applying them to the underlying filesystem—either wholly or partially (Fig. 1).

This opaque effect control is applicable broadly (§2): it can be used to inspect the effects of risky or cryptic LLM suggestions before applying them [26]; track the dependency graph for systems composed of opaque components, useful for parallelization or reordering [65]; provide a `--dry-run` capability, found today in some commands, that is general and command-agnostic [89]; and support specification inference for opaque components [45]. These and other examples drive `try`'s design requirements: effect control that allows hiding state, stacking effects, and partially or fully applying or rolling them back. No current abstraction and corresponding subsystem offers granular effect control with `try`'s wealth of features.

Applying `try` to real-world cases (§5) indicates that `try` controls all relevant component effects, maintains behavior equivalence with non-semisolated execution, and incurs a modest performance overhead relative to the needs of each use case. Semisolates and `try` offer a distinct set of features from, and better performance than, container systems such as Docker, OrbStack, and Podman [54], built using similar components arranged quite differently.

In summary, this paper makes several contributions: it

- identifies the shared needs of several case studies for which today's effect control is insufficient (§2);
- presents a novel effect-control abstraction, a semisolate, that meets the needs of these case studies (§3);
- describes the implementation of `try`, a new effect-control subsystem built for Linux environments (§4);
- characterizes `try` by applying it to several real-world components drawn from the earlier case studies (§5).

It also discusses `try`'s limitations and the experiences of organizations using `try` (§6), as well as prior related work (§7). Appendix A contains all LLM prompts used in the evaluation, Appendix B collects several testimonials on `try`'s potential impact, and Appendix C describes the artifact accompanying this paper. The `try` subsystem is open-source, MIT-licensed software, publicly available on GitHub [92].

2 Examples and Goals

To understand the need for controlling component effects, this section describes several real-world case studies (§2.1). Combined, these case studies highlight several shared requirements for the design of a flexible effect-control abstraction and corresponding subsystem (§2.2).

2.1 Motivating Examples

Risky or cryptic LLM suggestions: Recent agentic systems have incorporated large language models (LLMs), allowing them to act on behalf of the developer by executing arbitrary commands inside the host system [2, 3, 7]. Consider using an LLM to generate a script that "cleans up its containing directory"; it generates `delete.sh` containing the following:

```
rm -fr "$(cd "${0%/*}" && echo $PWD)"/*
```

Unfortunately, when called from some paths, the runtime expansion `${0%/*}` will expand to the script's path, `cd` will fail, and `rm` will delete everything user-writable. Prefixing this line with `try` indicates the deletion of all user-writable directories and offers the option to discard these changes.

```
try sh delete.sh
  /home (deleted)
  /etc (deleted)
  ...
  Apply these changes? [y/i/N]
```

A developer or system calling `try` can decide whether to inspect these changes and choose to discard them, or inspect them individually and choose which ones to apply.

Dependency tracking: Speculative execution reordering offers significant speedups [65], but ensuring it respects read-after-write dependencies across opaque components is particularly challenging. Consider the following program that compiles three and links two `C` files:

```
gcc -c a.c -o a.o; gcc b.c -o a
gcc -c c.c -o c.o; gcc a.o c.o -o b
```

The second call to `gcc` does not depend on the first, thus it can be executed in parallel. Unfortunately, detecting this opportunity automatically at runtime requires detecting effects and postponing their application to the broader environment until they are confirmed to not violate read-after-write dependencies—at times discarding these effects to effectively roll back command misspeculation. Crucially, subsequent invocations must start their execution with the illusion that prior effects have been applied—necessitating chaining reversible effect application across component invocations.

Prefixing `gcc` with `try` while explicitly asking it to stack sets of effects solves both problems:

```
try -t trace1.log -N env1 gcc -c c.c -o c.o
try -t trace2.log -N env2 -L env1 gcc a.o c.o -o b
```

The `-N` option instructs `try` to store, instead of directly applying, `gcc`'s effects for later use with a configurable name. The `-t` flag enables system-call tracing to capture ordered filesystem effects. Next, `-L` injects `gcc`'s uncommitted effects from `env1` into its own view, making `c.o` visible to `try`'s second invocation.

Third-party library risks: Public third-party libraries amplify developer capabilities, but risk introducing undesired effects [15, 56, 63]. Consider the popular `node-ipc` library [72], invoked as part of a larger codebase:

```
npm test node-ipc
```

Earlier versions of `node-ipc` included undesired effects modifying critical system files [18, 86]. Prefixing `npm test` with `try` highlights files about to be modified without making any modifications prior to approval:

```
try npm test node-ipc
  /etc/passwd (modified)
  /bin/bash (modified)
  /sbin/init (modified)
  ...
  Commit these changes? [y/i/N]
```

The output of `try` shows all such effects, allowing a developer to review any unexpected effects and, if necessary, selectively apply only the relevant ones. It is also possible to filter or aggregate over the set of effects to make review easier (§6).

Dry-run execution: Some commands offer specially configured dry-run modes (e.g., `--dry-run`, `--fake`, `--no-commit`, `--print`, `--just-print`, `--simulate`, `-n`, `-s`) that show the effects of simulating a command's execution [67]. Consider an invocation about to clean temporary files in the current directory using `find`:

```
find . -name '*tmp*' -delete
```

Unfortunately, `find` does not offer a built-in dry-run functionality. Prefixing the command with `try -n` instead executes the command in a semisolate, collecting and presenting its actual effects to the user while discarding them.

```
try -n find . -name '*tmp*' -delete
  ./tmp_build/ (deleted)
  ./tmp.log (deleted)
```

Using `try`, a user sees the concrete effects that the command's execution would have produced, even if it does not implement built-in dry-run functionality.

Partial-specification mining: Automated acceleration of programs that use opaque components [38, 71] depends on partial component specifications—*e.g.*, the order in which a component reads its input streams [34]. Generating such specifications automatically requires exploring a command's invocation space while carefully collecting the effects of different invocations. Consider the following invocation of `grep`:

```
grep -oE [a-zA-Z]+ one.txt two.txt
```

Unfortunately, understanding that `grep` first reads `one.txt` and *then* reads `two.txt` requires a more detailed view of its effects. Prefixing `grep` with `try -t` offers a detailed, ordered log of `grep`'s read and write effects:

```
try -t trace.log grep -oE [a-zA-Z]+ one.txt two.txt
```

The resulting `trace.log` file contains information that can then be compiled into a partial specification for `grep`.

```
r /usr/bin/grep
r /usr/lib/libc.so.6
r one.txt
r two.txt
w stdout
```

This order of effects extracted by `try -t` reveals invariants (*e.g.*, `one.txt` preceding `two.txt`) that need to be maintained when optimizing programs that invoke `grep`.

2.2 Desiderata for the Missing Abstraction

The aforementioned case studies illustrate an underlying common need to abstract away effect control. A suitable effect-control abstraction has several core requirements: (1, **I**) *effect introspection*, *i.e.*, the ability to detect, collect, present, and inspect a component's side effects in the same environment directly executing the component; (2, **A**) *selective application*, *i.e.*, the ability to decide whether to apply effects to the broader environment or roll them back; (3, **S**) *effect stacking*, allowing commands to execute in the context of earlier effects that have not been applied yet, potentially rolling back multiple stacks of effects; (4, **M**) *further effect manipulation* beyond direct application or discard, including partial application of only some effects, effect recording and delayed propagation, and selective hiding of the underlying environment. These requirements typically need to be met in the context of the current executing environment—*not* a virtualized or contained environment fully isolated from the current environment.

Apart from these core requirements, the abstraction's applicability and reach would further benefit from an implementation that combines streaming support, allowing its users to manipulate the effects of long-running components as they are generated; configurable effect handlers for tuning the granularity of effects; and runtime performance overheads that do not affect interactive use. These features are not essential to the core abstraction—*i.e.*, a batch-only, non-configurable, slow implementation would still fit all of §2.1's case studies—but they broaden its applicability and reach.

Other characteristics such as complete mediation against arbitrary adversarial behavior are out of scope: the abstraction aims at the inconvenient or undesired effects of everyday mistakes or accidents—not actively malicious, `try`-aware components trying to bypass its underlying mechanisms [49].

3 Abstracting Away Effect Control

To meet the aforementioned desiderata (§2.2) and abstract away effect control, `try` offers a language-agnostic and configurable abstraction that launches one or more components in a semisolate. A semisolate offers a constrained and configurable (Tab. 1) private view of the real host environment—*i.e.*, not a fresh environment in a container or virtual machine. In the example below, `sh` runs in the exact same environment as

Table 1: Control configuration and `try` flags. Controlling effects with `try` supports significant configurability during semisolate creation, execution, and conclusion—including core options (in black, *Cf.*§3) and peripheral features and subsystems (faded, *Cf.*§6).

Semisolate stage	Configuration	Flag
Creation	Stack over prior effects	`-L`
	Name current effect group	`-N`
	Ignore specific paths	`-i`
Execution	Disable the network	`-x`
	Create filesystem trace	`-t`
	Collect effect delta	`--diff`
Conclusion	Apply all effects	`-y`
	Discard all effects	`-n`
	Inspect effects	`-e`
	Include, exclude specific paths	`-I`, `-E`
	Summarize effects	`-s`
	Offer friendlier summary	`-h`

`curl`, but within a private view that controls, manipulates, and potentially discards the application of effects to the broader environment:

```
curl -sL https://sh.rustup.rs | try sh
```

This private view can be configured to, for example, completely mirror the global filesystem, partially mirror it while hiding subtrees, or correspond to one or more layers of as-yet-unapplied effects from previous `try` executions.

Semisolates: The abstraction of a semisolate provides the illusion of direct access to its outer environment and supports flexible effect manipulation. Semisolates collect the effects of opaque components in this private view and expose them to their callers for further manipulation. Using semisolates, `try` allows its callers to (1) selectively apply or discard these effects, with options to view partial earlier state; (2) collect the effects for possible application later; and (3) stack and expose as-yet-unapplied effects across invocations. This design allows the effect-mediated component to execute in partial isolation, without affecting the global filesystem until the caller explicitly consents.

To achieve effect control, a semisolate operates in three configurable stages: (1) *creation*: the semisolate sets up the appropriate view for the executing component to ensure appropriate effect mediation; (2) *execution*: the semisolate launches the target component within a private view, collecting relevant effects; and (3) *conclusion*: the semisolate optionally and selectively applies recorded effects into the main environment.

All three stages typically operate on the current directory and are highly configurable to support the nuances of various real-world uses (§2). The next few paragraphs detail such tuning, both at the level of individual stages and the current `try` flags summarized in Tab. 1, after first establishing which effects are controllable and their level of control.

Which effects are controllable: Unix and its descendants offer many well-studied, fine-grained tools for the pipe-and-filter abstractions—for program *output*. There are only coarser, less well-studied tools to help manage program *effects*. Analogizing the Unix environment to a single executable, existing abstractions focus on function inputs and outputs (Unix: standard streams, exit status), but not the heap (Unix: the filesystem). Semisolates offer a new, fine-grained tool for effect management. They add abstractions for manipulating effects around a child command—for example, the initial filesystem view, the final filesystem view, and the filesystem access trace. They can optionally be configured to support additional system, network, and stream effects as part of a unified abstraction.

Effects are made available to the semisolate caller as a combination of (1) filesystem paths or stream identifiers, and (2) optional metadata such as effect type and success. Each path can be a valid path pointing to an existing file or directory; it can also be a *non*-existent path that might lead to access failure—still useful when a command relies on a file's absence to exhibit the intended behavior. The effect type includes information such as read-only, write-only, and read-write: a read-write effect is, for example, `open`ing a file with any flag other than `O_RDONLY`; a read-only effect includes operations that only interrogate a file's metadata through, for example, `stat`ing a file; a write effect includes modifying filesystem metadata through, for example, `chmod`ing or `unlink`ing a file. Each recorded effect instance is accompanied by metadata that indicates whether an effect succeeded; or—if it failed—the reason for its failure.

By default, `try` manipulates effects across entire process subtrees. For example, if a `try`-controlled process launches a subprocess that writes to the filesystem, then `try` will include those write effects in the group of effects directly available for manipulation. A parent process can also use `try` to wrap and programmatically control child effects.

Semisolate creation: Upon creation, a semisolate configures the private view of the executing component—to allow both stacking the effects of different semisolates and prevent unintended effects (including reads), useful for hiding sensitive information from the executing component. Configuring this initial view translates to setting up a virtual-filesystem environment before any modifications to the filesystem.

Upon creation, semisolates may configure effect stacking and hiding. Stacking configures the component's initial view to import the effects produced from a previous semisolate. Selective hiding masks certain parts of the underlying filesystem from the executing component, given a specification that describes a filesystem subtree. These are implemented by `try`'s interface as `-L`, which accepts the name of a previous semisolate, itself produced by a previous call to `try` with the `-N` flag; and `-i`, which takes as input a regular expression that matches filesystem paths to be hidden from the component's view. The latter is semantically equivalent to stacking the

effects of `try -n N rm dir1 dir2...` over `try -L N`—but `-i` is more efficient as it directly sets up exclusions without first running an additional (potentially expensive) command.

Semisolate execution: During execution, semisolates additionally configure the classes of effects to interpose on and the corresponding interposition granularity—for example, whether to include system-call tracing. The current classes of effects include filesystem effects, network effects, signals, and interprocess streams.

The current interface of `try` supports: `-t`, which makes `try` produce a filesystem access trace, containing an ordered list of effects; and `-x`, which prevents the component from accessing the network. Apart from the effect path, this detailed view consists of the mode and the return code, which can be inspected to infer negative effects like failed accesses.

Semisolate conclusion: Upon conclusion, semisolates offer the ability to decide which effects to apply and which to discard, eventually generating the final filesystem view. They allow selective effect application at multiple granularities, from binary all-or-nothing to per-effect application, while also supporting path-oriented filtering. They can also hold individual effects and allow inspecting them directly using conventional Unix abstractions.

These options can be configured when a semisolate concludes. The current interface supports inspecting individual effects (`-e`) and, based on predefined caller policies, programmatically filtering these changes (`-E` and `-I`). It also supports applying, discarding, or mixing them (`-y`, `-n`, and `-e`). And `-N` stores effects in a named effect directory, potentially used earlier during creation with `-L`.

4 The Try Subsystem

This section describes how `try` implements the aforementioned abstraction (§3) for programs executing in Linux userspace. It first outlines `try`'s use of union filesystems, namespaces, and system-call tracing before diving into the details of semisolate creation (§4.1), execution (§4.2), and conclusion (§4.3), closing with a detailed walkthrough of multiple `try` invocations put together (§4.4).

Union filesystems: To achieve effect control, `try` needs to interpose on the component's view of the filesystem. This interposition is responsible for manipulating the underlying filesystem view, creating a partially private view that allows accessing the underlying contents while capturing and containing effects. This private view is implemented as a union filesystem, configured appropriately to either mirror the underlying filesystem, partially mirror it with sensitive paths hidden, or correspond to the as-yet-uncommitted state of a previously executed run of `try`. To contain effects, `try` uses the configured union filesystem to record filesystem changes into a temporary directory—without affecting the *host environment* until effects are applied.

To instantiate the concept of effect *layers*, `try` leverages OverlayFS—a specific implementation of a union filesystem part of the Linux kernel [24]. Union filesystems are a class of filesystems that allow multiple directories to be presented as a single unified directory without modifying the underlying kernel structures [70]. A union filesystem layers an upper directory (*upperdir*) and one or more lower directories (*lowerdirs*) into a single merged view—without merging their underlying data.

In the merged view, the content at a specific path `p` is determined by searching for `p` in the upperdir, followed by all lowerdirs in order until `p` is found. The first match is presented in the merged view; if `p` exists in multiple layers, content from the higher layer takes precedence.

Changes to the merged view are forwarded to the upperdir and persist inside it, even after unmounting the union filesystem directory. Changing a file at `p` in the merged view places the new version of the file at `p` in the upperdir. Removing `p` places a *whiteout file* at the corresponding upperdir location.

Namespaces: To execute privileged actions—while executing in an unprivileged manner—and interpose on the execution context of the component, `try` leverages Linux process namespaces. Namespaces isolate resources such as the network, pseudo-filesystems like `procfs`, permissions, and signals from the rest of the system, offering (groups of) processes the illusion of exclusive ownership of those resources—enabling the creation of a private (and controllable) view of the underlying system state. For example, the PID namespace assigns new PIDs to processes inside the namespace: processes in the namespace can only see and interact with each other using the PIDs assigned in the namespace.

Process-related interactions such as signaling between processes and adjustment of scheduling priorities are contained to the namespace. Components in `try` are only partly able to interact with ambient resources and objects such as processes, users, or network devices—with `try` interposing on all accesses to the broader system.

System-call tracing: To observe the order of a component's effects, and go beyond effects that modify the filesystem, `try` leverages system-call tracing—interposing between the operating system kernel and user-space components to monitor and record their interactions. Tracing commands such as `strace` on Linux offer visibility into exact calls performed by a process, their order, and their arguments, as well as the signals received by the process. Combined, they offer a wealth of information about the process—including filesystem operations, process management, inter-process communication, and network access. By selectively enabling tracing when necessary, `try` extracts ordered, finer-grained information about component effects beyond filesystem modifications.

Algorithm 1 Semisolate creation. Key steps in setting up a new semisolate, before running a component;

Require: *path*
1: **if** *path* is not provided **then**
2: `    path ← mktemp -d`

4.1 Semisolate creation

Each semisolate uses its own special writable directory to record effects—the `upperdir`—and a second temporary directory—the `workdir`—used by the union filesystem for internal bookkeeping (Alg. 1, lines 1–5). Each of these directories can be (1) a new, appropriately prefixed temporary directory created with `mktemp`; (2) a new directory whose name is provided by the `try` caller; or (3) an existing directory, potentially used in previous `try` invocations.

OverlayFS does not support certain filesystems to host the upperdir or the `workdir`. One such filesystem is OverlayFS itself, a common scenario when using `try` within Docker. In this case, `try` mounts an additional `tmpfs` over the semisolate directory (Alg. 1, line 5). This ensures that all of `try`'s side effects prior to the conclusion stage are confined within the semisolate directory.

Setting up mounting options: To bypass OverlayFS's restriction of overlapping the lower and upper directory, `try` creates an individual union filesystem mount for each top-level directory—*e.g.*, `/bin`, `/usr`, and `/home`—instead of using the root directory `/` as the union filesystem's lower directory.

Specifically, `try` first creates directories `upperdir`, `workdir`, and `tmproot` (Alg. 1, lines 5–12). In these top-level directories, it then creates a child directory for each top-level directory in the filesystem, such as `/etc`, `/usr`, and `/home`. Additional lower directories already containing effects are added to the mount options during this step—layered on top of the corresponding union filesystem merged views. The `tmproot` directory will become the final merged view presented to the executing component (§4.2).

Once inside the new namespace, `try` iterates over the mount options constructed in the previous step and mounts the union filesystem (Alg. 1, lines 12–14). It mounts the `/proc`, `/dev`, and `/devpts` pseudo-filesystems within the `tmproot` directory and symlinks all special files through which the component interacts with its standard input and output streams—*i.e.*, `/proc/self/fd/{0,1,2}` and `/dev/{stdin,stdout,stderr,fd,pts}`. Using bind-mounts [23], it duplicates device files such as `zero`, `null`, and `random`, into the `tmproot`'s `/dev` directory.

To implement file hiding, `try` creates an additional directory called `excldir`. This `excldir` directory is mounted as an intermediate layer right above the lower directory and contains whiteout files corresponding to files that will be hidden from the merged view.

Submount permissions: Unfortunately, filesystem submounts within any OverlayFS layer cannot be unmounted by the current user: mount points inside layers are ignored because these layers correspond to overlapping filesystem fragments. Consider an initial filesystem *A* that contains paths `/x`, `/x/y`, and `/x/y/z`, and a new filesystem *B* mounted at `/x/y`, effectively hiding `/x/y/z` as contents at that mount point by *B*. If `/x` is specified as an OverlayFS lower directory, it will include only the contents of *A* and ignore the submount to *B*—thus including `/x/y/z` in the merged view.

As `try` aims to limit access to information otherwise inaccessible without its use, it prevents unprivileged access to directories with submounts as lower or upper layers. Although the fresh mount namespace grants `try` the capability to create new overlay mounts, among other root-like capabilities, it is forbidden to unmount existing submounts.

To address this problem, `try` uses an additional union filesystem to "flatten" all content within the directory into a single filesystem (Alg. 1, line 14) when submounts are present. The union filesystem used by `try` for this purpose is mergerfs [62], which combines the entire directory, including its submounts, into a single, unified filesystem view. This contrasts with OverlayFS, which does not support submounts. By creating this flattened view of the directory, submounts are effectively eliminated, allowing OverlayFS to use the directory as a `lowerdir` without issues.

4.2 Semisolate execution

After preparing a semisolate, `try` launches the effect-controlled component in its own dedicated namespace and optionally traces its execution.

Execution namespacing: The semisolate executes components within a new user, PID, mount, and network namespace (Alg. 1, line 10). There are two distinct reasons for which `try` uses namespaces: (1) namespaces offer controlled isolation from the broader environment, restricting the process's view so that all effects—together with the filesys-

tem view shaped by the semisolate (§4.1)—are contained, (2) namespaces create the illusion of administrative privileges, allowing a semisolate to mount `/proc` and the union filesystem itself, which would otherwise require elevated privileges. The capability for user namespaces requires setting the `unprivileged_userns_clone` kernel flag, enabled by default in most modern Linux distributions and depended on by container runtimes like Podman [30]. This avoids the need to implement `try` as a `setuid` binary requiring elevated privileges to execute.

Finally, `try` enters a second new namespace (Alg. 1, line 19) to isolate the component's process tree from `try`'s own process, setting the component's root directory to `tmproot` using `unshare`, and finally executes the component under optional system-call tracing.

Execution tracing: To extract additional information about filesystem effects, `try` can interpose on relevant system-call invocations using `strace`. Rather than tracing all filesystem-related system calls when they occur, `try` focuses on collecting relevant information upon `open`—as this is typically a necessary step before subsequent operations on the file descriptor such as reads, writes, random accesses, or direct memory mapping. This approach lowers `try`'s performance overhead, as it avoids tracing reads, writes, and other latency-critical data manipulation operations, omitting further tracing during subsequent use of the file descriptor.

To improve its reach while still avoiding finer-grained tracing, `try` additionally traces other system calls that take paths as arguments—*e.g.*, `open`, `mkdir`, and `unlink`. To trap only this preconfigured set of system calls, `try` uses Seccomp-BPF [42] with a predefined filter—but allows users to pass additional filters if they need to track additional effects, including operations on already-opened file descriptors.

Non-existent paths: Non-existent or missing paths pose a challenge, as ignoring their accesses risks introducing effect holes: accessing non-existent paths generates an observable effect—*e.g.*, negative return value from `open`. Therefore, `try` records such accesses as negative dependencies. Such negative dependencies are useful for recording effects of searching dynamic library paths and configuration files.

4.3 Semisolate conclusion

Semisolates conclude their execution by going through all the effects in the `upperdir` and either applying predefined policies or logging effects to one of the standard streams. As all changes are captured in the effect directory, applying these effects amounts to carefully comparing the captured effects to the underlying filesystem and environment.

To apply filesystem-related effects, `try` recursively processes the upper directory in a preorder fashion, moving files out of the semisolate and into the real filesystem by handling directories before their contents. For regular files in the upper directory, `try` replaces the original file with the new file. For directories, it either (1) replaces the original file with the new directory, if a regular file exists at the directory's original path; (2) replaces the original file or directory with the new file, if the directory has the extended attribute `user.overlay.opaque`, indicating that directories in lower layers have been shadowed by new definitions in the merged view; or (3) replaces the original directory with the new directory. For symlinks, it removes any existing file at the original path and recreates the symlink with the same target as the one in the upper directory. If `try` encounters a whiteout file—a character device with 0 major and minor numbers—in the upperdir, it deletes the original file or directory at that path.

If the semisolate directory resides on the same filesystem as the target location, `rename` is used to avoid unnecessary disk copying. Otherwise, `try` falls back to the host's `mv` utility.

4.4 Putting it all together

Fig. 2 illustrates the internals of four `try` invocations.

The first invocation wraps p_1, eliding all network access inside the semisolate. It prepares an overlay layer with a whiteout mask at path π, and mounts it on top of the host filesystem's lowerdir, ignoring the underlying π in the filesystem. It then enters the new namespace, and launches p_1 inside it. While p_1 is running, `try` captures five effects in the upperdir, which it later processes to summarize the order of effects (`-t`): (1) reading α hits the lowerdir, which forwards the call to the underlying filesystem, (2) writing to β hits the upperdir, copying β there, (3) reading β hits the upperdir, which sees the latest write, (4) reading path π, masked in the overlay layer, thus failing and resulting in `try` recording a negative dependency; and deleting path δ, which places a mask file at δ in the upperdir, effectively hiding it from the merged view. The sequence of collected effects (α_R, β_W, β_R, π_R, δ_D) is fed to `stdout` but the effects themselves are discarded alongside the semisolate (`-n`).

Next, `try` wraps p_2, creating a new namespace and mounting the host filesystem inside a fresh overlay filesystem lowerdir, now without any path masking or network isolation. The three component effects it captures are: (1) writing β, with identical effects as before, (2) writing ψ, and (3) deleting δ—both operations captured in the upperdir. This time, `try` stores the semisolate (and by extension, its effects) inside a named directory on the host filesystem (`-N` σ), after filtering out excluded effects (`-E` ψ) by iterating over the upperdir and deleting them.

Next `try` wraps p_3 while stacking the effects of the latest `try` invocation (`-L` σ). It captures: (1) writing α, which brings it to the upperdir, (2) reading β, which hits the stacked lowerdir from semisolate σ, and (3) writing π—recorded in the upperdir. The effects stored in the semisolate are the two writes to α and π, and the delete of δ inherited from σ.

Finally, `try` commits the effects (`-y`). It iterates from bottom to top, first applying the effects from the stacked semiso-

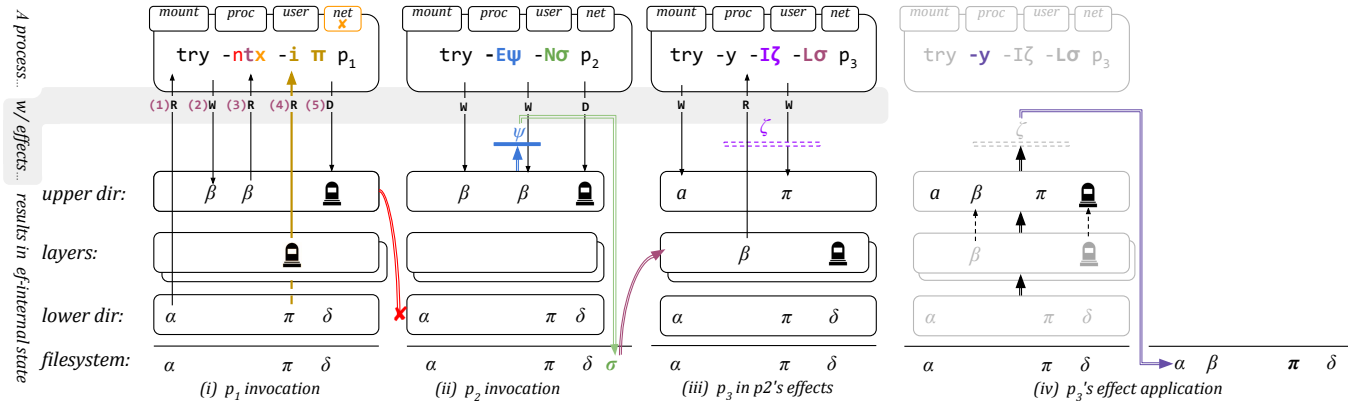

Figure 2: Detailed walkthrough of the internals of multiple `try` invocations. A detailed walkthrough of these invocations is presented in §4.4. From top to bottom: `try`'s invocation, component effects, `try` internal state, and host filesystem state. From left to right: different `try` invocations on different components on the same host filesystem. Single arrows indicate effects; double arrows indicate effect discard, storage, stacking, and application; and certain colors correspond to certain `try` invocation options.

late σ, followed by the current semisolate's effects, applying each one based on its type. It focuses on paths in ζ (`-I ζ`), *i.e.*, the writes to β and π, which are applied to the host system.

This approach implements the semisolate abstraction, allowing for effect control on arbitrary components without requiring any invasive instrumentation or modification.

5 Evaluation

This section reports on the results of applying `try` in several instances of each case-study application presented earlier (§2). Key dimensions of each study's characterization (§5.1–5.5) include (1) `try`'s ability to *control* all relevant effects; (2) `try`'s behavioral *equivalence* to semisolate-free execution when effects are finally applied to the host environment; and (3) `try`'s runtime *performance* relative to semisolate-free execution and full isolation (§2.2). A series of microbenchmarks zoom into `try`'s sources of overhead (§5.6).

Control focuses on confirming that `try` correctly identifies **`I`**, applies or discards **`A`**, selects **`S`**, or manipulates **`M`** all relevant effects during a component's execution in a semisolate.

Behavioral equivalence focuses on confirming two aspects of `try`: (1) the in-semisolate behavior during execution, meaning that the computation in the semisolate executes as expected and produces results identical to the non-semisolated execution; and (2) the eventual state of the filesystem, meaning that the filesystem state is indistinguishable from `try`-free execution. The former confirms that `try` does not affect the internal computation, including its direct effects; and the latter confirms that it correctly applies the manipulated effects.

Performance characterization compares runtime without isolation, with `try`, and with Docker v28.4.0 configured with full isolation; performing container (not image) creation, input copy-in, execution, container teardown, and copy-out. Experiments use an environment with 64 GB of RAM and an 8-core 3.70 GHz Intel Xeon W-2145. Software used is the Linux kernel v6.1 on Debian GNU/Linux 13 (trixie), GNU coreutils v9.7, Node.js v18.19.0, and Python v3.13.5.

Benchmark results are summarized in Table 2. In terms of effect control, `try` mediates desired effects, propagates them appropriately, and hides sensitive environment state. In terms of behavioral equivalence, `try` behaves equivalently to `try`-free execution, confirmed both via manual inspection and automated checksum comparison between the entire filesystem tree after executing each benchmark with and without `try`. In terms of performance, `try` incurs a 1.0×–8.3× performance overhead over vanilla, `try`-free execution and enjoys a 1.1×–225.7× performance improvement over containment in Docker. We do not provide a geomean or other statistical summary for overhead over vanilla execution or speedup over Docker, as each case study requires different semisolate configurations and corresponding `try` flags to control effects—and thus incur different overheads.

We discuss the benchmarks grouped by use case below.

5.1 Risky or cryptic LLM suggestions

These benchmarks consist of five scripts generated by ChatGPT for tasks distilled from a survey of LLM-mediated workflows, spanning conventional chat interfaces and autonomous agents such as Codex and OpenClaw [82] (prompts included in Appendix §A): (1) **`crawl`**, updates the timestamps of 10,000 files in a directory, using `find`, `exec`, and `touch` [90]; (2) **`fresh`**, compressing 10,000 10KB files that exceed a certain size, using `find`, `exec`, and `gzip` [35]; (3) **`archive`**, searching for files with a `.txt` extension in 100 directories of 10,000 files each, using `find` [37]; (4) **`logs`**, checking for errors in a 10-million-line file using `grep` [40]; (5) **`order`**, sorting a 10-million-line file using `sort` [6]. Benchmarks were executed with `try -y` and `try -n`.

Table 2: Benchmark summary. The benchmark applications for the five use cases evaluated. The **Control** column indicates `try`'s effect control between effect introspection (**I**), application and discard (**A**), stacking (**S**), and manipulation (**M**). The **Equivalence** columns indicate whether the output (O) and side effects (SE) match those of vanilla execution. The **Performance** columns show the **execution time ratio** relative to the baseline (Docker or Vanilla), and whether `try` comparatively has a speedup (↑) or slowdown (↓). The **Description** column describes each benchmark's purpose and `try`'s invocation. The **Source** column provides references to the original benchmark sources.

Use case	Name	Control		Equivalence O	Equivalence SE	Performance vs. Docker	Performance vs. Vanilla	Description	Source

Control: All computations executing in semisolates configured with `try -n` mediated all effects that were applied to the filesystem by `try`-free executions.

Equivalence: All computations executing in semisolates configured with `try -y` produce correct results; and their effects on the filesystem are identical to `try`-free executions.

Performance: When compared to vanilla execution, `try` introduces runtime overheads 1.1×–1.9×. Variations come from the complexity of effects interposed during execution. For example, in **`order`**, `try` achieves the lowest overhead (1.1×) as it interposes on a single write effect, writing the sorted file to disk. The **`crawl`**, **`fresh`**, and **`archive`** tasks exhibit higher overheads (up to 1.9×) because they operate on many files from the host system (use of `find`), which results in more upperdir copy-ups. Relative to Docker-contained execution, `try` demonstrates substantial performance improvements across all five benchmarks, achieving performance improvements of 1.3×–225.7×. Two benchmarks incur outlier speedups: the **`archive`** benchmark only interacts with its standard output stream (`find`'s output) which is effectively a symlink to the same file descriptor in the host environment, meaning that `try` boils down to vanilla execution, paying only the flat cost of semisolate creation, while Docker still pays the full container setup and teardown costs. Similarly, the **`logs`** benchmark reads from and writes to a single large file, meaning that again `try` pays only a single creation and copy-up cost, while Docker with full isolation needs to pay the copy-in and copy-out costs as well.

5.2 Dependency tracking

These benchmarks consist of several real-world shell programs from the Koala suite [44] with many and complex runtime dependencies between their components. (1) the **`covid`** benchmark, which processes bus schedule data collected during COVID-19 to generate summary statistics [94]; (2) the **`nlp`** benchmark, which performs natural language processing tasks on a text corpus [41]; (3) the **`spell`** benchmark, which

checks spelling in a large text file [13]; (4) the **unixfun** benchmark, which solves challenges from Unix 50th anniversary game [95]; and (5) the **ci-cd** benchmark, which compiles several C source files [19]. These programs contain a diverse set of commands that include GNU Coreutils, POSIX, and third-party commands. To stack effects across all component invocations without applying them on the host environment (§2.1), `try` was configured with `-L` and with `-t` to extract dependencies.

Control: All computations executed with `try -t -n -L` mediated all effects that were applied to the filesystem by `try`-free executions. Manual inspection and multiple re-executions confirm that executing these benchmarks with `try -t -L` identifies all true dependencies between components.

Equivalence: Tracking the dependencies discovered by `try -t` and later applying them with `try -y -L` produces correct results. Their effects on the filesystem are identical to the ones produced by `try`-free executions.

Performance: When compared to vanilla execution, `try` introduces absolute overheads 1.0×–1.7×, which is the flat cost of setting up the semisolate environment for each tracked command. However, while the semisolate setup cost is flat, tracing overheads scale with the number of effects a component produces. This is less evident in statically compiled components, such as commands from GNU coreutils, which are tightly packed binaries with very minimal dependencies (often just `libc`), but evident with components relying on interpreted runtimes (*e.g.*, a custom `lowercase.py` utility in **nlp**), which need to resolve their entire dependency tree during execution. The performance of `try` significantly outperforms fully-isolated execution across all five dependency tracking benchmarks, demonstrating speedups 1.1×–18.7×.

5.3 Third-party library risks

These benchmarks consist of `git` repositories with pre-commit hooks that introduce undesirable effects: (1) **LinOTP** [64] multi-factor authenticator; (2) the **frogmouth** [28] markdown reader; (3) Apache **kibble** [8] aggregating and visualizing software data; (4) the **okteto** [66] container orchestrator; and (5) **uv-metrics** [73], a machine-learning metrics reporter. The pre-commit hooks perform several operations on the filesystem, communicate with the network, and include a code-injection attack that leads to data exfiltration. They were prefixed with `try -i`, excluding the `/etc/passwd` file from the semisolate.

Control: All computations executed with `try -i` mediated across all effects present in the `try`-free executions, except `/etc/passwd`. This effect originated from the pre-commit hook at `.git/hooks`, which attempted to append `/etc/passwd` to `README.md`.

Equivalence: All computations executed with `try -i` produce correct results, correctly committing the intended changes, and the resulting filesystem state remains identical to that of `try`-free execution. Across both the vanilla pre-commit hook workloads and the five code-injection vulnerabilities evaluated, `try` preserves correctness.

Performance: When compared to vanilla execution, `try` has a performance impact of up to a 1.3×. The performance of `try` is comparable to vanilla execution for the **frogmouth** and **uv-metrics**, while maintaining low overheads for **LinOTP** (1.2×), **okteto** (1.3×), and **kibble** (1.2×), whose pre-commit hooks perform short-running computations, comparable with `try`'s semisolate setup overhead. It outperforms Docker-contained execution across all five benchmarks, achieving speedups 1.4×–4.2×. With blocking enabled, `try` reduces the effect surface and thus computation performed by the injected pre-commit hooks. This leads to `try` improving the runtime of the **frogmouth** and **kibble** workloads by 0.8× and 0.9× respectively.

5.4 Dry-run execution

These benchmarks consist of commands with built-in dry-run functionality: (1) **git** [31], using `git clean`; (2) **patch** [32]; (3) **rename** [96]; (4) **rsync** [75]; and (5) **stow** [27]. Each workload was executed twice: once with dry-run enabled, without `try`; once with `try -n`, without dry-run.

Control: All computations executed with `try -n` except two mediated on and reported the exact same effects as the corresponding `--dry-run` executions. One of the two exceptions was **rename**: instead of reporting `a -> b`, `try` reports equivalent `a (deleted) b (created)` pairs.

The second exception is more interesting: when combined with the `--log-file` flag, **rsync**'s dry-run mode omits effects in the produced log file [74], whereas `try` captures and reports all produced effects.

Equivalence: All computations executed with `try -n` correctly suppress all effects to the host environment and present the same output and side effects as the dry-run executions (excluding **rename**'s representation difference). Invocations executed with `try -y` correctly apply all effects to the host environment, equivalent to `try`-free execution.

Performance: When compared to dry-run execution `try` demonstrates overheads of 4.9×–82.6×. These overheads are expected since each command's native dry-run mode avoids performing any filesystem action and is implemented as a separate path that does not perform any effectful computation (average time 0.03s), whereas `try` executes the real computation and then discards its effects (average time 0.26s). Compared to full isolation in Docker, `try` improves performance across all five benchmarks between 1.2×–3.2×.

5.5 Partial-specification mining

These benchmarks evaluate `try`'s capability to support automatic specification mining for shell commands, focusing on determining the order of their read and write effects to their standard streams or the filesystem. These properties correspond to the ones required by PaSh [38] and POSH [71] to parallelize or distribute shell scripts. The commands evaluated in this section are: (1) **`ls`**, a command that lists directory contents; (2) **`cp`**, a command that copies files and directories; (3) **`rm`**, a command that removes filesystem entries; (4) **`sed`**, a stream editor that filters and transforms text; and (5) **`xargs`**, a higher-order command that executes command lines from standard input. The specification miner explores 11, 100, 40, 1408, and 3 configurations for these commands respectively. For **`xargs`**, it uses the `rm`, `ls`, and `cat` commands as arguments. All workloads were executed using `try -t`.

Control: All computations executed with `try -t` mediate all observed effects, capturing every read and write operation performed by the evaluated commands.

Equivalence: All computations executed with `try -t` produce correct results, and the resulting filesystem state remains identical to that of `try`-free execution. Across all commands evaluated, the inferred specifications match or extend PaSh's handwritten specifications. In three cases, `try` enables the miner to detect effects omitted from the original PaSh specifications. For example, although **`cp`** is marked as side-effectful in the original specifications, its behavior in these evaluation scenarios is effectively pure, as it modifies only files explicitly listed in its arguments.

Performance: Since the configuration miner needs to explore a large number of command invocations to infer their specifications, `try`'s overheads compound significantly. Compared to vanilla execution, `try` increases execution time 1.7×–8.3×, caused by `try`'s flat cost of setting up the semisolate environment and its tracing overhead. Vanilla execution is not meaningful in this use case, as the specification miner needs to observe effects to infer specifications. The performance of `try` improves relative to Docker-contained execution across all five mining benchmarks, achieving speedups 1.6×–2.2×. Benefits from `try`'s lighter semisolate setup and teardown times compound over the many invocations required by the specification miner (here, 1562 in total).

5.6 Microbenchmarks

The goal of the set of microbenchmarks is to analyze `try`'s sources of overhead. These benchmarks consist of three workloads: (1) **`echo`**, a Rust function that creates zero files, invoked 100 times; (2) **`files`**, a Rust function that creates 10,000 small files of size 16 bytes each; and (3) **`big_file`**, a Rust function that creates five large files of size 1GB each. All workloads were executed using `try -y` and `try -n`, yielding complete control and equivalence, thus we focus on performance breakdown (Fig. 3).

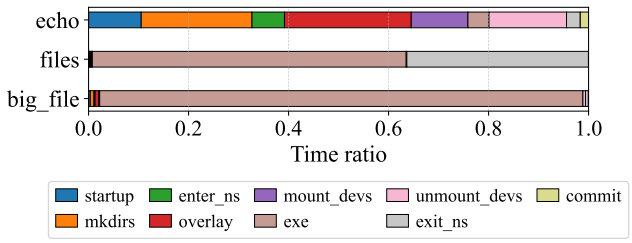

Figure 3: The performance breakdown of `try`. The performance of `try` in three microbenchmarks and its overhead breakdown across different execution stages.

The performance analysis breaks down the `try` runtime into nine stages: (i) *startup* parses command-line arguments and enumerates top-level directories; (ii) *mkdirs* provisions the upper, work, and temporary directories; (iii) *enter_ns* creates a fresh namespace; (iv) *overlay* establishes the OverlayFS mount points; (v) *mount_devs* bind-mounts selected device files; (vi) *exe* executes the target process; (vii) *unmount_devs* unmounts the device files; (viii) *exit_ns* exits the namespace, triggering the automatic unmount of remaining OverlayFS layers; and (ix) *commit* moves output files from the upper directory to the host filesystem. For the baseline **`echo`** command, which completes in 165ms, the overhead is caused by filesystem and namespace operations. Creating the OverlayFS (*overlay*) accounts for 25% (42ms), followed by directory creation (*mkdirs*) at 22% (37ms). Device management also creates measurable overhead, with *unmount_devs* taking 16% (26ms) and *mount_devs* taking 11% (19ms). In longer-running benchmarks, such as **`big_file`** (9.2s) and **`files`** (11s), these setup and teardown costs remain roughly constant, making the relative overhead comparable to the actual *exe* time. However, **`files`** presents an outlier in the teardown phase as *exit_ns* takes 6.3s. This latency is caused at semisolate conclusion because `try` needs to iterate over the many files created in the OverlayFS `upperdir`.

6 Discussion, Limitations & Experiences

Limitations: Current `try` limitations primarily impact compatibility in specific scenarios: restrictions and altered application behavior due to its use of user namespaces, challenges in handling pseudo-filesystems and physical devices, and inability to fully disable certain isolation mechanisms.

Due to its use of user namespaces, `try`-semisolated processes cannot interact with other users. Even when a process appears to be root in the namespace, it cannot switch UID or operate on files owned by other users. Components that rely on creating or switching users may behave unexpectedly.

Processes inside semisolates bypass writable permissions without needing to change the file permissions (a special

feature of UID 0 in Linux). This may affect components that rely on write permissions or ones running without elevated privileges, such as `npm`, when the user ID is 0.

As `try` requires user and PID namespaces for unprivileged OverlayFS mounting, it creates a non-configurable isolation barrier for IPC mechanisms such as signals, complicating interprocess coordination when such isolation is not desired.

External modules: Two additional modules augment `try`. For namespace-local root-like capabilities without host root privileges, `try` maps the current effective UID and GID to the superuser inside the new user namespace. Because `unshare` cannot map multiple UID or GID ranges, traversing directories owned by another accessible GID can trigger `EOVERFLOW`; `try-gidmapper` addresses this case, with security implications that go beyond `try`'s current scope.

As the number of effects can overwhelm a user, an external `try` module summarizes effects in a human-friendlier form. This module, called `try-summarize`, queries an opaque language model with the output from `try` and additional instructions requesting (1) a non-expert summary of the effects, starting from the most important ones; (2) information about whether these effects touch sensitive directories. Both prompts offer functionality `try`'s users could directly implement, but proved useful during recent user interactions with `try`.

Experiences: Colleagues and students using `try` have shared several notable experiences (see Appendix B for testimonials unrelated to the `try` authors). The `try` subsystem is also used in several research projects. An out-of-order execution engine called hS [48] and a bolt-on incrementalization system called Incr [99] use `try` to build a dependency graph between opaque components during execution and revoke their effects when appropriate. They achieve speedups of up to 9.3× and 373.3× over vanilla execution, respectively.

Users often discard effects when the wrapped component wrote outside the expected filesystem subtree, *e.g.*, creating auxiliary files in the home directory, or when its set of effects was larger than expected, *e.g.*, `chmod +x *` affecting all files in the current directory. In several cases, they discarded the effects of mistyped `pip` and `cpanm` invocations. A colleague, after running a training job under `try`, inspected the produced checkpoint files and selectively committed only the highest-performing one. A teaching assistant used `try` to shield against unintended effects from student submissions. Several students have used `try` to interpose on agentic workflows, wrapping their session with `try` and inspecting all produced effects before committing them. Even when the agent performed non-filesystem accesses (*e.g.*, access to webpages, interactions with email and messaging APIs), which often were read-only network effects, `try` remained useful. It allowed students to mediate all resulting local filesystem effects, critical when the agent performed an incorrect action based on misleading information it fetched from the web.

It is possible for users to arrive at an inconsistent set of updates when selectively applying or reordering effects. For example, the effect of creating file `f` in directory `d` depends on the effect of creating directory `d`. When `try` applies an inconsistent update, it issues a warning similar to standard filesystem manipulation commands (*e.g.*, `mv`). Since the semisolate is stored on disk, users are able to re-apply a different subset of effects or reorder semisolates differently—a capability that hS depends on [48].

7 Related Work

Containment and virtualization: There has been a significant amount of work on full isolation, including in containers [9, 54, 84, 87] and virtual machines [10, 12, 16, 53, 68]. These primitives create an isolated environment that is different from the host environment they execute in, completely avoiding sharing of any sort. Semisolates instead run a program in a simulacrum of the current environment—as if on the same environment, but with significantly lower risk—and allow for further and selective manipulation of its effects.

Software isolation and confinement: Earlier work on isolation and confinement [4, 36, 39, 69, 76, 78], focused on controlling and, if necessary, protecting against harmful component effects. These approaches offer structures at the operating system level, often not supporting unmodified Linux environments. In contrast, `try` leverages subsystems available in modern operating systems—requiring no modifications.

Tools such as bubblewrap [17] similarly rely on Linux kernel mechanisms to create isolated execution environments for unmodified programs. However, bubblewrap requires configuring the environment view available to the wrapped process ahead-of-execution, does not support layering, and either blocks effects during execution—potentially leaving the component at an inconsistent state—or reflects effects immediately to the host environment. In contrast, `try` requires no configuration (aside from optional path ignoring), supports layering unapplied effects across executions, and allows users to inspect and selectively apply effects *after* execution.

Other systems achieve confinement via system call interposition [14, 43]. For example, MBOX traces and interposes on system calls to inform the user of unintended or undesired effects. Such interposition meets only some of `try`'s requirements; it does not, for example, support stacking or further manipulation. Semisolates and `try` take a different approach, offering several more features—and compatibility across several modern environments.

Language-based wrapping and proxying: Semisolates bear resemblance to earlier research that attempts to control effects and capabilities using dynamic effect wrapping [5, 21, 51, 55, 57, 58]. In contrast to `try`, these approaches are not language-agnostic, as they are tightly integrated into a language and its runtime environment [5, 20, 21, 56], and often require developer effort through code modifications, or isolation policies [50, 57, 58, 61, 91]. Semisolates offer language-agnostic

effect control on unmodified programs.

Capabilities and sandboxing: Semisolates inherit ideas from early capability and sandboxing work [46,47,59,60,83]. Software fault isolation [97] rewrites object code to prevent execution reaching addresses outside a domain. Rather than completely restricting naming, `try` dynamically shadows names defined outside the compartment's context—a technique isomorphic to a combination of capability revocation followed by attenuation; but contrary to earlier efforts, `try`'s shadowing works with completely unmodified binaries.

Filtering and access prevention: Another class of sandboxing tools is based on software fault isolation [97], including NaCl [81], WASM [33], and RLBox [63]. These systems focus on intraprocess memory-level isolation. Instead, `try` supports effect control (not isolation) outside the process—including effects such as file modifications.

Other systems control effects by preventing file accesses [77, 98, 100], terminating processes that access files outside an allowed set, or filtering dangerous or unnecessary system calls [22, 29, 42, 85]. These approaches prevent effects completely—possibly breaking the application if it needs to perform the effects to complete its execution.

Transactional filesystems: Earlier research on transactional filesystems [25, 79, 80, 88] has developed support for atomically committing or reverting changes to multiple files in a filesystem. In contrast to `try`, which allows calling programs to inspect and apply some of the effects—or further manipulate them at will.

8 Conclusion

Software systems consist of many components, written in many languages, and interacting with each other and the environment. This paper showcases the need for and feasibility of building a new abstraction, the semisolate, for controlling potentially undesired effects, maintaining full compatibility with real-world components, and incurring a performance overhead that is aligned with several practical applications.

A LLM-Generated Scripts

This appendix lists the exact prompts used to generate the LLM-based benchmarks in §5.1, along with the scripts returned by ChatGPT.

`crawl`: Find & Touch

PROMPT

Write a simple Bash script that searches a directory (for example ./data) and runs a command on every file it finds. Use find with -exec and include comments explaining what the script does. The command should just touch each file.

GENERATED SCRIPT

```
directory="./data"
find "$directory" -type f -exec touch "{}" \;
```

`fresh`: Compress Files Larger Than 1 KB

PROMPT

Write a Bash script that finds all files larger than 1 KB in a directory (e.g., ./data) and compresses them using gzip. Use find with the -size filter and an -exec command. Include comments.

GENERATED SCRIPT

```
directory="./data"
find "$directory" -type f -size +1k \
  -exec sh -c 'gzip "{}"' \;
```

`archive`: Find All .txt Files

PROMPT

Give me a command to find all .txt files in the current directory and its subdirectories.

GENERATED SCRIPT

```
find . -name "*.txt"
```

`logs`: Extract Error Lines From Log

PROMPT

Give me a command to extract only ERROR, WARNING, or CRITICAL lines from a log file and save them to a new file. Make sure the command doesn't fail even if nothing is matched.

GENERATED SCRIPT

```
grep -E "ERROR|WARNING|CRITICAL" file.log \
  > filtered_errors.log || true
```

`order`: Sort a File

PROMPT

Give me a command to sort the contents of book.txt and save the result to another file.

GENERATED SCRIPT

```
sort book.txt > sortedBook.txt
```

B Testimonials

This appendix includes testimonials from users who have tried `try` and shared their feedback on social media platforms. They offer a snapshot of real-world experiences and community reception of the tool. The feedback was primarily gathered from platforms such as personal blogs and Hacker News.

Looks nifty—basically it's the "let me try that in a container first" except on your live system with no setup to get it going.

— **@mikepurvis**, *Hacker News*

This is a much needed software.

— **@johnsbullings**, *Hacker News*

Very interesting! This feels like something that should have always existed.

— **@Benjamin Oakes**, *benjaminoakes.com*

This is cool I probably will use this.

— **@jagtstronaut**, *Hacker News*

I love that their demo is to finally give me a dry run command for pip.

— **@gdevenyi**, *Hacker News*

The script is mounting an overlay filesystem for each root directory on the current system, then looking at what has been added as a new layer... Pure genius.

— **@MichaelMoser123**, *Hacker News*

I can see this being incredibly useful.

— **river**, *lobste.rs*

`try` is clever.

— **Jim Fowler**, *x.com*

I look forward to it helping me prevent programs polluting my laptop.

— **bfiedlera**, *lobste.rs*

This tool can bring a level of control that is typically only available in databases and VCSs, and make it a commodity.

— **@klabb3**, *Hacker News*

C Software Artifact

Abstract

The software artifact accompanying this paper consists of the `try` subsystem, its documentation, a test suite, and the scripts used to reproduce the evaluation in §5. It supports three goals: inspecting the implementation and its accompanying materials, exercising the system through its test suite, and reproducing the paper's main evaluation results, including the summary across the five use cases and the microbenchmark breakdown.

Scope

The artifact covers the claims made by the paper's implementation and evaluation sections. In particular, it includes: (1) the `try` subsystem and the semisolate abstraction described in §3 and §4; (2) the five use cases and supporting benchmarks from §2 and §5; and (3) the automation used to reproduce all key results in §5.

Contents

The artifact contains the following components:

- the `try` subsystem itself;
- documentation, including a top-level README, a manual page, and a short tutorial;
- a regression test suite covering `try`'s core functionality;
- the five evaluation workloads and their supporting utilities; and
- scripts for running the evaluation and generating all key result artifacts.

Hosting

The artifact is publicly available both as a GitHub repository and as a Zenodo archival snapshot. The GitHub version is hosted at `https://github.com/binpash/try/tree/osdi26-ae`, and the archival version is hosted at `https://zenodo.org/records/19444649`.

Abstract

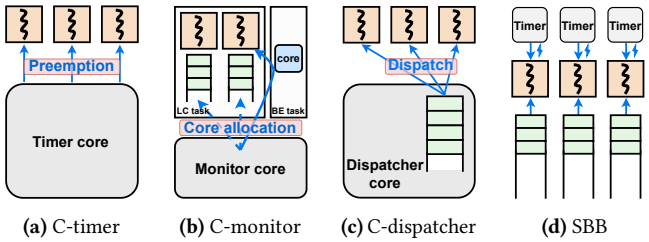
To achieve high throughput, low latency, and high CPU efficiency, userspace network runtimes must perform three types of scheduling: 1) *request preemption* to minimize tail latency, 2) *CPU allocation* among services to avoid wasting CPU cycles when the load is low, and 3) *request load balancing* across worker cores to achieve work conservation. However, prior designs rely on centralized components, which inevitably become scalability bottlenecks as the number of CPU workers increases, limiting system performance scaling.

This paper presents SBB, a purely decentralized userspace network runtime that simultaneously delivers high performance, high CPU efficiency, and high scalability by advancing in both system mechanism and scheduling policy. For system mechanism, SBB leverages the emerging User Interrupt mechanism in a novel way, delivering two types of device interrupts to the userspace runtime: 1) user-level timer interrupts for request preemption, and 2) user-level NIC interrupts for packet arrival to perform CPU allocation. For scheduling policy, SBB introduces a two-level algorithm, which marries flow migration (for persistent imbalance) with task stealing (for temporary imbalance), challenging the conventional wisdom that centralized load balancing outperforms decentralized approaches. Evaluation shows that SBB achieves 1.7× to 5.2× higher throughput when scaling to 48 cores, while meeting the same tail latency target.

1 Introduction

Modern high-speed NICs and links have enabled datacenters to enjoy high bandwidth, on the scale of hundreds of Gbps [1, 3, 8, 12]. On the other hand, CPU processing speeds in datacenters struggle to keep pace with the performance of NIC hardware [66, 82]. It is thus foreseeable that a single CPU core, or even a dozen cores, will be insufficient to handle the massive volume of requests in datacenters in a timely manner [52, 58, 69]. As a result, network runtimes must achieve great multicore scalability.

As tail latencies enter the microsecond realm, modern operating systems such as Linux fail to meet high-performance networking demands, which has motivated researchers to build userspace network runtimes that bypass the kernel and leverage fine-grained scheduling to achieve μs-scale request processing [16, 24, 52, 55, 59, 83, 87]. Besides high throughput and low latency, network runtimes also need to support high CPU efficiency, as even a small efficiency loss can significantly increase cost at scale [33, 67]. To meet these demands, network runtimes must perform three types of scheduling: 1) *request preemption* to prevent long requests from causing head-of-line blocking of short ones [43, 54], 2) *CPU allocation* among co-located applications to avoid wasting CPU cycles when the load is low [60, 74], and 3) *request load balancing* across worker cores to achieve work conservation [71, 76].



(a) C-timer **(b)** C-monitor **(c)** C-dispatcher **(d)** SBB

Figure 1: Comparison of userspace network runtime architectures. The centralized timer, monitor and dispatcher will all become bottlenecks as the number of workers increases (§2.3.2). SBB removes all centralized components and achieves great scalability.

Unfortunately, to perform the scheduling, existing works rely on standalone centralized entities, leading to scalability bottlenecks. For request preemption, a common design [43, 51, 54, 63] is to use a centralized timer to periodically send some specific signals to all workers (Figure 1a). For CPU allocation, many works [38, 74] deploy a centralized monitor that polls each worker's NIC queue, detecting packet backlog and making CPU core reallocation decisions (Figure 1b). For request load balancing, a common method [51, 53, 54, 74] is to rely on a centralized dispatcher to distribute requests to worker cores (Figure 1c). When scaling to more workers, these centralized entities will become the bottleneck (§2.3.2).

While this scalability limitation is widely recognized [43, 70], existing works fall short due to i) unvalidated assumptions and the lack of ii) scalable system mechanisms and iii) effective decentralized scheduling policies. To wit, conven-

tional wisdom is that one can scale centralized entities with multiple cores [54, 85], each handling a subset of requests or worker cores. Our measurement (Figure 3) challenges it, showing that using more cores achieves worse load balancing, and does not help with request preemption and CPU allocation. In addition, existing system mechanisms lack a μs-scale, decentralized approach to notify worker cores of scheduling events, like time quanta expiration or new packet arrivals, making a centralized timer or monitor the only option. Finally, for scheduling policies, centralized load balancing is chosen as it better approximates a shared FCFS queue, the ideal policy proven by queuing theory [81], but it overlooks the constraint of scalability.

This paper presents SBB[1], a highly scalable μs-scale network runtime that eliminates all centralized scheduling entities with even better scheduling quality than prior designs. SBB's design advances in both system mechanism and scheduling policy.

For the **system mechanism**, we find that centralized request preemption and CPU allocation stem from a lack of different types of hardware support. The former lacks an efficient timer for detecting and preempting long requests. For the latter, interestingly, the root cause is the use of polling to handle incoming packets. Polling prevents a timely detection of packet arrivals when multiple applications are co-located. Thus, a centralized entity is a must to monitor incoming packets and decide if each network application is runnable to perform CPU allocation.

To provide system mechanisms for scalable scheduling, SBB leverages the emerging User Interrupt (UINTR) feature [10, 17]. With UINTR, SBB delivers two types of device interrupts to userspace, a capability not documented in Intel hardware manuals [9]. SBB delivers per-core timer interrupts to the network runtime, thereby avoiding core count as a scalability bottleneck for request preemption. In addition, SBB delivers NIC interrupts to userspace, eliminating a centralized entity to detect packet arrivals, thereby enabling scalable CPU allocation.

For the **scheduling policy**, our main observation is that existing decentralized load balancing policies fail to consider both causes of imbalance, explaining their poor performance. To wit, existing designs [38, 71, 76] use a combination of NIC steering hardware (e.g., RSS [15]) and task stealing. The former maps a network flow to a worker core, while the latter enables idle cores to steal requests from busy ones. However, the flow-to-core steering in NIC is susceptible to both temporary (*e.g.*, a burst of requests in a single flow) and persistent load imbalance (*e.g.*, some cores are assigned too many flows). Task stealing is only effective for temporary imbalance, causing excessive cache coherence traffic for persistent imbalance, and hence, poor performance.

[1]The national railway company of Switzerland. While both countries enjoy efficient rail networks, Switzerland's is known for being highly decentralized, avoiding centralized busy hubs such as Shinjuku in Tokyo.

Thus, SBB introduces a two-level policy that marries task stealing with flow migration into μs-scale network runtime. For temporary imbalance, SBB uses an enhanced task stealing technique to balance at packet-level, while to handle persistent imbalance, SBB leverages flow migration, which programs the NIC to migrate flows away from overloaded cores, thereby addressing imbalance at flow-level. We show, with both simulation (as a platform-independent setup) and real-world experiments, that the scheduling quality of this two-level policy closely matches that of a centralized one, proving that centralized schemes are not inherently better. With it, SBB achieves scalable request load balancing.

We integrate SBB with DPDK [7] to benefit from its wide deployment. We evaluate SBB with synthetic workloads and real-world applications, showing that SBB scales well and achieves an SLO-compliant throughput increase of 1.7× to 5.2× over prior work.

In summary, this paper makes the following contributions:

- **Analysis.** We analyze and reveal the root causes of scheduling scalability bottlenecks in existing μs-scale network runtimes.
- **Mechanisms and Policies.** For scalable scheduling, we propose 1) the use of UINTR to deliver userspace timer and NIC interrupts for request preemption and CPU allocation, and 2) a two-level request load balancing policy to mitigate comprehensive imbalance problems.
- **SBB.** We implement our mechanisms and policies in SBB[2], a high-performance userspace network runtime that supports all three types of scheduling in a decentralized and scalable architecture.

2 Background and Motivation

This section identifies the three key scheduling types in userspace network runtimes (§2.1), presents an introduction to User Interrupt (§2.2), and introduces how prior work uses centralized entities to perform the scheduling (§2.3).

2.1 Scheduling in Network Runtimes

Modern network runtimes must meet three requirements: a) high throughput, b) low median and tail latency, and c) high CPU efficiency. High throughput and low median latency exploit the performance of modern NICs. Tail latency matters because network requests often fan out across multiple components, and thus the end-to-end latency is determined by the slowest response [33, 35]. For the last requirement, even marginal CPU efficiency gains can yield substantial cost savings in datacenters [67, 73, 74, 79].

To meet these requirements, userspace network runtimes perform three types of scheduling: 1) request preemption, 2) CPU allocation, and 3) request load balancing.

Request preemption happens during request processing to avoid head-of-line blocking, thereby reducing tail latency. Head-of-line blocking occurs because heavy-tailed network

[2]The artifact of SBB is at https://github.com/TELOS-syslab/SBB-Artifact.

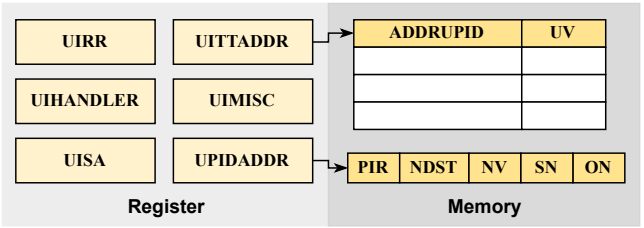


Figure 2: Key hardware components of User Interrupt.

services involve skewed workloads, where a small portion of requests take much longer to process than others [13, 14, 78]. To minimize tail latency, a network runtime needs to preempt long requests to prioritize short ones [81]. Furthermore, since network requests need to be processed at microsecond scales, the overhead of preemption and task switching must be minimal, making μs-scale preemption an essential feature for userspace network runtimes [54].

CPU allocation is necessary to maximize CPU efficiency, *i.e.*, the fraction of CPU cycles spent performing useful work. It is common practice to co-locate multiple applications on a single server, including latency-critical (LC) and best-effort (BE) applications [21, 50, 84]. Thus, the runtime needs to allocate an appropriate share of CPU time to each application and dynamically adjust allocations as load changes: it must reallocate idle cores from LC applications to BE tasks, and be able to promptly reassign cores back to LC applications to handle load bursts [60].

Request load balancing is performed to assign each incoming request to a processing core. The goal is to ensure that no cores are idle while requests are pending. It tries to mitigate the imbalance issue between workers: some workers are too overloaded to handle assigned requests, while some idle workers have no assigned requests.

2.2 User Interrupt

User Interrupt (UINTR) [9, 10, 17] is a new hardware feature introduced with Intel Sapphire Rapids CPUs, which allows processes to send and receive interrupts directly in user space without trapping into the kernel. By bypassing the kernel, UINTR avoids overheads such as switching address spaces or privilege levels, thereby offering high performance.

Main hardware resources. Figure 2 illustrates the key hardware resources for User Interrupt, which consist of registers and memory structures. Each core is equipped with six model-specific registers (MSRs): 1) *UIRR*: a bitmap in which each set bit indicates a pending interrupt, 2) *UIHANDLER*: stores the linear address of the user-interrupt handler, 3) *UISA*: controls stack pointer adjustment before delivering a user interrupt, 4) *UITTADDR*: holds the memory address of the User Interrupt Target Table (UITT), 5) *UIMISC*: contains UITTSZ (the highest index of a valid entry in the UITT) and UINV (the interrupt vector to be delivered to user space), and 6) *UPIDADDR*: stores the memory address of the User Posted Interrupt Descriptor (UPID).

In terms of memory resources, each thread has a UPID and a UITT. *UITT* is a table of entries, each storing UV (the user interrupt vector) and ADDRUPID (the address of the target UPID). *UPID* is a memory region storing the interrupt state (*e.g.*, the pending flag (*PIR*) and vector (*NV*)), so that both hardware and the OS can manage user-level interrupts.

User Interrupt sending. Intel provides a new instruction, *SENDUIPI*, to send UIPIs, which takes an index into the UITT as its parameter. Upon execution, the hardware first locates the entry in the UITT using the provided index. It then retrieves the ADDRUPID field to locate the target UPID, updates the PIR field according to the UV to post the interrupt, and finally delivers the interrupt to the target core.

User Interrupt handling. When a UINTR is signaled to a core, the receiving CPU proceeds through three sequential stages: 1) Identification: The CPU first checks whether the incoming interrupt vector matches UINV. If not, the interrupt is processed as a conventional kernel-managed interrupt; otherwise, it proceeds to the next stage. 2) Notification Processing: Once identified as a UINTR, the CPU copies the bitmap of pending interrupt requests from the PIR field of the associated UPID into UIRR, clears the PIR field, and proceeds to deliver each interrupt corresponding to a set bit in the UIRR. 3) Delivery: When the CPU subsequently enters user mode, and the UIRR indicates pending interrupts, the CPU transfers control to the user-level interrupt handler whose address is stored in the UIHANDLER register.

2.3 Related Work

The importance of μs-scale networking has motivated a rich body of prior work, summarized in Table 1. We draw two conclusions from the table: 1) Most prior work does not support all three types of scheduling, failing to be a fully functional network runtime; and 2) all prior work uses centralized entities for at least one scheduling type, hindering the whole

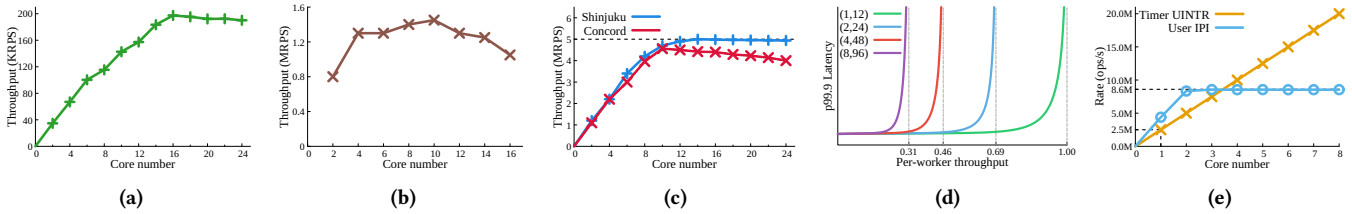

Figure 3: The centralized entities incur poor scalability. (a)–(c) show the scalability bottlenecks of centralized entities individually for request preemption, CPU allocation, and request load balancing. (d) shows that using multiple centralized entities for request load balancing causes imbalance again, in which (n, m) means n dispatchers and m workers. (e) shows the scalability problem of using user IPIs.

system's scalability.

We next introduce how prior work performs the three types of scheduling (§2.3.1), and analyze the limits of centralized entities (§2.3.2) in detail.

2.3.1 How Prior Work Performs Scheduling

Request preemption is often performed by a centralized timer that sends preemption signals to workers when time quantum expires. Although the specific preemption mechanisms differ, they all follow a similar architecture: a dedicated centralized component manages the preemption of a group of workers, which are responsible for actual request processing. Existing works use advanced preemption mechanisms to minimize the overhead. For example, Shinjuku [54] uses virtualization-hardware-assisted IPIs, Concord [51] employs compiler instrumentation, while Libpreemptible [63] and Aspen-KB [43] utilize Userspace IPIs. Despite this, all these advanced mechanisms still rely on a centralized entity.

CPU allocation uniformly uses a centralized entity when present. Some prior systems give up supporting multi-application co-location (see Table 1)—an approach that is increasingly unacceptable given the growing demand for CPU efficiency in datacenters. Other systems, such as Shenango [74] and Caladan [38], introduce a centralized component to dynamically manage CPU core allocation. They employ a dedicated monitor that continuously monitors queue backlog on NICs and decides whether cores need to be reallocated to LC tasks to handle load bursts.

Request load balancing can be 1) centralized or 2) decentralized. The userspace network runtimes at an early stage usually adopt decentralized architecture, only relying on Receive Side Scaling (RSS) [15], a modern NIC hardware mechanism to steer incoming packets to cores. This is achieved by mapping each packet to a flow (based on, *e.g.*, the source and destination IP addresses and ports, and the protocol number), and then assigning each flow to a core.

However, the flow steering hardware suffers from load imbalance, as different cores may be allocated skewed flows. Recent works [38, 43, 76] alleviate the hardware drawbacks with task stealing, but suffer from performance issues [54, 71]. By contrast, more recent systems [51, 53, 54, 70, 74] choose to use a dedicated dispatcher thread to poll the single NIC queue, handle network protocol processing, and send the packet to an idle worker.

2.3.2 The Scalability Bottlenecks

Although the three types of centralized components, *i.e.*, timer, monitor, and dispatcher, could support each scheduling type to some extent, they unavoidably become the bottleneck of the whole system, as the number of workers increases. In order to analyze each type of centralized component in a targeted manner, we select representative systems and conduct focused tests in the corresponding scenarios, showing their impact on scalability.

Scalability bottleneck 1: centralized timer. We select Shinjuku [54] as a representative system that implements request preemption, which uses one centralized timer to record the processing time of each worker, and when the processing time exceeds the time quanta, sends an IPI to interrupt it, forcing it to switch to the next packet.

To investigate Shinjuku's scalability problem, we conduct a heavy-tailed workload test with an increasing number of workers. As shown in Figure 3a, when the number of workers exceeds a threshold, the throughput of the system stops increasing and even decreases. Further analysis reveals that the timer becomes the bottleneck once the number of workers exceeds 16: when many workers need preemption simultaneously, the timer cannot send IPIs to all of them during the configured preemption interval (*e.g.*, 5μs). Previous studies have also shown the centralized timer's scalability limitation when using many workers [43, 70].

Scalability bottleneck 2: centralized monitor. Caladan [38] is state-of-the-art network runtime that supports multi-application co-location, and acts as a basis for subsequent works [39, 65, 71]. It introduces a component called iokernel, which acts as a centralized monitor, checking whether any LC task thread has accumulated packets in its NIC queue every scheduling interval (typically 10μs). If so, it preempts a core from a BE task and reassigns it to the LC task. If the backlog remains, iokernel repeats the process in the next interval, continuing until the load burst subsides.

To evaluate iokernel's ability to reallocate cores, we modify Caladan's load generator following on-off network patterns, which are common in the real world [25, 26, 41]. The gen-

erator alternates between two phases every 1 ms: Phase 1 produces a specified load, and Phase 2 stops sending packets. Other testbed configurations are the same as §6.3.

We set the SLO to a p99.9 latency below 50μs and measure the maximum load Caladan could sustain without SLO violations for different worker counts. As shown in Figure 3b, Caladan exhibits poor scalability. The reason lies in the iokernel: as the load and number of cores increase, it fails to reallocate enough cores to LC tasks in a timely manner when packets arrive in bursts, which easily causes SLO violations.

Scalability bottleneck 3: centralized dispatcher. To evaluate the centralized dispatcher's ability to perform load balancing, we select Shinjuku and Concord [51] to exclusively run Fixed(1) workload (see Table 3), to exclude the need for request preemption and CPU allocation. Figure 3c shows that the overall throughput has an upper limit of 5MRPS. A straightforward calculation validates this issue: even though Shinjuku employs various optimizations (such as batching and simplifying protocol logic) to largely reduce the packet's processing overhead for dispatcher (200ns measured on our machine on average), since all the packets are processed by dispatcher, the maximum packet processing rate of the system is capped at $1/200$ ns $= 5$ MRPS. It is analogous to a river whose overall flow remains constrained by the narrowest upstream section, no matter how much the downstream channel is widened.

Multiple dispatchers do not help. The scalability bottleneck of centralized dispatchers is widely admitted [43, 54, 71], and a common assumption is that a viable solution is to deploy multiple dispatchers, each responsible for dispatching a subset of packets [54, 85].

The experiment results refute this belief. Figure 3d shows that multiple dispatchers suffer from load imbalance again. We constrain each dispatcher to manage only 12 workers in a group. As the number of groups increases, the throughput on average decreases notably.

User IPIs do not scale. Although UINTR is a relatively new technology, it has already been adopted in several systems, primarily for sending userspace inter-processor interrupts (UIPIs) [39, 43, 63, 65].

However, although UIPI provides higher performance, it has a limited sending rate regardless of the number of cores used, as shown in Figure 3e. Although we increase the number of senders that use dedicated cores sending user IPIs, the rate of interrupts still has an upper limit, which is attributed to one NUMA's constraint. This result means the IPI operations still cannot scale with the workers, even when adding more cores to serve as the timer or monitor.

3 Enabling Decentralized Network Runtime

Based on the following analysis and experiments, this section concludes the design goals (§3.1) and presents the key design ideas behind SBB, enabling it to eliminate centralized entities for all three types of scheduling without sacrificing performance benefits (§3.2 and §3.3).

3.1 Design Goals

SBB aims to build a purely decentralized userspace network runtime, identifying the following as design goals:

High Scalability. Since multi-core collaboration is essential in datacenters to ensure that CPU processing keeps pace with the rapid evolution of NIC hardware, SBB's foremost goal is to construct a network runtime with strong scalability.

High Performance. SBB's scalability across multiple cores must not come at the cost of performance with fewer cores. Regardless of the number of workers, SBB should achieve better performance than existing systems, supporting higher throughput and lower tail latency across various workloads.

High Efficiency. To improve CPU utilization and save energy, SBB must support the co-location of LC applications with other applications on the same cores, saving idle CPU cycles without decreasing LC applications' performance.

3.2 Decentralized Preemption and CPU Allocation

Through further analysis, we next discuss, for request preemption and CPU allocation, (1) why prior work adopts a centralized design and (2) why SBB can leverage User Interrupt to eliminate it.

Request Preemption. For request preemption, prior work forgoes a decentralized design due to a lack of hardware support. Conventional interrupts trap to the kernel, thus being unsuitable for kernel-bypass runtimes. While Dune [23] enables direct access to privileged hardware features, it does not include timer interrupts, which the OS uses to regain CPU control. Hence, the only viable solution is to use virtualization-assisted IPIs or user IPIs [43, 54, 63].

CPU Allocation. This demand is fundamentally caused by the inherent conflict between polling and multi-application co-location [47]. While polling offers lower overhead, it carries an unavoidable drawback: without interrupts, an application can learn about packet arrivals only when it is actively running on a core and polling. Once descheduled, the application has no means of receiving notification of new packets until the scheduler assigns it a core again, which typically takes millisecond intervals, unacceptable for microsecond-scale network requests [65]. Facing this challenge, prior work requires an entity to monitor and perform CPU allocation.

Our approach. Our observation is that UINTR can eliminate the centralized entity for both scheduling types. To enable request preemption, SBB delivers per-core timer interrupts to userspace (§4.3), without an upper limit on preemption rates (Figure 3e). For CPU allocation, SBB forgoes polling and delivers NIC UINTR, enabling the worker core to be aware of packet arrivals promptly without a centralized entity (§4.2).

Our use of UINTR departs from most prior work. As discussed in §2.3.2, prior work focuses on UIPI as a faster alternative to IPIs for centralized preemption. Rather, SBB delivers NIC and timer interrupts to userspace, enabling a decentral-

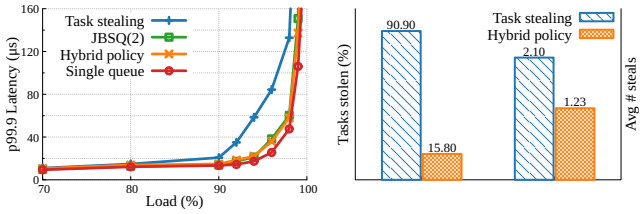

Figure 4: Simulation results of different load balancing policies.

ized design. A traditional concern about our design is that interrupts may be too expensive for μs-scale networking [22]. However, the breakdown experiments show that both NIC and timer UINTR are high-performance mechanisms (§6.5).

3.3 Scalable and Effective Request Load Balancing

Contrary to the conventional wisdom that centralized design performs better, we find that with proper scheduling policy, decentralized request load balancing achieves quality matching centralized schemes. We demonstrate this using a prior simulation system [71]. Keeping most setups unchanged, we add the simulation of NIC RSS mechanism and group the packets into flows.

We evaluate four designs. 1) **`Single queue`** represents the optimal case proven by queuing theory [81], where an idle worker always fetches requests from a shared queue, thus achieving perfect load balancing. However, this design is impractical on real systems, due to contention on the shared queue. 2) **`JBSQ(2)`** is the closest approximation [51] to `Single queue`, and thus the best centralized design. In this case, each worker owns a two-slot private queue, and a centralized entity dispatches requests from the shared queue to the shortest worker queue. 3) **`Task stealing`** is the prior best decentralized design, making idle workers steal requests from other workers. The stealing overhead is set to 200ns, following the prior work's configuration. 4) **`Hybrid policy`** is the two-level load balancing policy used by SBB.

Figure 4a shows that `task stealing` is still far from `JBSQ(2)`, and Figure 4b shows why. We record two metrics when the load is 95%: 1) **`Tasks stolen`** represents the percentage of completed tasks that are stolen at least once. 2) **`Average number of steals`** counts the average number of steal events among all the stolen tasks. It shows that task stealing performs badly due to too many stealing events, which cause cache misses. After collecting the information of those stolen packets, we are surprised to see that most packets belong to only a few flows, which means due to the randomness of RSS, some cores are assigned much fewer flows than other cores, making the former continue stealing packets in a flow from the latter.

Our approach. The analysis shows that the poor performance of a decentralized design is not inherent. Our main observation is that the flow-to-core mapping in NIC steering

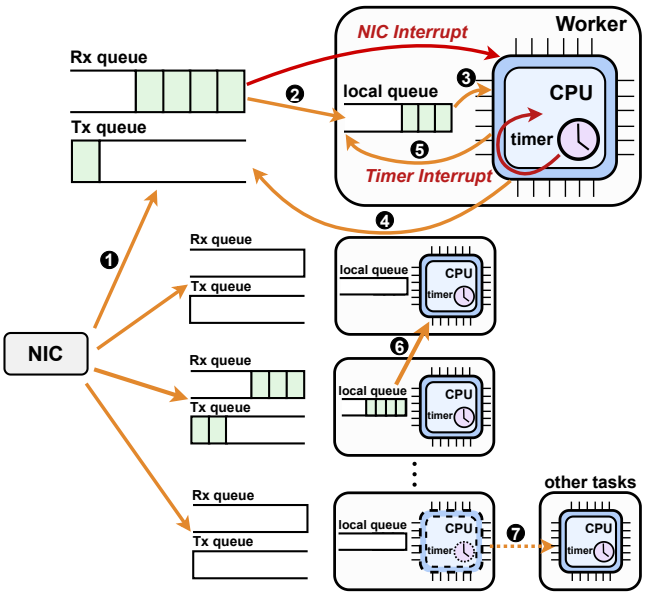

Figure 5: Overall architecture of SBB.

hardware causes both 1) temporary load imbalance, where a flow experiences a burst of requests, and 2) persistent load imbalance, where some cores are assigned too many flows. Task stealing enables a worker experiencing a sudden burst of incoming packets to offload packets to others, which is only suitable for the former, not the latter, where it suffers from continuous and excessive cache coherence overhead and thus underperforms.

Therefore, we propose a two-level decentralized load balancing design, marrying task stealing with flow migration to handle comprehensive load imbalance. The simulation shows that this hybrid policy largely reduces unnecessary stealing (Figure 4b) and achieves nearly the same performance as `JBSQ(2)` (Figure 4a).

4 Design

4.1 An Overview of SBB

Figure 5 illustrates the overall architecture of SBB. Instead of employing any centralized components, SBB builds a purely decentralized network runtime. Each worker thread is bound to a CPU core and maintains its own local queue and local timer. The NIC provides each worker thread with a dedicated set of Rx and Tx queues. As a result, from a global perspective, every component belongs exclusively to one worker thread—no shared components exist across multiple worker threads.

The workflow of SBB proceeds as follows: ❶ When a packet arrives at the NIC, it is assigned to one Rx queue via RSS (Receive Side Scaling) [15]. ❷ The Rx queue triggers a user-level NIC interrupt, which is handled by the worker thread in user space. ❸ The worker thread moves packets from its Rx queue into its local queue and then processes them. ❹ After processing a packet, the worker thread con-

structs a response and transmits it via its Tx queue. ❺ A local timer tracks the processing time of each packet, and triggers a timer interrupt if a packet's processing exceeds the predefined quanta. The worker's CPU then saves the packet's state, requeues it, and proceeds to the next packet. When a worker thread finds its Rx queue empty and has no packets to process, it ❻ performs task stealing or flow migration to balance the load; if still failing to obtain new packets, it ❼ yields the core to other co-located applications to increase CPU efficiency.

This purely decentralized architecture provides inherent advantages for scalability. All workers can directly send and receive packets through the NIC, enabling fully parallel dataplane processing without centralized dispatching. In the control plane, the removal of all centralized components eliminates the need for any central entity to issue control signals—including those for request preemption and CPU allocation. By eliminating centralized components (*i.e.*, timer, monitor and dispatcher) used by prior work (§2.3.2), SBB allows the system's overall throughput to scale nearly linearly with the number of workers.

However, this model also introduces key challenges: SBB still needs to perform three types of scheduling to provide high throughput, low latency, and high efficiency. The following sections describe how SBB provides each of these scheduling functions.

4.2 Timely CPU Allocation

Choosing interrupt over polling. As demonstrated in §2.3.2, polling has an inherent conflict with multi-application co-location, while Caladan's centralized monitor cannot solve this with great scalability.

Our observation is that interrupt is more suitable than polling for multi-application co-location. We build a prototype for test, which leverages DPDK's interrupt-driven packet reception [7]. The results indicate that while its tail latency is higher, the system shows promising scalability under the given conditions (Figure 3b). When a new packet arrives, the interrupt mechanism promptly wakes up the LC task even if it is not currently running on the core, enabling timely request processing without relying on external control components.

However, conventional interrupt mechanism involves kernel crossing, incurring higher overhead than polling [42, 62], which makes it unsuitable for userspace network runtimes. Therefore, we leverage a new hardware feature, User Interrupt (UINTR), to achieve timely CPU allocation. To the best of our knowledge, SBB is the first to adopt UINTR as a replacement for polling for NIC notification mechanisms.

Delivering device user interrupt. Although UINTR has been adopted in several recent works, most utilize it solely for UIPIs [19, 39, 43, 45, 63, 65]; no prior work has employed UINTR as a notification mechanism for NICs. This is because the current user-interrupt hardware is not designed to handle interrupts generated from devices, *e.g.*, NICs. As described in §2.2, the CPU can only proceed to the interrupt handler in the third step if two earlier conditions are met: 1) The interrupt vector from the NIC must match UINV, and 2) the PIR field must be non-zero.

Meeting the first condition is relatively straightforward: during initialization, the interrupt vector of each NIC queue can be obtained, and UINV can be set accordingly. However, satisfying the second condition is challenging because even if a bit in PIR is set initially, it will be cleared during the first UINTR handling cycle. To continuously receive NIC-generated user interrupts, the PIR must be rewritten after each interrupt is processed. The UINTR hardware does not provide a low-overhead mechanism for userspace programs to achieve this: either issuing a SENDUIPI to oneself, which would generate an IPI, or trapping into the kernel to modify PIR, thus forfeiting the performance benefit of kernel bypass.

To overcome this limitation at low cost, some systems have introduced software workarounds [53, 61]. We use the approach proposed by Aeolia [61]: during initialization, a new system call maps UPID into the address space of the user program. This enables the application to rewrite PIR after handling each NIC-generated user interrupt, thereby re-arming the next UINTR.

Reallocating cores via interrupt. We replace polling with UINTR as the NIC notification method, achieving a low-overhead mechanism that is suitable for CPU sharing. When a packet arrives at the NIC, the corresponding queue raises an interrupt to its assigned core. If the LC task is currently running on that core, the interrupt is delivered directly to the registered handler in user space, introducing minimal overhead compared to polling (see §6.5). If the LC task is not running, which is the case where polling cannot handle efficiently, the interrupt vector will not match UINV, causing the interrupt to be processed as a traditional kernel interrupt. During initialization, SBB registers a custom kernel handler for each NIC queue, which triggers when packets arrive while the associated LC task is inactive. This handler wakes up the LC task and invokes the scheduler, allowing the task to regain CPU resources and process the request promptly.

Compared to polling-based sharing approach, adopting UINTR fundamentally resolves the conflict between polling and CPU sharing. Furthermore, in contrast to Caladan's centralized and passive CPU scheduling, SBB enables each core to actively and promptly switch among multiple applications without relying on external components, demonstrating both high performance and strong scalability under load bursts.

Avoiding interrupt storm. One natural concern about interrupts is the interrupt storm, *i.e.*, packets arriving at high rates may trigger interrupts so frequently that interrupt handling consumes excessive CPU cycles and influences other packets' processing [48, 56].

SBB avoids this classic problem by leveraging NIC's auto-mask capability (introduced in §4.4), which is similar to in-

terrupt moderation [20]. As shown in Figure 6, SBB only unmasks NIC interrupt and receives packets at step 1; during other steps, SBB keeps NIC interrupt masked, to prevent it from influencing these packets' handling. Evaluation demonstrates that this approach can effectively mitigate the interrupt storm issue at high loads (Figure 8a).

4.3 Decentralized Request Preemption

Delivering user interrupt for LAPIC timer. Since a centralized entity that performs request preemption unavoidably becomes the bottleneck (§2.3.2), a decentralized preemption mechanism is needed, leveraging per-CPU capabilities to self-preempt. We observe that modern CPUs are equipped with a single LAPIC timer, which can be configured in various timing modes to trigger interrupts on the local CPU at preset intervals. This approach 1) does not depend on external components, thus offering good scalability [43, 54, 63], as well as 2) offers high precision that compiler instrumentation techniques cannot achieve [43, 51, 70].

However, the LAPIC timer has a critical drawback: its traditional preemption approach (Linux's *setitimer*) involves multiple switches between user and kernel space, resulting in an overall overhead of approximately 3μs, which is higher than several existing mechanisms (see Table 4). To integrate the timer interrupt mechanism into μs-scale network runtimes, it is essential to reduce the overhead.

Fortunately, we find that UINTR can be used to handle timer interrupts directly in user space, similar to NIC interrupts. During initialization, each worker thread configures its LAPIC timer to use the same interrupt vector as the NIC interrupt, which is also the same as UINV value. Therefore, when the timer interrupt is triggered, the CPU jumps directly to the user-level handler, completely bypassing the kernel.

Request preemption workflow. SBB performs request preemption as follows: before each LC task thread processes a request, the worker arms a one-shot timer interrupt that fires after a specified time quantum. If the current request finishes within the quantum, the LC task thread resets the timer for the next request. Otherwise, this means a long request is being processed, and a userspace timer interrupt is triggered. The worker preempts the current request, saves its execution context to the local request queue, and schedules the next request for processing.

Programming the timer interrupt costs only 50 cycles on our machine, incurring negligible overhead. This is because it only requires writing to two registers (APIC_LVTT and APIC_TMICT), both of which have been mapped into the userspace memory during initialization. As shown in §6.5, timer UINTR achieves both low latency and high scalability.

4.4 Combining Two User Interrupts

One challenge in SBB is to enable the coexistence of timer UINTR and NIC UINTR, which is not solved by prior work such as Skyloft [53] and Aeolia [61]. This challenge exists because when the CPU jumps to the user interrupt handler,

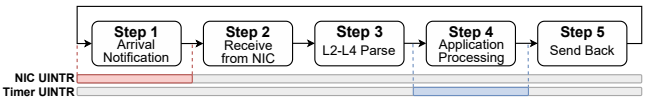

Figure 6: SBB's request processing flow.

there is a need to distinguish the interrupt source, as the CPU must handle timer and NIC UINTR differently. However, Intel does not provide support for this need. For a given CPU, there is only one set of UINTR register resources (*e.g.*, UIHANDLER, UINV). Regardless of the interrupt source, all UINTRs jump to the same handler address, making it impossible to distinguish their sources directly. Moreover, control functions such as *stui* and *ctui* can only enable or disable all UINTRs indiscriminately, which does not meet the need to disable one while keeping the other active. Therefore, enabling two device UINTRs to coexist—each performing its function without conflict—becomes a key problem that SBB must solve. To the best of our knowledge, SBB is the first work to attempt the coexistence of two UINTRs.

SBB's solution is based on two following observations. First, most modern NICs, *e.g.*, Intel E810 [2] and Mellanox ConnectX-5 [6], automatically disable interrupts after triggering them until the user program explicitly re-arms it. Second, the two types of UINTRs can be active at non-overlapping periods: NIC UINTR is used to notify the user thread of packet arrival, while timer UINTR remains active during application-layer operations. Hence, by carefully partitioning the packet processing stages, SBB can distinguish the interrupt source.

Based on these observations, we refine the packet handling flow in each worker, as shown in Figure 6. Following the Linux interrupt handling model, we divide network request processing into *top half* and *bottom half*. When a packet arrives at the NIC queue and triggers a NIC UINTR, the interrupt handler simply sets a pending flag and returns immediately. The subsequent steps, including dequeuing the packet from the NIC, protocol-stack parsing, application-layer processing, and sending back the response, are carried out by the worker thread.

By partitioning the packet processing flow at fine granularity, SBB ensures that the two UINTRs are never enabled simultaneously. SBB re-enables NIC interrupts only after completing the last batch of requests, excluding long requests that were interrupted and re-queued. As for the period during which timer UINTR should be active, we note that the variation among requests lies mainly in the application-layer processing; the durations of other stages are relatively consistent. Therefore, timer UINTR needs to be active only during application-layer execution to address head-of-line blocking.

This design involves three important advantages: first, keeping NIC UINTR disabled at other stages eliminates the interrupt storm issue when facing high RPC rates (§4.2); second, programming the timer UINTR only during application-layer execution avoids unnecessary interrupts; finally, since each

stage only has one possible interrupt source, this allows SBB to directly identify and control the corresponding UINTR, enabling two types of UINTR to coexist.

4.5 Two-Level Load Balancing Policy

4.5.1 Flow Migration

As shown in §3.3, task stealing is not suitable for handling persistent load imbalance. SBB leverages flow director functionality, which is commonly available in commodity NICs [2, 4, 6], to overcome this challenge. The NIC driver can install rules that steer packets matching specific flow characteristics (*e.g.*, 5-tuples) directly to designated receive queues, while unmatched packets continue to be distributed via RSS. The cost of installing rules is approximately 10 μs, making it suitable for infrequent use in μs-scale network runtimes.

Using this mechanism, when a worker becomes persistently overloaded due to hosting too many or overly heavy flows, SBB can migrate an entire flow to an idle worker. This enables faster and more effective balancing than packet-level stealing. By combining task stealing and flow migration, SBB employs a two-level hybrid load balancing policy that efficiently handles both temporary and persistent imbalance.

In detail, workers have two roles: victims and stealers. When a worker finds its Rx queue empty, it will become a stealer and try to obtain load from other workers, namely victims. Their behavior is as follows.

From the victim's perspective, each worker can be in one of three states: *Light*, *Busy*, or *Overloaded*. After each round of packet reception from the NIC, a worker updates its state based on whether the number of received packets exceeds or falls below predefined watermarks. To avoid transient fluctuations caused by bursty traffic, state transitions are only triggered after three consecutive rounds that satisfy the watermark condition.

Initially, all workers start in the *Light* state. When a worker receives packets above the *LIGHT_TO_BUSY_THRESHOLD* for three consecutive rounds, it transitions to *Busy* state, indicating a temporary burst in load. If a *Busy* worker continues to exceed the *BUSY_TO_OVERLOADED_THRESHOLD* for three consecutive rounds, this indicates persistent overload that cannot be alleviated by task stealing, and the worker transitions to the *Overloaded* state. Upon entering this state, the worker extracts and publishes the flow identifier of the next packet it processes, enabling other workers to migrate that flow. Conversely, if the load falls below low watermarks for three consecutive rounds, the worker transitions back to *Busy* or *Light* accordingly.

On the other hand, from the stealer's perspective, when a worker finds its NIC receive queue empty, it scans other workers to steal tasks. For each candidate worker, the stealer first checks its state. If the worker is *Light*, it likely has sufficient capacity to handle its own load, and stealing is unlikely to be beneficial, so it is skipped. If the worker is *Busy*, this indicates temporary overload, and packet-level task stealing is sufficient. The stealer attempts to access the victim's queue and steal half of the pending requests for processing. If the worker is *Overloaded*, this indicates sustained overload and flow migration is preferred. In this case, the stealer retrieves the published flow information and installs a NIC rule to redirect the corresponding flow to its own queue.

4.5.2 Enhanced Task Stealing

Although SBB introduces flow migration, we find that task stealing remains necessary. If only flow migration is used, even if we directly control flows to be perfectly the same across workers in terms of number and size—ensuring equal load over longer time scales—performance still degrades. This is because the bursty nature of network traffic leads to short-term load imbalance that flow migration alone cannot address. In summary, task stealing and flow migration are complementary: the former is effective for handling temporary imbalance, while the latter addresses persistent imbalance. Only by combining both can SBB robustly handle diverse network load conditions.

Therefore, in addition to introducing flow migration, SBB also incorporates several optimizations to task stealing. We first describe the baseline task stealing workflow, and then present the optimizations applied in SBB.

Baseline task stealing workflow. Each worker receives incoming packets from the NIC and enqueues them into a request queue. Since DPDK achieves optimal performance when receiving packets in a batch of 64, SBB sets the request queue capacity to 64 accordingly. Workers process requests in FIFO order. A worker polls the NIC for the next batch of packets only after its local request queue becomes empty, except for long requests that may be preempted and re-enqueued. Each request queue is protected by a lock.

Optimizations to task stealing. Building on this baseline design, SBB introduces the following optimizations to improve performance:

O1: Owner-exclusive block. SBB reserves the first 16 entries of each request queue as an owner-exclusive block. Requests in this region are invisible to stealers and therefore do not require locking. When the number of incoming packets in a round is below 16, all requests reside within this owner-exclusive block and are processed entirely by the owner worker, avoiding unnecessary stealing at low load. When the number of incoming packets exceeds 16, only the excess requests are placed in the stealer-visible region and may be stolen. This design significantly reduces lock contention and cache coherence overhead under low load.

O2: Avoid multi-stealing per task. A common inefficiency in task stealing systems is multi-stealing, where a request stolen by one worker is subsequently stolen again by another, as shown in Figure 4b. To eliminate this overhead, SBB ensures that once a stealer acquires requests, it processes them directly instead of enqueuing them again

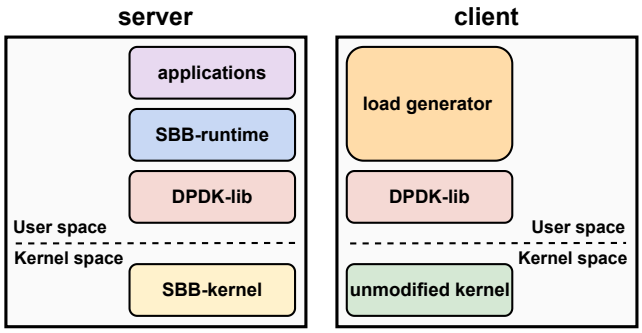

Figure 7: Implementation of server and client.

into its own queue. This prevents repeated stealing of the same request and improves overall efficiency.

O3: Batch dequeuing and stealing. Since each access to the request queue requires locking, SBB amortizes this cost via batching. The owner dequeues a batch of requests (*e.g.*, 16) per lock acquisition and processes them sequentially. Similarly, a stealer acquires the lock once and steals half of the currently available requests in the queue. This reduces the frequency of lock operations and improves cache locality.

O4: Use of try-lock. When attempting to acquire a victim's queue lock, the stealer uses a non-blocking try-lock. If the attempt fails, the stealer does not spin but immediately proceeds to the next candidate worker. This avoids unnecessary contention and wasted CPU cycles.

O5: Victim selection strategy. SBB adopts a locality-aware victim selection policy. A stealer begins scanning from the victim it successfully stole from in the previous round, as that worker is likely to remain in a *Busy* or *Overloaded* state. It then continues scanning other workers in a round-robin fashion. To further reduce contention among multiple stealers, SBB initializes each worker with a different starting point, thereby minimizing the likelihood that multiple stealers target the same victim queue simultaneously.

5 Implementation

SBB's implementation mainly consists of two parts: a kernel patch and a network runtime (Figure 7). The kernel patch, based on Linux kernel 6.12.20, comprises 2,095 lines of code (LOC) and primarily adds support for both NIC and timer UINTR. The network runtime is built on DPDK v25.07.0 [7], to benefit from its wide deployment. It contains 4,343 LOC, implementing all the designs presented in this paper. In addition, it includes a lightweight TCP/UDP network stack used in much prior work [51, 54, 70]. Although the protocol stack lacks some key features (*e.g.*, congestion control), we use it for a fair comparison.

Similar to most prior designs [38, 43, 51, 53, 74], SBB requires application rewrites to integrate with its runtime. SBB defines a runtime interface layer, as shown in Table 2. An application can be ported to the SBB runtime by implementing these three hook functions.

Function Hooks	Description
init_application()	Initialize application's data and modules.
process_request()	Process the request at application layer.
build_response()	Build the payload of application response.

Table 2: The hooks defined by the runtime interface.

For evaluation, we also implement a full-featured client packet generator. Built on unmodified kernel and DPDK, this client can produce workloads with configurable request duration distributions, packet arrival patterns, and transmission rates, consisting of 2,067 LOC.

6 Evaluation

We evaluate SBB to answer the following questions:

1. How does SBB perform with dedicated cores across various workloads? (§6.2)
2. How does SBB behave under multi-application co-location? (§6.3)
3. How well does SBB scale with an increasing number of worker cores? (§6.4)
4. What is the performance impact of each design component in SBB? (§6.5)

6.1 Methodology

Testbed. Our testbed follows the RFC 2544 [29] setup with two directly connected machines: a server running SBB or the baseline systems, and a client generating the load. The server is equipped with two NUMA nodes, each containing a 64-core Intel Xeon Platinum 8592 processor operating at 1.9 GHz. We configure the server following prior work [38]: TurboBoost, CPU idle states, CPU frequency scaling, and transparent hugepages are disabled. The client machine is equipped with a single-socket Intel Xeon 6780E processor, containing 144 physical cores running at 3.0 GHz.

For the NICs, both server and client are equipped with a 100 Gbps Intel E810 NIC [2]. We found that Caladan suffers from performance degradation when using the Intel NIC, so we run Caladan with ConnectX-5 [6] to achieve the best performance, following its guidance [5].

As for the kernel configuration, SBB runs on Ubuntu 24.04 with its custom kernel; while for baseline evaluations, we follow each specific demand: Shinjuku and Concord run on Ubuntu 18.04 with kernel 4.4.0; Caladan and TQ run on Ubuntu 22.04 with kernel 5.15.0; Skyloft runs on Ubuntu 24.04 with its custom kernel. As SBB and baselines are userspace network runtimes, we believe that this does not change the conclusions we reach.

Systems evaluated. Since SBB integrates three types of scheduling, we conduct experiments to evaluate each scheduling type individually. As most prior work does not perform all these scheduling (Table 1), we compare with each

Workloads	Request	Runtime (μs)	Ratio
Fixed(1)	N/A	1	100%
High Bimodal	Short	1	50%
	Long	100	50%
Extreme Bimodal	Short	0.5	99.5%
	Long	500	0.5%
RocksDB-lt	GET	1.25	100%
RocksDB-ht	GET	1.25	50%
	SCAN	613	50%

Table 3: The list of some evaluated workloads.

only for the problem it targets. Since request load balancing is the basis of network runtime, it is evaluated in all experiments. For request preemption, we select Shinjuku [54], Concord [51], and TQ [70] to evaluate SBB's preemption mechanism. For CPU allocation, we compare with Skyloft [53], Caladan [38], and its optimized version, Caladan-DL, which trades off tail latency against CPU efficiency using a Delay Range policy [71].

Workload. To make a fair comparison with each baseline, we follow these prior works to select workloads. Overall, these workloads either run on dedicated cores (§6.2) or share cores with other tasks (§6.3), to evaluate SBB's ability to perform request preemption and CPU allocation, respectively.

To evaluate request preemption, we follow prior work [43, 51, 70] to use one synthetic and one real-world application. The synthetic workload is a server application that spins for the duration specified by each request, which allows us to evaluate SBB under a range of service time distributions. Specifically, we run the Fixed(1), High-Bimodal, and Extreme-Bimodal workloads. Fixed(1) is a low-dispersion synthetic workload with a fixed 1 μs service time for all requests [51, 54]. High-Bimodal is modeled after YCSB's Workload A, which has a balanced read/update mix [31]. Extreme-Bimodal is modeled after Facebook's USR workload, which is dominated by short GET requests with a small fraction of much longer requests [18].

For real-world evaluation, we use RocksDB [14], a popular and widely deployed key-value store developed by Facebook [37]. We build a custom network server atop the RocksDB storage backend. We disable logging and keep all data fit in memory to better stress networking.

To evaluate CPU allocation, we follow Caladan's configuration: Memcached [11] serves as the latency-critical (LC) task, and the swaptions benchmark from PARSEC [27] serves as the best-effort (BE) task. Memcached is an in-memory key-value store with light-tailed workload patterns, while swaptions application computes portfolio prices using Monte Carlo simulations.

6.2 Handling Various Kinds of Loads

Table 3 summarizes the distribution of request duration for various workloads. Unless otherwise specified, all systems use 16 threads, each on a dedicated core.

We first compare the systems under a low-dispersion workload: Fixed(1). In such a scenario, no head-of-line blocking occurs; hence, preemption provides no benefits. Figure 8a shows the results. SBB sustains 9.7MRPS under the 99.9th-percentile slowdown SLO of 50×, achieving over 90% higher throughput than TQ, Concord, and Shinjuku. This improvement mainly stems from SBB's decentralized load balancing policy: when faced with high rates of requests, there is no centralized dispatcher becoming the bottleneck of the system.

We evaluate SBB's ability to perform request preemption with two synthetic high-dispersion workloads, with Figure 8b and Figure 8c showing the results. For the High-Bimodal workload, SBB reaches 260KRPS, outperforming baselines by more than 30%. Under the Extreme-Bimodal workload, SBB achieves more than 40% increase in throughput. These gains are attributed to SBB's decentralized, low-overhead preemption mechanism, demonstrating that even with a modest number of cores and without scalability in mind, SBB delivers superior performance.

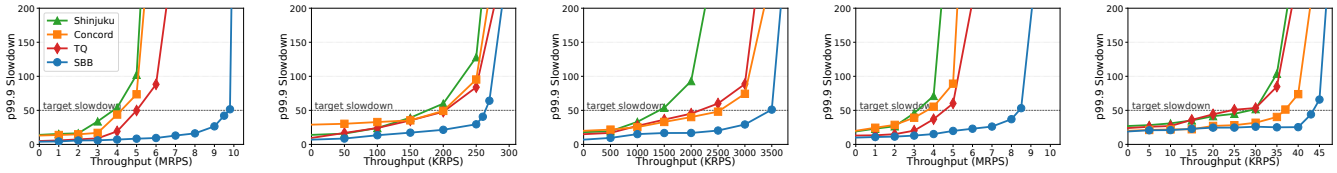
To evaluate SBB's performance on real-world workloads, we run RocksDB with both light-tailed (Figure 8d) and heavy-tailed patterns (Figure 8e). At the same SLO target, SBB supports 20% to 80% higher throughput over prior work. Notably, these comparisons use a small number of workers for all systems; thanks to its better scalability, SBB will exhibit even larger performance gains as the number of workers increases.

Summary. SBB provides high performance with dedicated cores across various workloads, due to its load balancing policy and request preemption mechanism.

6.3 Sharing CPU Resources

To demonstrate that SBB can improve CPU utilization by yielding CPU resources to BE tasks while LC tasks have low load, we compare it with Skyloft, Caladan and Caladan-DL. We use 16 CPU cores, where Memcached and swaptions are each launched with 16 threads and bound to dedicated cores. For Skyloft and Caladan, one more dedicated core is required for the iokernel. In contrast, SBB has no centralized component; each core runs both a Memcached thread and a swaptions thread. Clients send packets following a Poisson distribution [72]. When a packet arrives at the NIC, the Memcached thread is scheduled to run and yields the CPU core to the swaptions thread during idle periods.

Figure 9a shows the results of the LC task. Skyloft performs worst for the same reason as Shinjuku: the centralized dispatcher limits the overall throughput. Unlike Skyloft, by allowing each worker to receive packets directly from the NIC instead of relying on a centralized dispatcher, both SBB and Caladan surpass the 5MRPS limit. Under an SLO of p99.9 latency less than 100μs, SBB achieves throughput improvements of 28% and 15% over the two Caladan variants, respectively. We attribute this to its proactive scheduling



(a) Fixed(1) **(b)** High Bimodal **(c)** Extreme Bimodal **(d)** RocksDB-lt **(e)** RocksDB-ht

(a) Tail latency for Fixed(1). **(b)** Tail latency for Memcached.

Figure 10: Co-location of multiple LC tasks.

mechanism: when a packet arrives while a BE task is running, SBB uses interrupt-based notification to immediately trigger a process switch. This approach yields lower tail latency and higher load tolerance compared to Caladan's passive strategy, which reassigns cores only after detecting packet delays.

Figure 9b illustrates the throughput of the BE task, excluding Skyloft, which runs Memcached on dedicated cores. All three systems yield CPU resources to the BE task under low load, with BE utilization decreasing as load increases. Compared to the original Caladan, Caladan-DL increases tolerance to packet delays, thereby improving CPU efficiency at the cost of higher tail latency. SBB, on the other hand, achieves the lowest tail latency while delivering CPU efficiency comparable to that of Caladan-DL, demonstrating its strength in sharing CPU resources across applications.

SBB also supports other co-location patterns, *e.g.*, multiple LC tasks co-location. We run a Memcached instance and a synthetic application on a set of cores, and use the client to generate a mix of Memcached and synthetic requests. Figure 10 shows SBB's ability to perform CPU allocation when running multiple LC tasks.

Summary. Using NIC UINTR to perform CPU allocation, SBB achieves both lower latency and higher efficiency when co-locating multiple applications.

6.4 Scaling to More Workers

By leveraging User Interrupt and two-level load balancing policy, SBB effectively performs three types of scheduling, outperforming prior work. A further and more important question is: how does SBB scale? As NIC hardware advances, processing network requests at line rate requires an increasing number of worker cores, placing greater demands on the scalability of the network runtime.

We demonstrate SBB's strong scalability through the following experiments that individually evaluate SBB's scalability for three types of scheduling (Figure 11).

First, we evaluate Fixed(1) with varying numbers of workers, using the same configuration as in Figure 8a. Under the same SLO, the achievable throughput for 16, 32, and 48 workers is approximately 9.5, 19, and 26.5MRPS, respectively (Figure 11a). For reference, we also plot ideal linear scalability, corresponding to 2× and 3× the throughput of the 16-worker case. The results show that when scaling from 16 to 32 workers, throughput nearly doubles, indicating great scalability. Scaling from 16 to 48 workers yields 2.8× higher throughput, although the growth rate slightly declines. We attribute this sublinear scaling mainly to overhead from load balancing when using too many cores, which we will discuss in §7. Despite this minor limitation, we expect SBB's throughput to continue increasing up to at least 64 cores. In contrast, Shinjuku, Concord and TQ show almost no improvements when increasing from 16 to 32 workers, due to the bottleneck of the centralized dispatcher.

Second, we use the High Bimodal and Extreme Bimodal workload to measure the maximum SLO-satisfying throughput across different worker counts. As shown in Figure 11b and 11c, when increasing from 16 to 32 workers, the throughput scales from 260 to 520KRPS, and from 3.4 to 6.8MRPS, demonstrating the perfect scalability for performing request preemption. With 48 workers, we observe a pattern similar to that of Fixed(1): though the gain is slightly below ideal linear scaling, throughput still increases by more than 35% compared to the 32-worker case. This confirms that the timer UINTR mechanism introduces no scalability issues and effectively resolves head-of-line blocking.

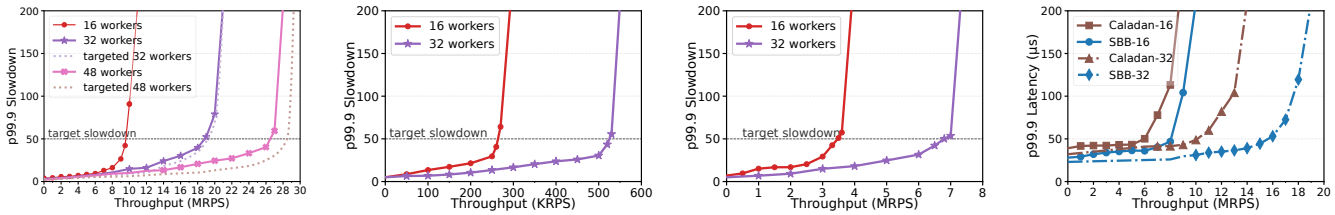

Figure 11: Scalability evaluation for various workloads. (a), (bc) and (d) are used to individually evaluate SBB's scalability for performing request load balancing, request preemption and CPU allocation.

Finally, we run experiments with both Memcached and swaptions co-located on varying worker counts to evaluate how well SBB scales while improving CPU efficiency. The setup resembles that of Figure 9. For a fair comparison focused on low tail latency, we use the original Caladan rather than Caladan-DL. Results in Figure 11d show that, under a p99.9 latency SLO of 50μs, SBB's throughput scales from 8 to 16MRPS, demonstrating excellent scalability. In contrast, Caladan scales only from 6 to 10.2MRPS. In fact, at 32 workers, Caladan nearly reaches its scaling limit: we find adding more workers slightly reduces its SLO-compliant throughput, consistent with prior observations [65]. This is because, beyond a certain number of workers, the centralized iokernel becomes a bottleneck when scanning NIC queues and assigning cores, ultimately limiting scalability.

Summary. SBB achieves good scalability for all three types of scheduling, across various workloads.

6.5 Breakdown of Each Design Component

We now evaluate the individual components of SBB using microbenchmarks.

NIC UINTR. For an actively running application thread, the fastest notification mechanism for packet arrival is continuous polling of the NIC queue, which introduces nearly negligible latency. In contrast, interrupt-based mechanisms, no matter whether they bypass the kernel or not, involve at least interrupt handler processing and thus incur additional latency. A natural concern is that interrupt latency may impose substantial overhead compared to polling.

To assess this, we design the following microbenchmark: we implement a network program that simulates processing a 1μs request while keeping all other logic identical, and vary the packet notification mechanism among polling, UINTR, and the conventional interrupt mechanism provided by DPDK. We timestamp each stage of the process and collect the results on the client side. Figure 12 presents the breakdown of round-trip latency.

The results show that on two Intel E810 100 Gbps NICs, the end-to-end propagation delay over the data link is 9μs, packet parsing in the network stack takes about 0.3μs, and the application layer consumes the specified 1μs. Compared with polling, UINTR adds an extra 0.45μs in notification latency

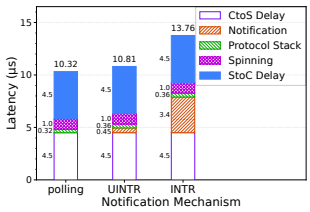

Figure 12: Breakdown of round-trip latency.

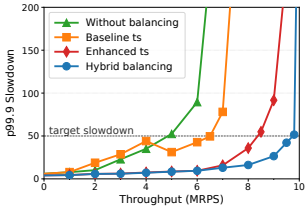

Figure 13: Different load balancing configurations.

and increases network stack overhead by 0.04μs—which we attribute to cache effects caused by the interrupt. Thus, the total additional overhead of UINTR over polling is 0.49μs, accounting for 4.7% of the end-to-end latency. We also repeat the measurement on a ConnectX-5 NIC, where the baseline link propagation delay is 4.7μs; in this case, UINTR increases the end-to-end latency by 8.1%. Given that UINTR directly enables CPU sharing and its overhead remains modest, we consider it acceptable, especially for SLOs that typically allow a slowdown factor of up to 50×.

We also compare conventional interrupts with UINTR. The notification overhead of a conventional interrupt is 3.4μs, significantly higher than UINTR's 0.45μs. This is because conventional interrupts traverse the kernel and incur scheduling overhead; the interrupt mechanism itself constitutes only a small fraction of the total cost. In conclusion, adopting NIC UINTR as the packet-notification mechanism fundamentally enables network runtimes to perform CPU allocation, while incurring low additional latency.

Timer UINTR. Table 4 compares the overhead of several common preemption mechanisms used in userspace network runtimes. Timer UINTR exhibits notably lower overhead than signals, IPI, and UIPI, allowing it to employ a smaller preemption quantum and further mitigate head-of-line blocking. Although the compiler instrumentation technique achieves lower overhead by polling, it suffers from the imprecise preemption problem [43]. More importantly, timer UINTR offers a unique architectural advantage: it enables each worker to preempt itself, eliminating the centralized component that other methods rely on.

Preemption Mechanism	System	Latency (cycles)
Signal-based timer	Linux	7697
Custom IPI	Shinjuku [54]	1878
User IPI	Aspen-KB [43]	1381
Timer UINTR	SBB	688

Table 4: Latency comparison of preemption mechanisms.

Load balancing policy. To evaluate SBB's two-level load balancing policy, we run the Fixed(1) test with various balancing strategies. Keeping all other configurations the same, we modify the balancing policy as follows: 1) **`Without balancing`**: each worker only processes requests in its own Rx queue assigned by RSS; 2) **`Baseline ts`**: a basic task stealing implementation similar to Shenango's; 3) **`Enhanced ts`**: the improved task stealing scheme described in §4.5.2; 4) **`Hybrid balancing`**: the two-level load balancing policy used by SBB.

Without any balancing policy, SBB reaches its SLO limit much earlier because, under RSS's random packet-to-queue assignment, system capacity is constrained by the most heavily loaded worker. With basic task stealing, SBB achieves higher throughput, but an interesting phenomenon is that it suffers from even higher tail latency at lower loads. Through further analysis, we find that this is due to too much unnecessary task stealing, which provides no benefit but instead introduces synchronization overhead. Based on the analysis, we enhance task stealing with several optimizations (§4.5.2), which mainly reduce unnecessary stealings and synchronization overhead, and increase the throughput by 30%. Nevertheless, when the load is too high, there are still too many stealings incurring overhead, most of which come from only a few flows. SBB's two-level load balancing policy effectively mitigates this problem. By addressing temporal imbalance with task stealing and persistent imbalance with flow migration, SBB achieves notably higher throughput, which demonstrates the necessity of the combination of task stealing and flow migration.

Summary. NIC and timer User Interrupt can function with low overhead, and the hybrid policy can perform load balancing effectively.

7 Discussion

Hardware-offloaded scheduling. To process RPCs at microsecond-scale latencies, besides those works running on commodity hardware (Table 1), there are also some recent works leveraging NIC-CPU co-design [32, 46, 49, 64, 77, 85]. They use the on-board FPGA or ARM of SmartNICs to offload the scheduling, such as implementing JBSQ policy for request load balancing [49, 57].

The hardware-offloaded approach does have some exclusive advantages, as the programmable NIC has a global view and higher processing speed. However, they also have some challenges: some hardware is able to compare only a limited number of registers in one pass, which means the performance also degrades when scaling to more workers [57]. More importantly, these approaches rely on specialized hardware modification, which precludes wide adoption in the near future [51]. In comparison, SBB uses only a software implementation and relies on commodity hardware functions (*i.e.*, User Interrupt, RSS, flow director), suitable for both datacenters and VMs in public clouds.

SBB's scalability limitation. Although SBB eliminates all centralized components and exhibits much better scalability than prior work, it is not perfectly scalable beyond 48 cores (Figure 11a). This is attributed to the synchronization overhead of inter-core communication, *i.e.*, task stealing and flow migration. Although SBB leverages user interrupt to enable each core to perform request preemption and CPU allocation independently, and introduces the two-level load balancing policy to largely reduce task stealing frequency, the overhead still exists, and will enlarge when scaling to more cores.

We identify three potential directions to achieve better scalability. First, we can offload scheduling to SmartNICs, as discussed earlier. Second, we can continue to improve task stealing algorithm to satisfy the commutativity rule [30], which enables better scalability. Although there is already much work improving task stealing [28, 36, 40, 44, 80, 86], no algorithms follow the commutativity rule. Third, we may leverage some commodity hardware features, similar to using UINTR to perform request preemption and CPU allocation. We notice that Dynamic Load Balancer (DLB) is a new feature in Intel Xeon Scalable Processor, which is designed to mitigate the load imbalance problem [68]. Although it could not be used trivially in SBB's purely decentralized architecture, we view leveraging this to perform load balancing with better scalability as promising future work.

8 Conclusion

This paper presents SBB, a purely decentralized userspace network runtime. Designed with scalability as its foremost objective, SBB performs request preemption, CPU allocation, and request load balancing to provide high performance and efficiency, without any centralized components as potential bottlenecks. Our evaluation demonstrates that SBB outperforms baseline systems by 1.7× to 5.2× across a variety of scenarios and workloads.

Abstract

Delivering RPCs with high throughput and low latency demands work-conserving scheduling across many CPU cores and eliminating head-of-line (HOL) blocking across all messages. By exposing per-connection byte streams rather than messages to userspace, the POSIX TCP API inherently induces HOL blocking both within and across connections. To mitigate HOL blocking, RPC frameworks such as gRPC must reconstruct message semantics in userspace through additional abstractions including dedicated I/O threads, work queues, and worker thread pools, introducing significant context switching and synchronization overheads.

This paper presents Rakaia, a framework that hides all TCP-level abstractions from userspace and exposes a purely message-oriented API. By performing message parsing and work-conserving scheduling directly in the kernel's TCP receive path, *at the earliest possible point*, Rakaia efficiently eliminates HOL blocking and avoids the heavy userspace machinery imposed by stream-based APIs.

We implemented Rakaia as a Linux kernel module with support for kTLS. Rakaia is compatible with the kernel's TCP stack and existing RPC protocols. We also adapted gRPC to use Rakaia's API. Our evaluation shows Rakaia: *(i)* consistently eliminates HOL blocking across a wide range of connection counts; *(ii)* achieves up to 5× higher throughput-under-SLO than KCM, Linux's current in-kernel message API over TCP; *(iii)* improves gRPC-Go's throughput-under-SLO by up to 1.56×, and gRPC-C++'s by up to 2.69×; and *(iv)* improves the throughput-under-SLO for real-world applications including Silo running TPC-C and OpenTelemetry Collector by 1.39× and 1.42×, respectively.

1 Introduction

Remote Procedure Calls (RPCs) [6] underpin nearly all communication in modern datacenters [5, 21, 41, 48, 52, 65]. A single cloud application may consist of hundreds of microservices deployed across thousands of containers, all communicating via RPCs. This centrality of RPCs has motivated extensive research in transport protocols, middleboxes, dataplanes, and frameworks [1, 2, 4, 7, 10, 11, 19, 27, 34, 35, 40, 51, 60, 61], with one goal: minimizing tail latency to meet strict service-level objectives (SLOs) [3, 13].

Cloud applications commonly multiplex RPCs over TCP, which remains the de-facto transport in production. Yet TCP's stream-oriented abstraction is a poor fit for message-oriented RPCs [57]. When exposed to userspace through the POSIX API, the kernel's TCP/IP stack delivers unstructured byte-streams, with no notion of message boundaries. As a result, RPCs sharing the same TCP stream are processed sequentially by default, causing HOL blocking whenever a slow RPC delays subsequent ones. Moreover, uneven request arrivals across connections can severely imbalance work across cores.

Existing RPC frameworks attempt to compensate for this mismatch entirely in userspace. To enable concurrent, out-of-order RPC processing on top of a sequential TCP stream, frameworks like gRPC must reconstruct message semantics using additional userspace abstractions: dedicated I/O threads to demultiplex byte streams and reassemble messages, work queues to hand messages across threads, and worker thread pools to execute RPCs. This layered, interaction-intensive pipeline introduces significant context switching, communication, and synchronization overheads. In practice, these overheads limit scalability: for example, increasing the number of TCP connections to a 20-hardware-thread gRPC-Go server from 80 to 5,000 increases the number of goroutines by 16×, and reduces throughput-under-SLO by 11% (§5.3). This poor scaling persists even though the Linux kernel's TCP stack can easily handle millions of concurrent TCP connections.

A rich body of prior work addresses this problem by avoiding TCP altogether. These systems do so either by introducing a custom message-oriented transport (*e.g.,* Homa) [8, 51, 56, 60] or relying on userspace network stacks (*e.g.,* eRPC) [29, 32, 35, 40]. By abandoning TCP's stream abstraction, they eliminate HOL blocking at its source and can deliver excellent RPC performance. While effective, these systems are difficult to deploy. They often require custom clients, non-

standard infrastructure, or dedicated hardware, which limits their practicality in today's multi-tenant cloud environments.

We therefore raise the following question: *Can one achieve high-performance RPCs free of HOL blocking, without the complex userspace machinery or deployability tradeoffs?*

We answer this question with **Rakaia**, an in-kernel architecture that eliminates HOL blocking for RPC frameworks, while preserving TCP wire compatibility. Our two key insights are: *(i)* message parsing and scheduling should occur in the same `softirq` context that processes incoming TCP packets. Since the kernel is already executing the TCP receive path on every packet arrival, adding message extraction and scheduling logic at this point incurs minimal overhead, and avoids building a separate userspace message-processing pipeline with its own threads, queues, and synchronization; *(ii)* messages must be decoupled from their underlying TCP connections to allow global scheduling. Exposing a connection-agnostic, message-oriented API to userspace enables true work conservation and concurrent RPC processing across all connections.

Kernel Connection Multiplexor [37] (KCM), the first upstream Linux attempt to expose a message API over TCP, embraces the first insight but violates the second: messages remain tied to their TCP connection and are scheduled locally. As a result, it falls short for production settings: it suffers from inter-connection HOL blocking, scales poorly, and is not suitable for high-performance RPCs.

Following both insights, Rakaia provides high-performance, work-conserving scheduling by introducing three mechanisms: *(i)* Rakaia attaches a message parser to each TCP connection to extract discrete messages directly from their incoming streams, avoiding application-level demultiplexing; *(ii)* Rakaia introduces a logically centralized, message-granular request queue that decouples message scheduling from individual connections, eliminating HOL blocking both within and across connections; and *(iii)* Rakaia uses a lightweight delegation mechanism on the transmission path to avoid contention when multiple threads try to send messages via a single TCP socket, efficiently integrating with the TCP/IP stack.

Our implementation of Rakaia on Linux kernel v6.8 targets easy deployments and upstream integration: the core functionality of Rakaia is implemented as a standalone, dynamically loadable Linux kernel module of ∼3000 LoC. Rakaia does not require any core kernel changes, except for the registration of a new socket type (∼60 LoC). Rakaia supports TLS-encrypted traffic by leveraging kernel TLS (kTLS) [68].

Our evaluation shows that Rakaia delivers high-throughput RPCs with low tail latency by eliminating HOL blocking. Its performance matches the theoretical expectations and remains consistent across a wide range of workloads, including coarse-grained (100µs) and fine-grained (20µs) tasks; varying number of connections (20, 80 and 5,000); with and without TLS encryption. To assess practical impact, we modify both gRPC-Go and gRPC-C++ to use the Rakaia API and compare them against the standard POSIX-based implementations.

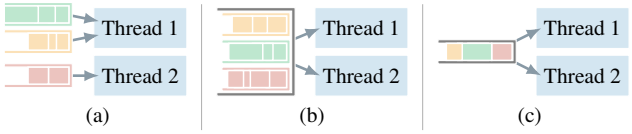

Figure 1: Three queuing models for two application threads: (a) connection-partitioned FIFO (**CP**), (b) connection-shared FIFO (**CS**), and (c) message-shared FIFO (**MS**)

Rakaia-enhanced gRPC-Go improves throughput-under-SLO by up to 1.56×, while maintaining stable performance as the number of connections scales. Rakaia also improves gRPC-C++ throughput-under-SLO by up to 2.69× across the evaluated APIs. Finally, Rakaia improves realistic gRPC workloads, increasing throughput-under-SLO by up to 1.39× for Silo [67], an in-memory database, and by 1.42× for OpenTelemetry Collector [54].

2 Motivation and prior work

2.1 The case for layering on top of TCP

The most popular RPC protocols [5, 21, 48, 65] almost universally rely on TCP for transport and TLS for security. TLS and PKI offer end-to-end confidentiality and integrity, while TCP remains the protocol of choice for its ubiquitous kernel support and its reliability in deployment.

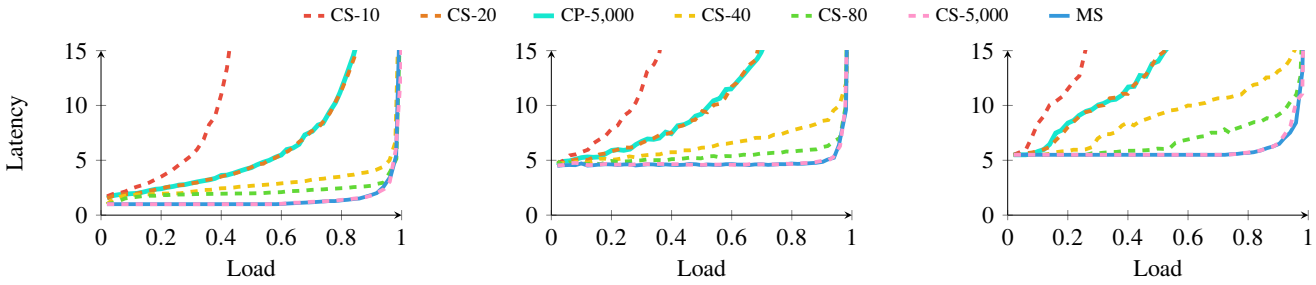
Despite decades of optimizations in the Linux TCP/IP stack [62, 64, 66], the nature of TCP continues to hinder RPC frameworks. The connection-oriented POSIX TCP API introduces two forms of head-of-line (HOL) blocking: *(i)* inter-connection HOL blocking when traffic is unevenly distributed across TCP connections; *(ii)* intra-connection HOL blocking, where a slow RPC delays all subsequent ones on the same connection. Both forms of HOL blocking lead to work imbalance, degrading tail latency and throughput.

These issues are inherent to the connection abstraction of TCP. To mitigate them, userlevel frameworks commonly bring additional layers of abstraction to break TCP's sequential stream semantics and enable concurrent RPC processing within and across connections, a process we detail in §2.3.

2.2 A quick queuing-theoretical detour

To understand the implications of delivering RPCs over TCP streams, we simulate the following queuing-theoretical models of an RPC server (Figure 1).

Connection-partitioned FIFO (CP): the server statically partitions connections across threads, leveraging RSS [62]. This approach minimizes synchronization overheads among threads. However, since connections are statically assigned to threads, this model suffers from both inter- and intra-connection HOL blocking and is not work-conserving.



(a) Deterministic (b) Exponential (c) Bimodal

Figure 2: Simulation results for the 99^{th} percentile tail latency for three service time distributions on a 20-core server.

Connection-shared FIFO (CS): the server places all authenticated connections into a single pool. Any idle thread can poll any connection in this pool, which in turn requires application-level synchronization. This improves load balancing across threads, but the connection remains the unit of ownership during request processing. At any time, only one thread can process messages from a given connection, even if other threads are idle. While CS eliminates inter-connection HOL blocking, it still suffers from intra-connection HOL blocking. Therefore, it is also not work-conserving.

Message-shared FIFO (MS): the server explicitly extracts requests from connections, enqueues them in a shared queue, and assigns requests to idle threads for processing. This model makes scheduling independent of connection ownership, allowing any idle worker to process the next available message. It eliminates both inter- and intra-connection HOL blocking at the cost of an intermediate extraction and queuing stage, typically implemented by a dedicated thread or thread pool.

We use a discrete-event simulator to model an open-loop workload generator with a Poisson arrival process and zero system overheads. This lets us isolate the queuing effects of each scheduling model from implementation overheads such as context switching. Generated requests are distributed across a varying number of connections. Figure 2 illustrates the impact on 99^{th} percentile tail latency, for three well-known service distributions (see §5.1 for details), and for different numbers of simulated client connections (*e.g.,* CS-40 denotes the CS model with 40 connections). The results show that *(i)* the connection-partitioned (CP) model fails to balance load, even with a large number of connections (CP-5,000); *(ii)* the connection-shared (CS) model suffers from intra-connection HOL blocking; *(iii)* yet, the severity of HOL blocking in the CS model depends strongly on the number of connections, *e.g.,* CS-5,000 nearly matches the performance of **MS**.

We derive two insights that inform our system design: *(i)* eliminating both intra- and inter-connection HOL blocking through a shared message queue (MS) reduces tail latency; and yet, *(ii)* larger connection-to-core ratios (*e.g.,* CS-5,000) reduce the impact of HOL blocking. Therefore, the throughput overheads of a centralized MS model implementation must remain low for the solution to be acceptable.

2.3 gRPC and HTTP/2

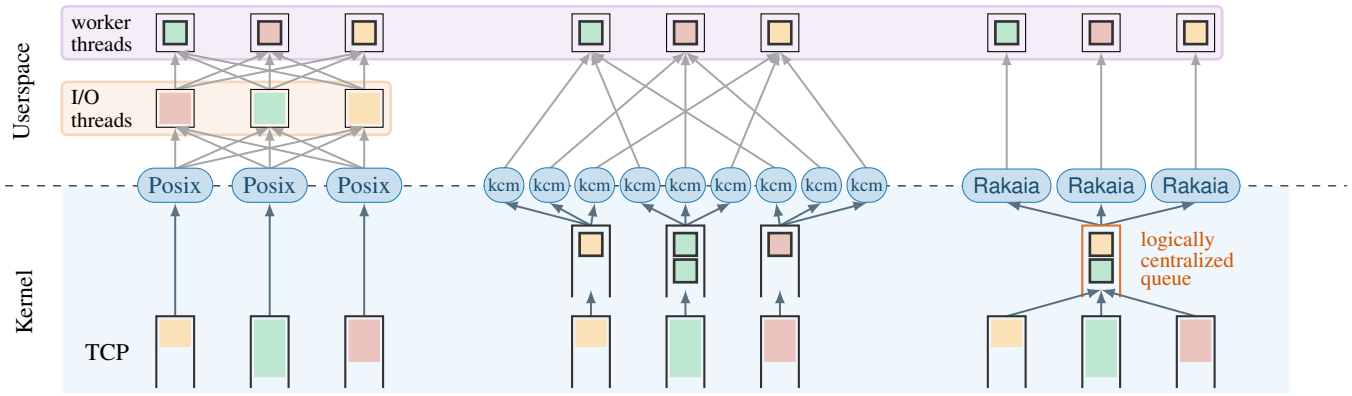
Figure 3(a) depicts the high-level architecture of gRPC, a popular userspace RPC stack that approximates the **MS** model. To achieve this, gRPC uses dedicated I/O threads to read TCP streams, reassemble RPC messages, and enqueue them into work queues, from which worker threads dequeue and execute RPCs. This design effectively decouples messages from their originating connections and distributes them to worker threads in a global FIFO manner, providing the logically centralized scheduling assumed in the **MS** model. gRPC is additionally built on top of HTTP/2 [5], which allows concurrent RPCs to interleave on a single connection, and supports out-of-order replies, thereby removing protocol-level HOL blocking.

However, achieving this concurrent RPC processing entirely in userspace is costly. gRPC must reconstruct message semantics through a layered pipeline of I/O threads, work queues, and worker thread pools. This introduces substantial inter-thread communication, synchronization, and context-switching overhead. Even the most performant gRPC implementation, Go-based gRPC [24], which relies on lightweight goroutines to mitigate these costs, experiences scalability challenges: as the number of goroutines grows, throughput eventually suffers (§5.3).

2.4 KCM – the previous in-kernel attempt

Shown in Figure 3(b), KCM [37] is the first in-kernel attempt to expose a message API on top of TCP. It relies on `strparser`, a Linux kernel facility for detecting message boundaries in TCP streams, to parse messages directly in the kernel. For each TCP connection, KCM then creates a separate KCM socket for every application thread and delivers each parsed message to one of these sockets. Replies are routed back along the same path to the underlying TCP connection.

While this avoids the inter-thread communication required by userspace frameworks like gRPC, it falls short of providing a true **MS** model. Scheduling remains fundamentally connection-driven rather than message-driven: each TCP socket independently selects among its own KCM sockets with no global view across connections or threads. Consequently, KCM suffers from inter-connection HOL blocking,



(a) gRPC (b) KCM (c) Rakaia

Figure 3: Three RPC-oriented architectures on top of TCP that aim to eliminate HOL blocking (receive side).

where idle threads cannot pull work from busy connections.

KCM scales poorly. With T threads and C connections, it creates $T \times C$ KCM sockets, a quadratic blow-up that quickly becomes impractical for high-connection services [26].

Combined with its poor performance (§5.2) and current lack of support for kTLS or userspace TLS libraries (*e.g.*, `openssl`), KCM is not considered a viable foundation for high-performance RPCs.

To summarize, high-performance RPCs built on top of TCP require a framework that approximates the **MS** model with minimal overhead. Existing userspace frameworks incur substantial overheads due to their threading and I/O models. While KCM is the only prior in-kernel attempt to expose message boundaries over TCP, it fundamentally retains the connection as the primary scheduling abstraction, making message-level work conservation impossible. In the next section, we describe how our design, Rakaia (Figure 3(c)), addresses these limitations by enabling low-overhead, message-oriented scheduling directly in the kernel.

3 The Design of Rakaia

Rakaia's design is driven by two key insights. First, message parsing and scheduling can be performed directly in the kernel's TCP receive path, in the same `softirq` context that processes incoming packets. Since the kernel is already executing to handle each packet, delineating messages and making scheduling decisions at this point adds minimal additional overhead. Second, decoupling messages from their TCP connections as early as in the kernel enables message-level scheduling and the exposure of a purely message-oriented API to applications. Together, these insights allow Rakaia to approximate the **MS** model with low overhead (through a logically centralized scheduler), while remaining fully compatible with the unmodified Linux TCP/IP stack.

At a high level, we set the following goals for Rakaia:

- **Message-level work conservation:** Rakaia schedules at the level of messages instead of per connection, ensuring no core stays idle while work exists.
- **Performance:** Rakaia outperforms existing TCP-based RPC frameworks in terms of throughput and tail latency.
- **Scalability:** Rakaia scales with an increasing number of TCP connections.
- **Compatibility:** Rakaia is fully compatible with the unmodified Linux TCP/IP stack and transport-level security mechanisms like kTLS. Any updates or optimizations in the underlying stack are automatically inherited by Rakaia.

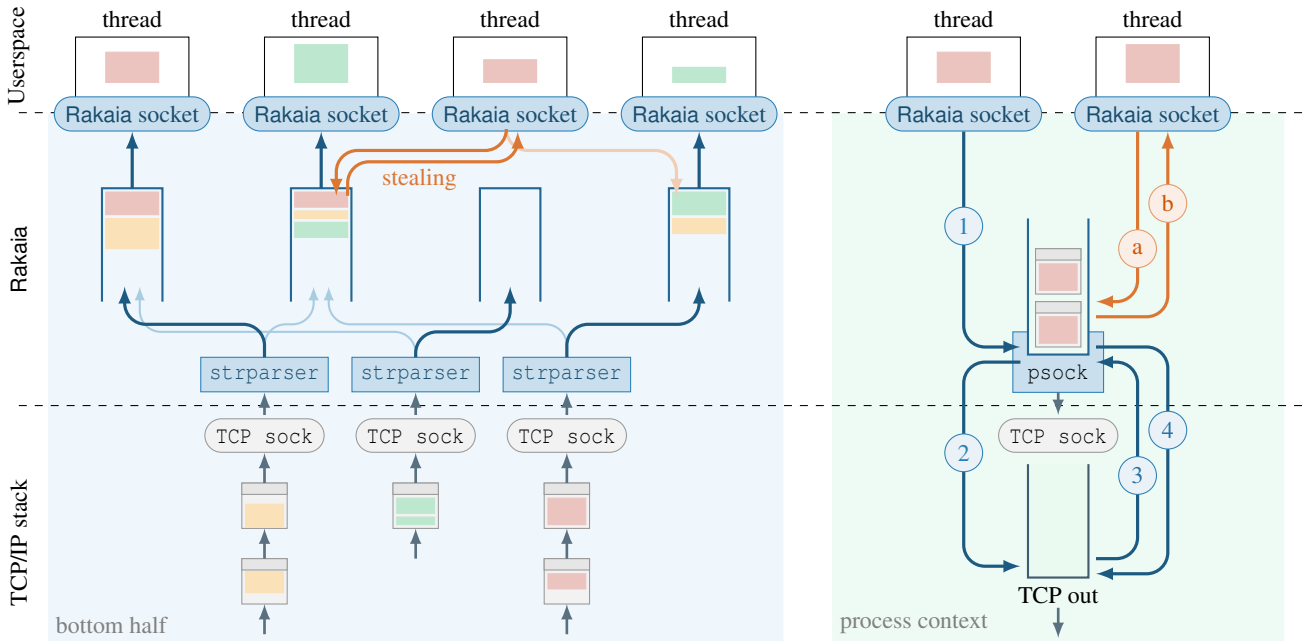
3.1 Overview

Figure 4 shows the high-level design of Rakaia, a lightweight in-kernel layer for message processing, demultiplexing, and scheduling atop the TCP/IP stack. Rakaia exposes a message-granular API to userspace (§3.2) and is fully compatible with TLS (§3.5). Rakaia operates in three layers:

Hook with the lower TCP/IP stack: Rakaia leaves the Linux TCP/IP stack unmodified and leverages `strparser`, which also underpins KCM, to extract message boundaries directly from the TCP byte stream. We extend `strparser` beyond length-delimited protocols to support HTTP/2. A protocol-specific parser is attached to each TCP socket and incrementally reconstructs complete messages from the receive queue before exposing them to the upper layers.

The scheduling layer: Once a message is parsed, it enters Rakaia's logically centralized but physically distributed scheduler, which maintains one FIFO queue per core. Any message may be assigned to any queue: Rakaia uses a power-of-two-choice (P2C) policy [50] to sample two queues and place the message on the shorter one, balancing load with constant overhead. Workers dequeue from their local queue first and invoke stealing if it is empty, preserving work-conserving scheduling without the scalability bottleneck of a global queue.

Message reception and transmission: Rakaia exposes a single message-oriented socket per application thread. On reception, the Rakaia socket delivers complete messages from



(a) Receiving Path

(b) Transmission Path

Figure 4: Overview of Rakaia's design. In the receiving path, solid arrows ( ) show the chosen execution path, while faded arrows ( ) indicate unselected candidates under power-of-two choices. In the transmission path, (1) - (4) shows a thread sending messages along the fast path, while (a) - (b) illustrates a case where message sending is delegated.

the scheduler to userspace. After the application processes messages, this socket transmits the responses over their associated TCP connections. When multiple threads attempt to send over the same TCP connection concurrently, Rakaia resolves contention using a lightweight delegation mechanism. After completing a transmission, a worker immediately fetches the next message or transitions to idle.

3.2 Rakaia API

It is well known that POSIX was not designed for scalability or message-oriented communication [12]. Further, RPC frameworks for TCP typically rely on dedicated I/O threads to demultiplex traffic, thereby introducing significant scheduling, queuing and synchronization overheads.

Rakaia simplifies this architecture by exposing a message-oriented, connection-oblivious socket API. Each worker thread communicates with the kernel through a single socket that directly sends and receives discrete messages over any TCP connection. Because all transport state remains in the TCP stack, the Rakaia socket maintains no per-connection bookkeeping. This design removes the need for I/O threads and provides a lightweight and scalable RPC interface.

At the API level, Rakaia was initially inspired by Homa/Linux, a Linux kernel implementation of the Homa transport protocol [51, 56]. Both Rakaia and Homa/Linux expose a single socket for sending and receiving discrete messages to and from arbitrary peers, a common practice in message-oriented communication, where applications exchange discrete messages with remote endpoints, *e.g.,* the POSIX UDP socket semantics. Unlike UDP and Homa, whose sockets directly communicate with remote peers, Rakaia's socket abstraction is built entirely atop TCP and serves only as a kernel-facing interface. It therefore does not maintain any remote-peer state, making it a lightweight layer over the underlying TCP stack.

Table 1 shows the APIs provided to the applications by Rakaia. We introduce a new protocol family `AF_RAKAIA` for the Rakaia socket. Each worker thread creates a Rakaia socket using the standard `socket` system call with `AF_RAKAIA`, and a custom protocol identifier `RAKAIAPROTO_CONNECTED`. Since each application thread only needs a single Rakaia socket to handle all TCP traffic, this design reduces resource consumption and simplifies file descriptor management. For instance, when using `epoll`, a thread needs to monitor only one file descriptor instead of one for each individual TCP connection.

Rakaia introduces a single new control operation: `rakaia_attach`, exposed as an `ioctl` on the Rakaia socket. The `rakaia_attach` call associates an existing TCP connection with the Rakaia framework and selects which built-in message parser should be used via `proto_id`. Rakaia currently provides parsers for `Memcached` and `HTTP/2`-based protocols (*e.g.,* gRPC). It can easily be extended to support additional ULP protocols. Once a connection is attached, Rakaia

Table 1: The API provided by Rakaia for applications.

Function	Description
`socket(AF_RAKAIA, SOCK_DGRAM, RAKAIAPROTO_CONNECTED)`	Creates a Rakaia socket
`close(int rakaia_fd)`	Closes the Rakaia socket
`rakaia_attach(int rakaia_fd, int csock, int proto_id)`	Attaches a TCP socket to Rakaia and selects the built-in message parser (e.g., Memcached or gRPC).
`recvmsg(int rakaia_fd, struct msghdr *msg, int flags)`	Receives a complete message from the Rakaia socket
`sendmsg(int rakaia_fd, const struct msghdr *msg, int flags)`	Sends a complete message through the Rakaia socket

begins to reconstruct incoming messages for that connection and makes parsed messages available to worker threads. Although the file descriptor of a Rakaia socket is passed to the kernel when invoking `rakaia_attach`, it serves merely as an entry point and does not create a persistent association between that Rakaia socket and the attached TCP connection. Message reception and transmission continue to use the standard `recvmsg` and `sendmsg` calls on the Rakaia socket.

3.3 Receive Path

Figure 4(a) shows the three main tasks of the receiving path: *(i)* parsing TCP byte streams into discrete messages, *(ii)* completely decoupling messages from their original connection, and *(iii)* work-conserving scheduling across Rakaia sockets.

Connection setup and message parsing: When a TCP connection is registered via the `rakaia_attach` system call, Rakaia initializes a `rakaia_psock` data structure to wrap the target TCP socket. This wrapper serves two primary purposes. First, it holds a new `strparser` instance for message parsing. Second, it stores the necessary fields to support the transmission path, which we describe in detail in §3.4.

On the RX path, Rakaia reconstructs complete application messages directly from the TCP byte stream. As illustrated in Figure 5, message parsing differs between supported protocols. For simple length-delimited protocols like Memcached, parsing only consists of inspecting a fixed-size header and extracting the encoded payload length. For Memcached, Rakaia uses the binary protocol's `opaque` header field to match responses to requests [49,58]. In HTTP/2-based protocols, each RPC is mapped to a single HTTP/2 stream, which in turn consists of one or more frames. The parser reads each frame's header, extracting its stream ID, length, type, and flags. Each complete frame is then appended to a per-stream buffer maintained in a hash table, which enables Rakaia to assemble messages that span multiple frames. When a frame carrying the `END_STREAM` flag arrives, the buffered frames for that stream are coalesced into a complete message and passed to the upper layer. Note that control frames such as `PING` or `WINDOW_UPDATE` are handled entirely in-kernel, allowing immediate flow control updates and acknowledgments.

Message insertion and origin tracking: Once a message has been reconstructed, Rakaia embeds a pointer to the corresponding `rakaia_psock` into the first `skb` of the message before enqueuing it into the central message queue. When a Rakaia socket dequeues this message and copies it to userspace, it extracts and caches the `rakaia_psock` pointer internally. This allows the subsequent `sendmsg()` call on the same Rakaia socket to access the correct underlying TCP connection, without revealing connection information to userspace.

Work-conserving scheduling: Rakaia presents a logically centralized message queue to applications while physically distributing scheduling across per-socket receive queues. Each Rakaia socket maintains a local FIFO queue and primarily serves messages from this queue. When a new message becomes ready, Rakaia assigns it to a socket using P2C load balancing: it randomly samples two candidate sockets and enqueues the message into the one with the shorter local queue. If the selected socket's queue is empty, indicating that at least one worker is idle, the message is instead delivered immediately via direct handoff. When a socket exhausts its local queue, it attempts to steal work from another active socket. To do so efficiently, Rakaia maintains a bitmap that tracks non-empty queues and again applies P2C to select a victim among them. If no work exists anywhere in the system, the socket enters idle state until new messages arrive. This design preserves work conservation across all load regimes. Under light load, messages are dispatched immediately via direct handoff. Under heavy load, queues naturally build up and sockets dynamically rebalance load through work stealing, approximating a centralized queue without its scalability bottleneck. Moreover, because Rakaia uses P2C for message-level distribution, its load balance is insensitive to the number of TCP connections: even with a small number of connections, P2C ensures tightly bounded queue lengths and maintains near-uniform load across sockets [50].

3.4 Transmit Path

The transmission path of Rakaia consists of two major stages: *(i)* copying the message into the kernel, and *(ii)* transmitting it over TCP with minimal lock contention.

Independent message copying: On `sendmsg`, Rakaia copies the message (and its associated TCP socket identifiers) into

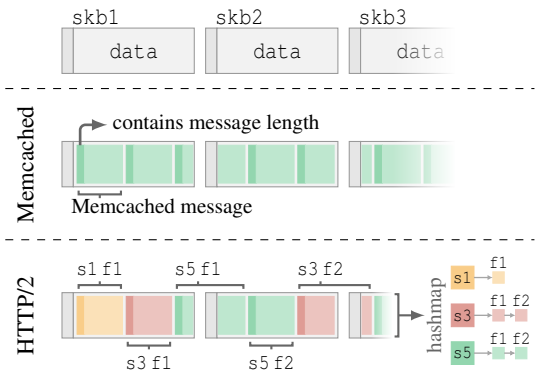


Figure 5: Parsing Memcached and HTTP/2. `s1`, `s3`, and `s5` refer to stream with ID 1, 3, and 5. `f1` and `f2` refer to the first and second frames of a stream.

the kernel. Rakaia copies each message independently into its newly allocated `skb`. A natural alternative is to batch messages destined for the same TCP socket into a shared sending queue so they can be packed into a single `skb`. While this may reduce `skb` allocation overhead, it introduces extra latency, substantial synchronization complexity, and difficult corner cases. In particular, under memory pressure, partial copy failures make it hard to free an `skb` that contains multiple messages. Our design avoids these pitfalls by copying each message independently, ensuring that `skb`s can be created and freed cleanly even in failure paths.

Direct or delegated transmission: Before message copying, Rakaia retrieves the cached `rakaia_psock` pointer (recorded by `recvmsg`) to identify the corresponding TCP socket. At this point, Rakaia does not directly enqueue messages into the TCP socket's `sk_write_queue`, since doing so requires acquiring the TCP socket lock, a mutex-like lock that would serialize all concurrent senders and put some to sleep.

Rakaia therefore employs a two-phase delegation mechanism for transmission, illustrated in Figure 4(b) and detailed in Algorithm 1. For each TCP socket, the `rakaia_psock` wrapper structure maintains a lightweight virtual sending queue (`virt_queue`) for temporary message accumulation. Access to that queue is shown as ① in Figure 4(b). This queue is merely a staging buffer: it accumulates messages without touching TCP's socket lock. Rakaia checks a boolean flag within the `rakaia_psock` to determine whether another thread is currently handling message transmission. If the flag is set, the sender returns to userspace immediately without further action (ⓑ). Otherwise, it sets the flag and becomes the designated transmitter: it acquires the TCP socket lock, moves all staged messages from `virt_queue` into `sk_write_queue`, and initiates message transmission via the standard TCP stack by calling `tcp_push` (②).

To avoid leaving behind messages that are concurrently enqueued by other threads to `virt_queue`, the designated transmitter repeatedly rechecks `virt_queue` (③-④) and flushes any newly arrived messages before relinquishing the TCP socket lock. When the queue is observed empty, it clears the flag and then releases the TCP socket lock, allowing future senders to proceed.

Algorithm 1 Delegation mechanism in the transmission path

```
1:  function SendMessage(psock, msg)
2:      set csk ← psock.sk                    ▷ associated TCP socket
3:      Enqueue(psock.virt_sndbuf, msg)
4:      if psock.tx_in_use is true then
5:          return
6:      end if
7:      set psock.tx_in_use ← true
8:      lock_sock(csk)
9:      while true do
10:         if psock.virt_sndbuf is empty then
11:             set psock.tx_in_use ← false
12:             break
13:         end if
14:         RequeueAll(psock.virt_sndbuf, csk.sndbuf)
15:         sk_flush_backlog(csk)             ▷ process rx backlog
16:         ...                               ▷ Omitted TCP stack logic
17:         tcp_push(csk)                     ▷ send out messages
18:     end while
19:     release_sock(csk)
20: end function
```

3.5 Composing with TLS

Rakaia's in-kernel message parsing relies on visibility into plaintext TCP streams, and the design described so far assumes unencrypted traffic. At first glance, this may suggest that Rakaia cannot handle encrypted traffic. However, Linux provides built-in kernel TLS (kTLS), which enables in-kernel TLS encryption and decryption. In kTLS, the TLS handshake is performed in userspace, typically right after accepting a TCP connection. Once the handshake completes, applications share the session key with the kernel, offloading TLS record processing to kTLS. This mechanism allows Rakaia to operate over TLS connections, preserving end-to-end confidentiality.

Figure 6 shows how Rakaia integrates with kTLS. In the receiving path, when a TCP socket receives encrypted TLS traffic, kTLS intercepts the data and parses it into discrete TLS records. These records are handed directly to the `strparser` attached to the TCP socket. The `strparser` then queries the kTLS decryption module to obtain the plaintext bytes and invokes its parsing program to extract application-level messages. Processing then proceeds as in §3.3.

The transmission side is simpler. Rakaia hands plaintext messages to the kTLS encryption module, which encrypts and transmits them via the corresponding TCP socket.

Note that kTLS commonly performs decryption in process context, typically when `recvmsg` is called. Although kTLS

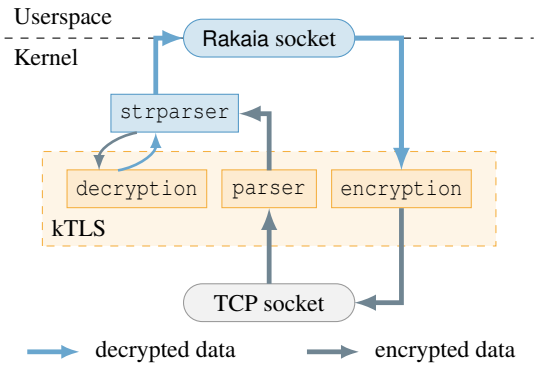

Figure 6: Rakaia running atop kTLS

exposes an interface for decryption in `softirq`, its current implementation is not robust and suffers from contention. To avoid this, Rakaia invokes the kTLS decryption module from a Linux workqueue [44], ensuring that decryption runs in an appropriate context. We plan to patch kTLS to support reliable `softirq` decryption, enabling tighter integration with Rakaia.

4 Implementation

We implemented Rakaia as a dynamically loadable kernel module on Linux version `v6.8`, consisting of approximately 3,000 lines of C code. In addition, we provide a kernel patch of around 60 lines to register the new Rakaia socket type. This patch makes minimal modifications to the existing kernel codebase and does not alter the TCP stack semantics.

Extending `strparser`: We extend `strparser` to support HTTP/2 stream parsing. In the default `strparser`, when a single message spans multiple skbs, the parser links them by using the head skb's `frag_list` and the `next` pointers of subsequent skbs. HTTP/2, however, introduces an additional layer of structure: messages are formed from multiple *frames*, and frames belonging to the same stream may arrive in separate skbs. To correctly assemble full HTTP/2 streams, Rakaia retains the original linking mechanism for individual frames and then uses reserved space in `skb->cb` to maintain per-stream linkage. This produces a single skb chain per stream, which the kernel can deliver as a complete logical message.

Offloading HTTP/2 transport logic: Supporting gRPC requires more than extending `strparser` to extract HTTP/2 messages. HTTP/2 introduces a substantial control plane (*e.g.,* flow control, PING frames) that would normally be handled in userspace. To fully eliminate transport-layer work from the application runtime, Rakaia offloads these mechanisms into the kernel as well. During parsing, Rakaia identifies HTTP/2 control frames and processes them directly (*e.g.,* applying and generating window updates), rather than delivering them to userspace. This not only simplifies the userspace logic, but also makes responding to control events far cheaper, since no syscalls or context switches are needed. Rakaia supports all HTTP/2 control-plane features used by gRPC.

Custom TCP path until `tcp_push`: While we keep the semantics of the TCP/IP stack intact, we cannot simply invoke the normal `tcp_sendmsg` in the transmission path after copying messages into the kernel. This is because `tcp_sendmsg` contains the logic for TCP socket lock acquisition, `skb` allocation, and data copying, all of which are unnecessary for Rakaia. To allow efficient transmission, we move the TCP stack logic such as sequence number initialization and rx backlog processing directly into `rakaia_sendmsg`. Afterwards, we call the existing function `tcp_push`, which is provided by the kernel for pushing `skb`s onto the network.

5 Evaluation

We evaluate Rakaia's performance and compare it against a range of RPC frameworks to answer the following questions:

- Does Rakaia behave according to the theoretical expectations of the **MS** model across various service-time regimes and levels of connection scaling? (§5.2)
- Does Rakaia bring performance gains to gRPC? (§5.3)
- Can Rakaia integrate efficiently with TLS, in comparison with other approaches? (§5.4)
- Does Rakaia deliver benefits for real-world RPC workloads beyond synthetic benchmarks? (§5.5)

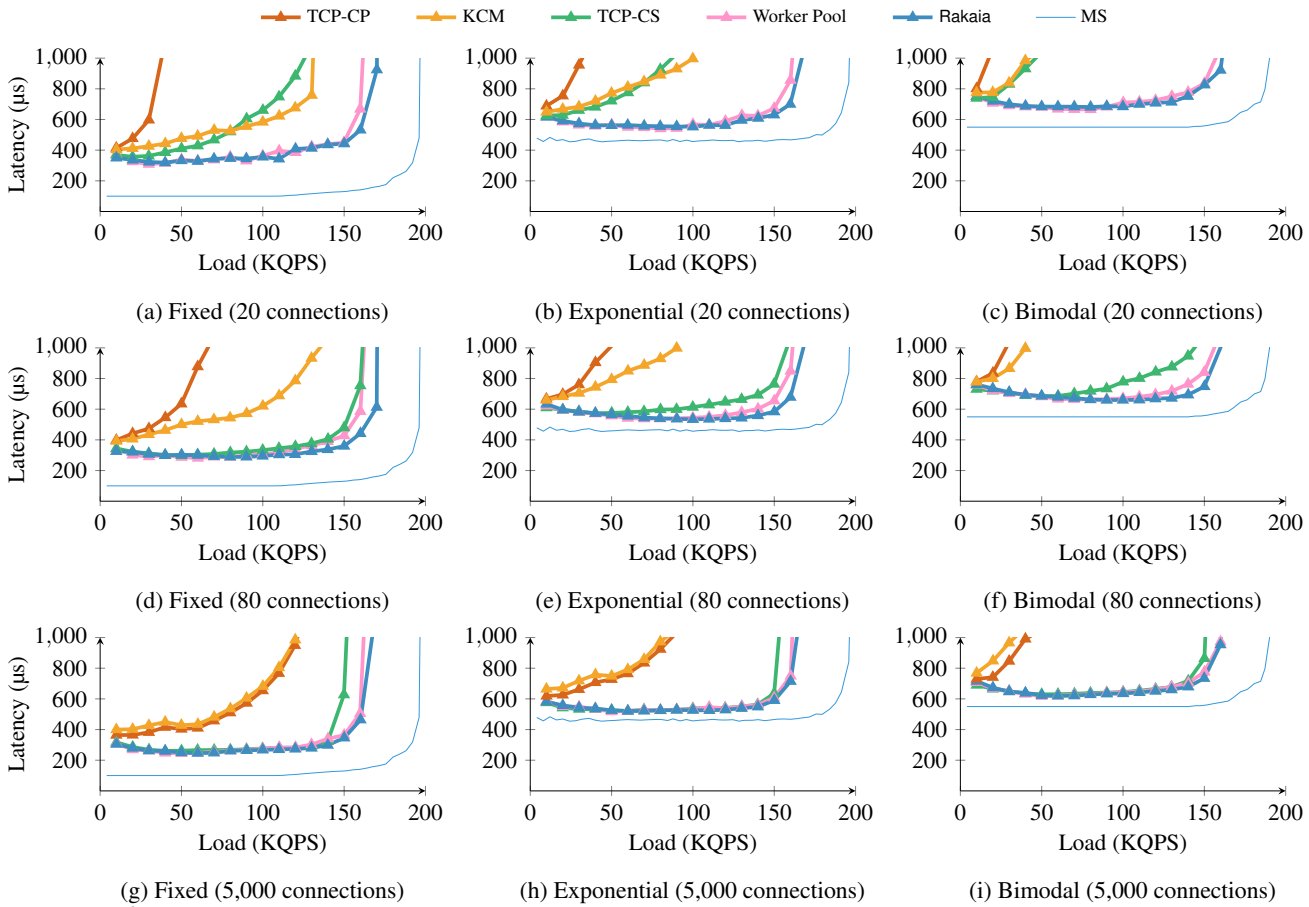
5.1 Experimental setup and methodology

Hardware: All experiments are conducted using Cloudlab [16] xl170 nodes. Each machine is equipped with one Intel Xeon E5-2640v4 CPU (10 cores, 2.4 GHz). Hyperthreading is enabled. The machines run an Ubuntu LTS 24.04 distribution with the Linux kernel version `6.8`.

In all experiments, the server is set up to use 20 hyperthreads. For most experiments, this implies a 20-way multithreaded application. For gRPC-Go, the server is set up with 20 worker goroutines for both gRPC-POSIX and gRPC-Rakaia. All experiments are compute-bound.

Experimental setup: In all experiments, we report the 99^{th} percentile tail latency (y-axis) versus the achieved load in RPCs per second (x-axis), both measured at the client when responses are received. We use an extended version of Lancet [39] as the load generator. Lancet first opens all connections at once, then issues requests according to a Poisson process in an open-loop fashion. Lancet supports multiple RPC protocols, including Memcached [48] and gRPC, with optional TLS support.

Synthetic distributions: For our synthetic microbenchmarks, clients send requests, encoded using a specified RPC protocol, to the server that executes them. The service times for these



(a) Fixed (20 connections) (b) Exponential (20 connections) (c) Bimodal (20 connections)

(d) Fixed (80 connections) (e) Exponential (80 connections) (f) Bimodal (80 connections)

(g) Fixed (5,000 connections) (h) Exponential (5,000 connections) (i) Bimodal (5,000 connections)

Figure 7: 99^{th} percentile latency as a function of throughput for 100µs tasks. Top, middle, and bottom rows correspond to 20, 80, and 5,000 client connections, respectively.

requests follow one of three well-known distributions from the literature [14, 32, 38, 42, 45–47, 61]:

- deterministic: $P[X = \bar{S}] = 1$
- exponential with mean service time $\bar{S}$
- bimodal: $P[X = \bar{S}/2] = .9$; $P[X = 5.5 \times \bar{S}] = .1$

Comparison: We compare the following systems:

1. **TCP-CP**, a simple lock-free `libevent`-based program where connections are split among threads (as directed by RSS [62]). Each thread both processes the requests and sends back the replies, ensuring natural in-order delivery.
2. **TCP-CS**, a simple connection-sharing, `libevent`-based program where threads temporarily lock access to a TCP socket to process requests and then return replies in-order.
3. **Worker Pool**, a userspace design that implements the **MS** model. It uses a small number of I/O threads and a pool of worker threads. The I/O threads block on a shared `epoll` instance and reconstruct messages from TCP streams. Once a complete request is received, the I/O thread enqueues it into a shared lock-free ring buffer, from which a worker thread dequeues it for processing. After processing the request, the worker attaches the response to the corresponding connection and marks the connection as having pending output. If the worker can acquire the I/O ownership of the connection, it flushes the response directly. Otherwise, it arms the connection with `EPOLLOUT` so an I/O thread can flush it once the socket is writable.
4. **KCM**, as available natively in the Linux kernel. We equip KCM with the same parsing program for extracting RPC messages and delivering them to userspace.
5. **gRPC-POSIX**, the official implementations. We evaluate both gRPC-Go (v1.75.0) and gRPC-C++ (v1.78.1).
6. **Rakaia**, our contribution, implemented as a kernel module.
7. **gRPC-Rakaia**, our contribution, modified gRPC-Go and gRPC-C++ implementations running on top of Rakaia.

5.2 Rakaia follows the MS model

We conduct the first set of experiments with varying TCP connections to the server, TLS disabled, and an open-loop load generator issuing as many outstanding requests per connection as needed. We measure the latency of replies at clients. For the Worker Pool, we sweep the number of I/O threads and

gRPC-POSIX-5,000	16,946	4.1	32.2	60.0	5.5	12.3
gRPC-Rakaia-80	29	22.9	33.2	38.0	0.8	0.1
gRPC-Rakaia-5,000	33	23.5	34.0	37.3	1.0	0.1

worker threads and use the best-performing configuration for each service time.

Figure 7 shows the 99^{th} percentile latency for 100µs service time across three different numbers of client connections (20, 80, and 5,000), following the three distributions described in §5.1. For reference, we plot the theoretical **MS** curve for an $M/G/20$ queue, scaled by the service time and assuming no CPU or network overheads.

Connection Scaling: Figure 7 shows that Rakaia remains close to the **MS** model across all tested connection counts. With only 20 connections, Rakaia sustains about 160 KQPS throughput across the three service-time distributions, whereas TCP-CS reaches only about 40 KQPS in the bimodal case. Thus, when intra-connection HOL blocking is most severe, Rakaia delivers roughly 4× the throughput of TCP-CS. The Worker Pool tracks Rakaia more closely than other baselines and exhibits the same overall scaling trend, showing that a userspace design can approximate **MS**-like behavior, at the 100µs scale.

As the number of connections increases to 80 and then 5,000, TCP-CS improves substantially because the requests are spread across more connections, reducing intra-connection HOL blocking. This trend is in line with the simulations in Figure 2. Nevertheless, even with 5,000 connections, Rakaia still consistently outperforms TCP-CS by 7%, though they are expected to behave almost identically in theory. Likewise, Rakaia also retains a small advantage over the Worker Pool. In both cases, the additional performance comes from Rakaia's in-kernel message scheduling, which avoids the userspace locking and coordination overheads among application threads, required by both TCP-CS and the Worker Pool. All other approaches (KCM and TCP-CP) are not competitive because they suffer from HOL blocking, *e.g.,* KCM only achieves around 30 KQPS in the bimodal case, 19% of Rakaia's throughput.

Shorter tasks: Figure 8 evaluates 20µs tasks with 80 client connections. At this granularity, system overheads account for a much larger fraction of end-to-end latency, making implementation costs more visible. The Worker Pool is particularly sensitive and suffers from significant performance degradation. We tune the I/O-thread and worker-thread configuration for the fixed service-time case, where it performs competitively. However, even with the same configuration, its performance degrades under the exponential and bimodal distributions, where higher service-time variability causes earlier tail-latency growth. KCM introduces high system overheads and performs worse than the vanilla TCP-CP and TCP-CS models, despite its in-kernel message parsing advantages. In contrast, Rakaia has low system overheads, and consistently maintains its advantages over TCP-CS.

(d) Fixed ($\bar{S} = 20\mu s$). (e) Exponential ($\bar{S} = 20\mu s$). (f) Bimodal ($\bar{S} = 20\mu s$).

Figure 10: 99^{th} percentile latency as a function of throughput with TLS enabled for 100µs and 20µs tasks, respectively.

5.3 gRPC over Rakaia

Figure 9 shows that Rakaia improves gRPC's performance across a range of connection counts, for both the Go and C++ gRPC stacks.

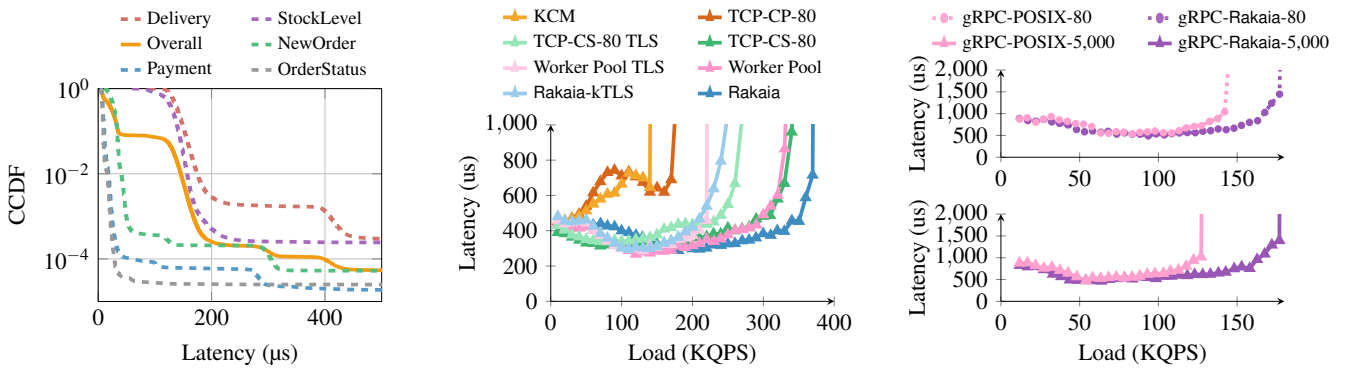
In the gRPC-Go case, with 80 connections, gRPC-Rakaia already sustains 39% higher load than gRPC-POSIX by avoiding the userspace I/O goroutines and inter-goroutine synchronization on the receive path. The benefit becomes even more pronounced as the number of connections increases. At 5,000 connections, gRPC-POSIX sustains 11% lower throughput than in the 80-connection case, suggesting that its per-connection goroutine structure begins to impose measurable scheduling overhead at scale. In contrast, gRPC-Rakaia maintains nearly identical throughput from 80 to 5,000 connections. As a result, its advantage over gRPC-POSIX grows to 1.56× at 5,000 connections.

Table 2 shows the CPU time breakdown for gRPC-POSIX and gRPC-Rakaia when serving 170 KQPS. **%I**, **%K**, and **%U** denote idle, kernel, and userspace time, respectively. **%sched** captures time spent in the Go runtime scheduler, while **%mstack** accounts for time spent on Go stack growth and management (*i.e.,* `morestack`). With POSIX sockets, gRPC relies on a large number of goroutines to emulate the **MS** model, scaling from 1,077 goroutines at 80 connections to around 17,000 at 5,000 connections. This explosion in concurrency significantly increases runtime overhead, reflected in high scheduler activity (6-8%) and substantial Go stack management overhead (up to 12.3%). In contrast, gRPC-Rakaia requires only a few dozen goroutines (20 workers plus a small number of runtime goroutines) regardless of connection numbers, as message multiplexing and scheduling are handled in the kernel. As a result, scheduler and stack management overhead becomes negligible. At 5,000 TCP connections, the shift from userspace to the kernel increases kernel time by only 1.8 pp, while reducing userspace CPU time by 22.7 pp.

Figure 9(b) repeats the experiment with gRPC-C++, comparing the `async` [22] and `callback` [23] APIs against gRPC-Rakaia. We omit gRPC-C++'s `sync` API because it runs RPC handlers on a dynamically growing thread pool [25]. Under high concurrency, this pool can grow with the number of active RPCs, leading to poor performance. Note that gRPC-Rakaia exposes the same user-facing API as `sync`, allowing existing applications to use it as a drop-in replacement. Unlike the standard `sync` implementation, it does not inherit the scalability bottleneck of a dynamically growing thread pool. The results show that gRPC-Rakaia improves gRPC-C++ throughput by 2× and 2.33× for the `async` and `callback` APIs, respectively, at 80 connections. At 5,000 connections, the corresponding improvements are 2.69× and 2.67×, respectively. This improvement is even more pronounced than in the gRPC-Go case, because gRPC-C++'s threading model incurs higher overheads than gRPC-Go's goroutine-based design.

5.4 The impact of TLS

Figure 10 compares the performance of Rakaia, TCP-CS and the Worker Pool, with and without TLS enabled. We omit *(i)* KCM, as it does not work out-of-the-box with kTLS on recent kernels, and *(ii)* gRPC-Rakaia, as Go's standard library does not yet support kTLS. Support for kTLS in gRPC-Rakaia will become available once the recently accepted proposal to integrate kTLS into Go [20] is implemented. Enabling kTLS has a measurable impact in terms of throughput for Rakaia. This is due to the use of the Linux workqueue to perform



(a) CCDF of task execution time

(b) 99^{th} percentile latency vs. throughput

(c) 99^{th} percentile latency vs. throughput

Figure 11: Silo running TPC-C benchmark

decryption on the receive path (see §3.5), which becomes a bottleneck. This limitation is not fundamental: once kTLS supports safe decryption in `softirq` context, this bottleneck can be removed.

For 100µs tasks, Rakaia-kTLS reaches about 120–130 KQPS, close to TCP-CS-TLS and the Worker Pool TLS at about 130–140 KQPS. For 20µs tasks, TLS overhead becomes more prominent. Rakaia-kTLS still reaches about 320–340 KQPS, reasonably close to TCP-CS-TLS at about 380 KQPS, while the Worker Pool TLS drops to only about 200–220 KQPS. This drop occurs because the I/O-thread configuration for the Worker Pool is tuned for the unencrypted case. With TLS enabled, the same I/O threads must handle higher per-request processing cost, so they saturate early and cannot feed workers fast enough. With Rakaia, I/O processing scales automatically through RSS, removing this responsibility from userspace.

5.5 Real-world applications

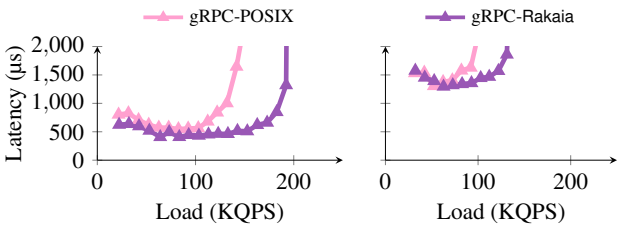
The impact on TPC-C query latency: To assess the benefits of Rakaia in the real world, we use Silo [67], an in-memory database optimized for multicore scalability. Using a methodology similar to [61], we run a networked server layer on top of Silo, which generates transactions from the TPC-C benchmark upon receiving new requests. Silo's garbage collection is disabled as it introduces large variability in 99^{th} percentile latency. Additionally, we did not implement marshalling for SQL queries and responses.

Figure 11(a) shows the multi-modal service time CCDF of the 5 TPC-C query tasks measured without queuing or network delays. The workload is substantially more complex than the synthetic distributions we used up to this point. Figure 11(b) plots tail latency as a function of achieved throughput for Rakaia (w/ and w/o TLS), TCP-CS-80 and the Worker Pool (w/ and w/o TLS), and the TCP-CP-80 and KCM baselines (w/o TLS). It shows that Rakaia's systematic elimination of HOL blocking delivers the highest throughput-under-SLO. TCP-CP-80 and KCM still collapse early because of their inferior scheduling policies. While TCP-CS-80 and the Worker Pool come much closer to Rakaia, they both still show earlier tail-latency growth as load increases. At 500µs tail latency, Rakaia sustains 350 KQPS, compared with 309 KQPS for TCP-CS-80 and 299 KQPS for the Worker Pool. This remaining gap indicates that, even when intra-connection HOL blocking is reduced, Rakaia still benefits from in-kernel message scheduling rather than paying the userspace coordination overheads required by TCP-CS and the Worker Pool.

Figure 11(c) compares Silo served through gRPC-Go over gRPC-POSIX and gRPC-Rakaia under 80 and 5,000 connections. gRPC-Rakaia improves upon gRPC-POSIX's throughput by 1.25× and 1.39×, respectively. This confirms that Rakaia's benefits extend to real-world RPC workloads, even when layered beneath a full gRPC stack.

OpenTelemetry: We also evaluate OpenTelemetry Collector [54], a widely used telemetry service for receiving, processing, and exporting traces, metrics, and logs in cloud deployments. In our benchmark, clients export traces to the Collector using the OpenTelemetry Protocol (OTLP) over gRPC-Go. This exercises the same gRPC-Go receive path as our earlier gRPC experiments, while replacing synthetic RPC payloads with realistic telemetry messages.

We evaluate two Collector configurations. The first uses a no-op exporter, which isolates the cost of processing OTLP requests without introducing backend storage or export traffic. The second uses a Jaeger-backed configuration [30], where the Collector batches incoming spans and exports them asynchronously to a Jaeger backend running on a separate machine. Following the OpenTelemetry testbed-style workload, each frontend RPC carries 10 spans, and the Collector uses the default batch size of 8192 spans with a 200 ms timeout. For the Jaeger configuration, we reserve two exporter consumers for asynchronous backend export and run gRPC-Rakaia workers on the remaining cores. Figure 12(a) shows that, with the no-op exporter, gRPC-Rakaia improves throughput-under-SLO by 1.35× over gRPC-POSIX at a 2 ms 99^{th} percentile tail-



(a) No-op (b) With Jaeger

Figure 12: 99^{th} percentile latency according to throughput for OpenTelemetry Collector with POSIX and Rakaia transports.

latency SLO, sustaining 192 KQPS compared with 142 KQPS. Because the no-op exporter removes backend work, this result isolates the benefit of accelerating the Collector's server-side gRPC. Figure 12(b) shows that this benefit persists with the Jaeger-backed configuration, where frontend RPC handling competes with batching, protobuf serialization, OTLP/gRPC export, and Jaeger ingestion. The backend export path remains an unmodified gRPC client path and is not accelerated by Rakaia. Even so, gRPC-Rakaia improves frontend throughput-under-SLO by 1.42×, sustaining 131 KQPS compared with 92 KQPS for gRPC-POSIX. These results show that Rakaia improves the performance of realistic gRPC server frontends, in addition to synthetic RPC handlers.

6 Discussion

Support for other gRPC implementations: Rakaia currently supports gRPC-Go (the most performant of the official gRPC implementations [24]) and gRPC-C++ out of the box. Extending Rakaia support of gRPC to other languages (*e.g.,* Java, Rust) is straightforward and would similarly remove the need for dedicated I/O threads and transport logic in userspace.

Compatibility with stack optimizations: Rakaia is compatible with standard kernel and NIC offloading mechanisms (*e.g.,* TSO/GSO, GRO), as it operates atop the TCP stack. It also supports TLS offloading, such as kTLS and NIC-based TLS, since decryption occurs in the kernel before messages reach Rakaia. Rakaia is, however, incompatible with SmartNICs that fully offload the TCP stack, as it relies on the kernel TCP pipeline to extract and queue messages. Finally, `io_uring` is compatible with Rakaia's `recvmsg`/`sendmsg` interface and could amortize syscall overhead.

Limitations inherited from TCP: Rakaia removes message-level HOL blocking caused by multiplexing RPCs over a TCP stream. However, because it leaves the TCP/IP stack unmodified, Rakaia necessarily inherits TCP's transport-level limitations. First, since TCP provides in-order delivery, a lost or reordered segment can stall progress on the affected connection until the missing data is retransmitted. Second, Rakaia inherits TCP's sender-driven congestion control, which is known to perform poorly under incast [8, 28, 60] compared to receiver-driven transports such as Homa [51, 56]. These tradeoffs are the inherent cost of preserving TCP wire compatibility and support for unmodified clients.

Complex scheduling policies and other RPC protocols: While Rakaia uses a logically centralized queue with run-to-completion workers, it can support richer queuing models (*e.g.,* priority queues). We leave this to future work. Rakaia can be easily extended to support other RPC protocols, provided they embed each message's length in their headers. Current parsers reside directly in the module, but additional ones can be implemented as in-kernel extensions or via eBPF.

kTLS: Linux's current implementation of kTLS does not correctly handle concurrent decryptions within a `softirq` context; Rakaia therefore falls back to a workqueue [44], incurring scheduler overhead. We plan to patch kTLS to support safe, scalable `softirq` decryption.

7 Related Work

Eliminating HOL blocking of TCP: Built atop HTTP/2 [5], gRPC [21] multiplexes multiple logical streams over a single TCP connection. While this design eliminates both inter- and intra-connection HOL blocking, it requires complex user-space orchestration. Rakaia instead performs message parsing, demultiplexing, and scheduling entirely in the kernel. Supporting HTTP/2 and other length-delimited message protocols, Rakaia enables efficient out-of-order delivery over TCP and integrates seamlessly with gRPC.

Addressing HOL blocking beyond TCP: Prior work also addresses HOL blocking by moving beyond TCP's byte-stream abstraction. One class of systems layers atop userspace UDP stacks: Shinjuku [32] and Concord [29] employ dedicated dispatchers and preemptive scheduling to achieve work conservation and low tail latency; Machnet [63] similarly bypasses the kernel via DPDK but as a networking sidecar, exposing a message-passing API over shared memory. QUIC [41], a reliable transport built over UDP, eliminates TCP's transport-level HOL blocking by multiplexing independent streams over a single connection. Apart from UDP-based approaches, recent custom transports [8, 51, 56, 60] treat messages as the fundamental unit of transfer and enable receiver-driven scheduling. While delivering excellent performance, these systems require either modified clients, custom network stacks, or dedicated infrastructure, limiting compatibility with existing TCP-based applications and hindering incremental deployment. In contrast, Rakaia preserves TCP/TLS wire compatibility, enabling easy deployment with unmodified clients across both WAN-facing and datacenter services.

Dataplane TCP stacks: Research dataplane TCP stacks often rely on DPDK [15] to bypass the Linux network stack for higher throughput and lower latency [4, 17, 31, 35, 36, 43, 59,

61, 63, 69]. Among them, IX [4], Arrakis [59], mTCP [31], and MICA [43] rely on NIC RSS to statically assign TCP flows to cores and are therefore not work-conserving. ZygOS [61], Shenango [55], and Caladan [18] address load imbalance through work stealing. However, they still follow the connection-shared queuing model and therefore suffer from intra-connection HOL blocking. Junction [17] aims to make kernel bypass practical for cloud operators by using advanced NIC features to enable high-density deployments of unmodified applications. While these systems support TCP, they replace the Linux TCP stack with custom userspace implementations. Rakaia instead runs atop the unmodified Linux TCP/IP stack, preserving its mature ecosystem.

Linux and BSD network stack optimizations: Because of its centrality, the Linux network stack is constantly being optimized [62, 64, 66]. In this context, KCM [37] provides message-granularity scheduling in the kernel, but suffers from several design flaws and fails to scale with increasing numbers of connections. Outside the kernel tree, Minion [53] enables out-of-order delivery of TCP segments and offers a datagram abstraction, thereby mitigating HOL blocking caused by packet loss or in-order delivery. Unlike Rakaia's logically centralized message queue, Minion exposes connection semantics to the application. Syrup [33] enables user-defined scheduling for network traffic using eBPF hooks but it is limited to UDP traffic. MegaPipe [26] uses per-core channels and batched system calls to minimize contention and improve throughput for short-lived connections and small messages, but remains a connection-oriented design. SKQ [70] extends FreeBSD's Kqueue to perform event scheduling but still suffers from HOL blocking as it schedules at the granularity of TCP connections. NetChannel [9] is an end-to-end transport redesign that multiplexes virtual sockets over underlying transport channels (*e.g.,* TCP connections) to scale network processing across cores. Like Rakaia, it decouples the application-facing socket abstraction from underlying channels. Unlike Rakaia, it requires virtual socket support at both endpoints, while Rakaia is purely server-side and works with unmodified TCP clients. Moreover, because NetChannel still binds packet delivery to the virtual socket chosen at connection setup, it cannot provide Rakaia-style work-conserving scheduling across sockets.

8 Conclusion

We presented Rakaia, a new in-kernel architecture for message-oriented scheduling atop the unmodified TCP/IP stack, eliminating both inter- and intra-connection head-of-line blocking. Rakaia provides a connection-oblivious API with a logically centralized message queue for applications and uses in-kernel transmit delegation to reduce contention across shared TCP connections. Rakaia is compatible with existing RPC protocols and supports transport-layer security out of the box. By combining connection-oblivious message scheduling with in-kernel transmit delegation, Rakaia outperforms KCM by 5× and improves gRPC-Go and gRPC-C++ throughput by up to 1.56× and 2.69×, respectively. Rakaia advances beyond Linux's current in-kernel solution, KCM, and is a practical replacement.

Abstract

We present an in-depth study of CPU scheduler bugs, covering both functional violations and misalignments between implementation and policy. Our study shows that these bugs are hard to observe and even harder to trigger. To close this gap, we introduce kSTEP. kSTEP gives testers fine-grained control over scheduler-invoking events and runs them deterministically on isolated CPUs. kSTEP produces noise-free, repeatable traces that expose subtle behavior. We then build a coverage-guided fuzzer on top of kSTEP for automated CPU scheduler testing. We demonstrate kSTEP's effectiveness by reproducing seven real-world scheduler bugs and uncovering four new ones. kSTEP is publicly available at https://github.com/kstep-dev/kstep.

1 Introduction

Linux CPU scheduling is critical to application performance and service quality [2,24,49,55,77,82,85,93–97]. Real-world services inevitably experience severe performance drops due to scheduler bugs. CoreOS (a container-optimized OS [84]) reported that a scheduler bug caused a 50% performance loss in web applications [12]; another bug caused system hangs on 30% of nodes in a production Hadoop cluster every week [87].

CPU schedulers have complex correctness expectations. Prior work focuses on *functionality bugs* [8,43–45,67,107], but schedulers must also keep their implementation aligned with intended policies (*e.g.,* policies specify when and where a task runs while balancing desirable properties like fairness, efficiency, and migration costs). We call violations of this alignment *policy bugs*. When they occur, schedulers still make functional choices, but compromise service quality. Policy bugs have especially low observability; to external users, there is no clear signal confirming a bug has occurred (*e.g.,* a fairness drop may be a bug or an intentional trade-off).

Despite its importance and complexity, the scheduler remains poorly tested and poorly understood. First, existing scheduler tests are surprisingly inadequate. Developers mostly rely on long-running workloads to catch performance regressions [10,34,36,40,69,74,88], rather than using systematic tests targeting specific code paths and corner cases. Furthermore, we lack a quantitative understanding of the real scheduler bugs that have accumulated over the years. This raises the question: *What types of bugs exist in modern schedulers? Why are they so difficult to test? How can testing be improved?*

Characterization study (§3). To answer these questions, we conduct an in-depth characterization study of modern Linux scheduler bugs. We examined 232 bug-fix commits since 2020, uncovering how these bugs are triggered, what causes them, and what they break. Our study reveals twelve key findings, organized into three main categories.

First, scheduler bugs are important. Their consequences are non-negligible: 15% lead to fatal failures; many others break strict guarantees, directly undermining functional correctness; and even when functionality holds, policy bugs compromise important properties (*e.g.,* balance, fairness, locality, energy efficiency) that services depend on. The community's response confirms this importance: fixes are carefully backported, showing a sustained commitment to reliability.

Second, scheduler bugs are hard to find. The first issue is that they suffer from poor observability: only 27% manifest as clear panics or warnings, while the vast majority (73%) are silent functional faults or policy misalignments that leave no warnings or sufficient triggering traces. Most root causes (75%) are subtle semantic faults, such as state or logic errors. These arise from extensive functionality requirements and accumulated heuristics, and uncovering them necessitates deep domain knowledge. Moreover, triggering conditions are complex: many bugs require exploration of a large space of scheduler attributes, and some (28%) further depend on kernel events or specific CPU attributes.

Third, current practice does little to compensate. Many bugs (45%) stay hidden for years, sometimes for over a decade. Most policy bugs are still caught by manual review. These bugs are rarely reproduced: most have no clear trigger sequence, and only 22% of user-submitted fixes include developer validation. Preventive actions are uncommon as well: patches rarely add tests, warnings, or tracepoints, leaving the subsystem prone to regressions. It is surprising that such a fragile, review-driven process remains the state of the art.

Together, these findings show that scheduler bugs are important, deeply hidden, and systematically underserved by today's testing practices, highlighting the need for a systematic approach to scheduler testing.

Controlled and deterministic testing with kSTEP (§§4-5). We then propose kSTEP[1] for *controlled* and *deterministic* CPU-scheduler testing. kSTEP offers two key capabilities.

[*] Major contributor to the design and implementation of kSTEP.

[1] kSTEP: **K**ernel **S**cheduler **T**est and **E**valuation **P**latform

First, controlling the timing of scheduler-invoking events (*i.e.,* external events that invoke the scheduler to make decisions or change its state) is crucial for triggering scheduler bugs. Almost all scheduler bugs are time-sensitive, as scheduler state evolves continuously with frequent timer ticks. Tiny shifts in event timing can alter subsequent state transitions and scheduling decisions. Yet, traditional userspace tests lack such precise control. To achieve controlled testing, kSTEP provides a rich set of events for userspace tasks, kernel activities, CPU attributes, and explicit scheduler ticks. Testers specify the sequence of events in a *driver program*, and a kSTEP kernel module dispatches them in the specified order. Thus, testers can precisely drive scheduler state changes through kSTEP events (*e.g.,* testers can reach a target scheduler state with controlled ticks and insert an event at that moment). Scheduler testing is similar but orthogonal to controlled concurrency testing that focuses on discovering concurrency bugs by manipulating thread interleavings [29, 33, 37, 38, 59, 72, 78, 79]. These frameworks use their own schedulers instead of exercising the existing Linux scheduler code.

Second, kSTEP ensures repeatable, noise-free scheduler execution. Many scheduler bugs, especially policy bugs, can only be diagnosed by inspecting the internal state. Without determinism and isolation, it is difficult to tell if trace differences are due to bugs or normal variability. To achieve deterministic scheduler execution, kSTEP: mocks clock sources; isolates test CPUs from noisy activities; and resets the initial scheduler state before the driver program runs. Existing record-and-replay techniques for userspace programs [14, 15, 25–27, 66, 75, 80, 81, 91] and virtual machines [4, 31, 90, 106] also ensure determinism on the same input. However, these methods are not applicable to scheduler testing as they record noise (*i.e.,* not stable [104]), making it hard to compare across similar inputs or different kernels.

These properties provide a foundation for advanced scheduler testing tools. We build the kSTEP tracer, which records stable execution paths for CPU scheduler, helping developers infer event sequences to reproduce bugs. We further build the kSTEP fuzzer to explore scheduler behaviors automatically: it uses clean coverage as feedback, deterministically replays prefixes of interesting tests, and mutates subsequent events.

Evaluation with a case study (§6). Finally, we evaluate kSTEP through a detailed case study of seven sampled scheduler bugs. Despite the difficulty of triggering and observing these bugs in practice, kSTEP enables simple, effective testing. kSTEP makes it feasible to trigger every sampled bug with at most 20 events instead of hours-long benchmarks; kSTEP makes observation deterministic, producing stable, noise-free traces that expose buggy behaviors with measurable impact. We also uncovered four previously unknown bugs (*i.e.,* two by manually written tests and two by the automated kSTEP fuzzer). These results show that kSTEP enables concise, deterministic tests for scheduler bugs that would otherwise be especially challenging to trigger or inspect in practice.

2 Background and Motivation

2.1 Linux CPU Scheduler

The scheduler decides which runnable thread each CPU executes next. Linux implements multiple scheduling policies through scheduling classes, each encapsulating its own policy. CPU scheduling is critical for quality of service. For example, cloud platforms rely on the Linux scheduler to determine who runs where and when; containers and microVMs depend on its policies for proportional CPU time sharing and quota enforcement [1, 2, 52, 89]. Over decades, the kernel has accumulated complicated scheduling policies [16, 24, 69], including early designs like Round Robin in 2000, the Completely Fair Scheduler (CFS) in 2007 [77], Deadline (DL) scheduling in 2014 [94], and later NUMA-aware [93], capacity-aware [96], and energy-aware [97] refinements. Recent years have brought even faster evolution, including Earliest Eligible Virtual Deadline First (EEVDF) [108] and the extensible userspace scheduling framework `sched_ext` [95].

2.2 Scheduler Bugs Are Not Well Understood

CPU schedulers have two tiers of correctness expectations: they must preserve functional correctness and keep the implementation aligned with policy. Accordingly, we classify scheduler bugs into *functionality bugs* and *policy bugs*.

Functionality bugs. The *first tier of correctness expectations* for the scheduler is functional correctness. Functionality specifies what must hold for the system to be valid: services remain available and all strict guarantees are respected. For example, the scheduler must always run tasks only on allowed CPUs, prevent starvation of runnable tasks, and avoid crashes.

Prior work has extensively examined functionality bugs. Fail-stop, fail-slow [8, 43, 71, 92], and gray failures [45] all expose strong external signals (*i.e.,* crashes, timeouts, or unacceptable performance drops). Prior work on silent semantic bugs [67, 68, 70] studies non-fatal functionality bugs. They are quieter, but still surface through unambiguously incorrect results or inconsistent states (*e.g.,* missing replicas, stale reads, or lost data). Thus, people can confidently identify bug occurrences by validating outputs or persisted states.

Policy bugs. The *second tier of correctness* for schedulers is to keep their implementation aligned with their policies. Policy guides how to choose among many functional actions to deliver "good" service (*e.g.,* the scheduler aims to deliver fairness, cache locality, and efficiency).

We refer to a *policy bug* as an implementation defect where the scheduler is functional, but its implementation misaligns with the intended policy. When policy bugs occur, service quality can degrade unpredictably: workloads may experience unfairness, performance drops, short-term work conservation violations, or high scheduling cost. Policy bugs matter as service quality is central to modern systems [9, 18, 28, 102, 103]. We cannot assume these service quality drops are less harmful than rare crashes: at scale, small but persistent inefficiencies translate into continuous waste in capacity and energy.

```
int wake_affine_idle(int this_cpu, ..., int sync) {
  struct rq *rq = cpu_rq(this_cpu);     // curr runqueue
  if (sync &&                           // sync wakeup
-     (rq->nr_running == 1))            // single runnable
+     (rq->nr_running - cfs_h_nr_delayed(rq) == 1))
    return this_cpu;                    // stay on core
}
```

Figure 1: Excerpt of a policy bug in waker CPU selection: aa3ee4f (*sched/fair: Fixup wake_up_sync() vs delayed dequeue*).

Unlike well-studied functionality bugs [8,43,67,68], policy bugs cannot be confidently identified by external operators. System calls succeed, tasks complete, and the system appears "healthy." Their symptoms are performance anomalies, but these are not sufficient evidence of a bug, since intentional policy trade-offs may also degrade performance for certain workloads. As a result, it is difficult to construct principled oracles for policy bugs without internal state inspection.

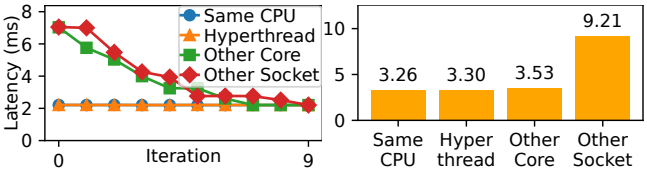
Prior work on performance bugs [48, 60] focuses on implementation inefficiencies that slow the system without affecting its outputs. Policy bugs can impact performance in two ways. Some, similar to traditional performance bugs, slow down the scheduler itself without changing its output. Most of them, however, alter scheduling decisions, thereby impacting application performance.

Bug #1: A real-world policy bug. Figure 1 shows a policy bug in CFS (aa3ee4f). During a synchronous wakeup, the waker is about to sleep. In this case, the wakee should run on the waker's CPU if the waker is the only runnable task. This ensures the local CPU retains its warm cache and boosted frequency. The code checks for this condition by testing whether `nr_running` == 1. However, EEVDF's delayed-dequeue feature [108,109] breaks this rule. Sleepers that overshoot their slice stay enqueued to burn off debt, still counting to `nr_running`. These "ghost" sleepers make the runqueue look busy, so the wakee is pushed to another CPU, needlessly sacrificing a warm cache and boosted frequency.

Figure 2 shows the performance impact. In Figure 2.1 (CPU-bound), the waker wakes the child, which then runs 10 identical busy-loop iterations. Selecting the waker's core keeps latency low as it is already frequency-boosted; a remote core makes the first iteration 3× slower and requires ~40ms to recover. In Figure 2.2 (cache-bound), accessing parent-touched data takes 3× longer on a remote socket than the local CPU. Such slowdowns matter: prior work shows it costs 1% of revenue per additional 100 ms tail latency [3, 28].

When a user sees a wakee run on a remote CPU, they cannot assume this bug occurred. The scheduler may legitimately prefer a remote CPU (*e.g.,* with higher capacity to fit the wakee). Thus, an external observer cannot tell whether the behavior reflects a bug or an intended policy design. Exposing it requires inspecting internal scheduler state and decisions. In §6.1, we show how kSTEP exposes this buggy behavior.

Our contribution. Despite their impact on service quality and complexity, scheduler bugs (both functionality violations and misalignment between implementation and policy) remain understudied. To narrow this gap, we conduct a comprehensive characterization study (§3) and detailed case studies (§6).



(1) CPU-bound child latency. **(2)** Cache-bound child latency.

Figure 2: Impact of sync-wake misplacement.

2.3 Scheduler Bugs Are Difficult to Test

In this section, we examine current approaches to scheduler correctness, their limitations, and challenges in testing.

Current efforts toward scheduler correctness. We review existing approaches and demonstrate why they are inadequate.

• *Testing.* Existing scheduler tests leave most behavior untouched. In the Linux Test Project [53], the CFS category consists of only three tests for bandwidth throttling, starvation, and hackbench [88], despite 30k lines of code (LoC) in CFS. In practice, existing tests focus primarily on basic operations such as thread creation and CPU affinity, along with a handful of stress tests using synthetic workloads.

• *Benchmark.* Performance benchmarks are often used to evaluate schedulers [10, 34, 36, 40, 69, 74, 88]. However, this approach is neither reliable nor complete. First, benchmarks may show performance drops but cannot expose incorrect behaviors without a reference result. Second, their results are often noisy, making bugs hard to diagnose. Third, benchmarks lack the control needed to reliably reproduce bugs.

• *Simulation.* LinSched [19] is a Linux scheduler simulator, allowing developers to write and execute tests outside the kernel. Its development highlights the need for scheduler testing tools. However, it lacks fidelity as a simulator: it omits many kernel interactions and does not support symmetric multiprocessing (SMP). Furthermore, due to high maintenance costs, it has not been maintained since Linux v3.3.

• *Verification.* Existing work has produced verified schedulers [51, 58] and proofs for specific Linux scheduling functions [56, 57]. These efforts either rely on overly simplified scheduling policies or cover only small code sections, and thus cannot capture the full range of Linux's scheduler policies.

Challenges for scheduler testing. Tests consist of event sequences designed to trigger failures; people inspect test outputs to determine whether a bug occurred [105]. In a scheduler context, event sequences (fork, wakeup, quota updates, *etc.*) invoke scheduling operators (enqueue, dequeue, reschedule, *etc.*) and generate diverse behaviors. However, schedulers are not tested extensively in practice using the standard approach.

• *Challenge 1: Scheduler behavior is highly time sensitive.* Testing the scheduler demands more than simply replaying a sequence of events: precise control over the timing of every event is essential. The scheduler's internal state evolves with every tick, so even small differences in when events occur can result in significantly different scheduling outcomes. For

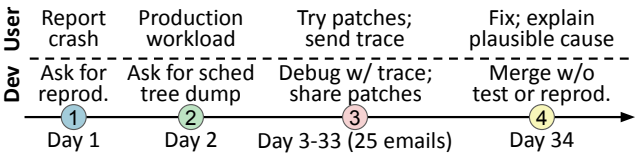


Figure 3: Timeline of a production scheduler bug (bbce3de): weeks of remote debugging without a confirmed reproducer. No test was added to prevent future regressions.

instance, Bug #1 is triggered only if a kthread's synchronous wakeup happens during a narrow, transient window when the waker's runqueue contains more queued than runnable tasks.

• *Challenge 2: Userspace events are insufficient.* Current tests focus on specifying userspace events to trigger the scheduler, overlooking many crucial events that originate from the kernel or hardware. Other kernel subsystems call scheduler-exported methods or create kernel threads; the hardware timer triggers ticks, invoking load balancing and task switches. Controlling these events is challenging from userspace. In addition, scheduler decisions depend on CPU attributes (*e.g.,* topology, capability, frequency). Hardware diversity is growing: from asymmetric cores to multi-level topologies (*e.g.,* chiplet [7], sub-NUMA clustering [46]). Testing across this diversity is impractical. Physical hardware is costly, and virtualization platforms do not emulate all variations. Thus, many hardware-specific bugs are surfaced only in production (*e.g.,* ee6e44d).

• *Challenge 3: Identify bugs from noisy traces.* When a bug is triggered, it is also difficult to observe. The scheduler is highly nondeterministic, so traces differ across runs, making it difficult to tell whether differences come from bugs or from normal variability. Modern kernels add noise with interrupts, RCU callbacks, workqueue activity, and clock behavior. Long-running benchmarks worsen the problem: a bug may surface occasionally, buried among unrelated event traces.

Bug #2: Month-long debugging without a reproducer. Figure 3 shows a recent case [23]. ① A user reported a null-pointer dereference, and the developer asked whether it was reproducible. ② The user could only describe the symptoms (`pick_task_fair` crashes more often) and could not reproduce it outside production. ③ Tedious rounds of remote debugging followed: the user dumped scheduler trees, the developer studied them and suggested patches, and the cycle repeated (25 emails in total). Both sides mentioned trying to reproduce the bug "to crank up the iteration speed," but without success. ④ Eventually, the user assembled a complex failure path and proposed a patch, which was merged later (bbce3de). The bug was not reproduced; the fix was never validated against a test. The patch was approved as developers thought it made sense. In contrast, a 20-event reproducer with kSTEP can reproduce it deterministically (§6.1).

Our contribution. To address these challenges, we introduce kSTEP (§4) and the testing tools built on top of kSTEP (§5). Users write driver programs to specify an event sequence; kSTEP executes them deterministically in an isolated environment with unmodified Linux kernels.

	Type	Responsibilities	#Bugs
Framework	Core	Skeleton and orchestration among sched classes	108
	Topology	Builds the hierarchy of scheduling domains	10
	Account	CPU time accounting and cgroup CPU statistics	9
Classes	Fair	Fair scheduling via vruntime and load balancing	106
	RT	Fixed-priority real-time scheduling	9
	Deadline	Earliest deadline wins scheduling	25

Table 1: Logical components. The per-component bug counts exceed the total because one commit can affect multiple components.

3 Characterization Study

In this section, we present key findings from our scheduler bug analysis. Do some components contain more bugs (§3.2)? How long do bugs exist in the kernel (§3.2)? How hard are they to observe (§3.3)? What consequences do they cause (§3.4)? How are they found and handled (§3.5)? Why do they occur (§3.6)? What triggers them (§3.7)? Overall, our findings show that the CPU scheduler is hard to test and that current practice falls short. Many bugs are hard to observe and even harder to trigger, pushing developers towards code inspection and long-running benchmarks instead. These results also highlight opportunities for more effective scheduler testing.

3.1 Methodology and Limitations

In this section, we give a brief description of how we collect bugs and discuss the limitations of our methodology.

Methodology. We collected all bug-fix commits in the Linux CPU scheduler from mainline [61] and stable branches [42] since 2020. We scanned all commits modifying files in `kernel/sched/`, excluding `sched_ext`, and classified a commit as a bug fix if it contained a *Fixes:<SHA>* trailer or indicated a defect (*e.g.,* using terms such as *fix*, *regression*, *inversion*, *stall/hang*, *violate*, *revert*). We excluded commits that added features, optimized design, maintained code, or modified comments. After filtering, we obtained a study set of 232 scheduler bugs, each investigated and classified by one of the authors.

Limitations. As with all characterization studies, there is an inherent risk that our findings may not be representative.

• *Representativeness of the selected bugs.* First, our study covers bug-fix commits, and it may miss real-world scheduler bugs that were encountered by users but never reported or fixed. Second, our study should be interpreted as characterizing bugs in the Linux scheduler rather than scheduler implementations in general. Third, our bug-filtering criteria rely on signals such as *Fixes:<SHA>* trailers and bug-indicating keywords. We use conservative criteria to reduce false positives, but this may miss bug-fix commits without these signals.

• *Possible observer error.* Although we manually examined each collected patch, some classification decisions require judgment and may be subject to researcher bias.

3.2 Overview of Scheduler Bugs

The Linux CPU scheduler has grown from 15k LoC to 50k LoC in 15 years, turning a once-small subsystem into one of the largest subsystems in Linux. Where does the code live, and how do scheduler bugs and fixes move through releases?

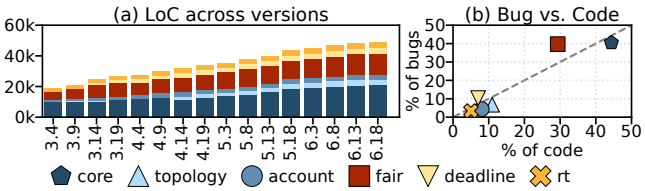

Figure 4: Code size and bug counts of different components.

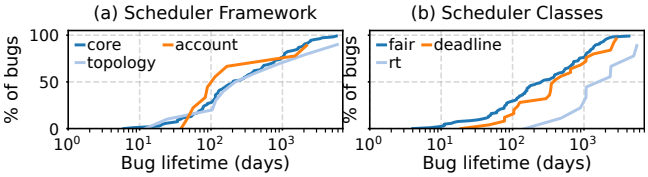

Figure 5: Distribution of bug lifetimes across different components.

Logical components in the CPU scheduler. We divide the CPU scheduler into 2 components with 6 logical subcomponents (Table 1). The scheduler does two things: the *scheduler framework* provides the core mechanisms and *scheduler classes* implement specific policies. The framework has three parts. *Core* defines the policy-agnostic skeleton: it runs *schedule()* for task switching, manages task states, and exposes exported functions used by syscalls and other subsystems (cgroups, power, *etc.*). *Topology* maps hardware layout into scheduling domains for load balancing and CPU selection. *Accounting* tracks and reports runtime statistics to users, forming the observability layer. The scheduler classes then plug into this framework. *Fair* implements the default CFS policy, *RT* implements fixed-priority real-time scheduling, and *Deadline* implements earliest-deadline-first scheduling, ensuring tasks receive X runtime every Y period, as configured.

Bug distribution across components. Table 1 lists the bug counts by component. Figure 4a shows how each component grows across kernel versions, and Figure 4b compares each component's share of code to its share of bugs.

• *Scheduler framework.* The *Core* component accounts for nearly half of all bugs and about 40% of the scheduler's code. Although *Core* is mostly policy-agnostic, it orchestrates the entire scheduling pipeline and interacts with user workloads, other kernel subsystems, and hardware signals. This infrastructure is complex and thus a major source of failures.

• *Scheduler classes.* Among the classes, *Fair* grows fastest and contains more bugs relative to its size. CFS accumulates a large number of heuristics over the years (*e.g.,* NUMA balancing, EEVDF, energy-aware hooks) with little structural cleanup. For example, *select_idle_sibling()* is the final step in CPU selection, deciding whether to use the candidate CPU or its nearby idle sibling. Despite its simple task, it spans 72 LoC and 33 predicates with heuristics accumulated over years.

Finding 1: *The scheduler framework accounts for nearly half of bugs, due to extensive functionality requirements; the Fair scheduler has accumulated heuristics and is bug-prone.*

Lifetime. Figure 5 shows how long bugs stay in mainline Linux before being fixed. Roughly 45% remain for over a year, and 5% survive for more than a decade. These bugs often stay hidden because they require specific hardware topologies or unusual workloads that standard benchmarks never hit. Many also compromise scheduler properties like fairness or work conservation, which are soft targets with no ground-truth curves to compare against. The presence of multi-year bugs stresses how hard it is to trigger and expose scheduler bugs.

Finding 2: *45% of bugs hidden for years, 5% over a decade.*

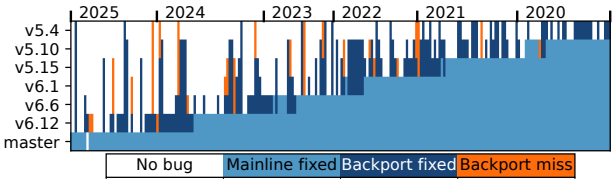

Figure 6: Backported versions for 232 bugs. Columns represent bugs, rows represent versions, and cells represent backport status.

	Type	Description
	Crash/Hang	Kernel becomes unusable or makes no progress
Functionality	Sched Attr	Violation of sched attribute guarantees (*e.g.,* CPU affinity)
	Trace	The scheduler's trace records incorrect values
	Task State	Invalid state (*e.g.,* runnable task missing from all queues)
	Hotplug	CPUs fail to online/offline (*e.g.,* task remains on offline CPU)
	Starvation	Starvation occurs in starvation-free scheduler classes
	Return Val	Functions exposed to other subsystems return wrong values
	Config	Feature-config violation (*e.g.,* enabled feature not used)
Policy	Balance	Leaving some CPUs overloaded while others idle
	Fairness	Some tasks get more than their fair share of CPU
	Freq Ctrl	Miscoordination with frequency/utilization control
	Locality	Reduces cache efficiency or degrades NUMA locality
	Energy Eff	Degrades energy efficiency (*e.g.,* waking too many CPUs)
	Sched Cost	Increases scheduling overhead or cost in hot paths
	Class Prio	Wrong order across classes (*e.g.,* DL lock holder not boosted)
	Benign	Little impact (*e.g.,* warning triggered but corrected instantly)

Table 2: Categories of bug observability and consequences.

Backport. Figure 6 shows how scheduler bug fixes propagate from mainline Linux to Long-Term Support (LTS) branches. Each cell shows how a version handles a fix: (1) the bug is absent, (2) the fix is present before release, (3) the fix is correctly backported, or (4) the fix should have been backported but is missing. We find that once a scheduler fix lands in mainline, it is propagated to all affected versions in most cases, even when those branches differ significantly in age and code.

Finding 3: *The community shows a sustained commitment to scheduler reliability: most bugs are backported properly.*

3.3 Bug Observability

As discussed in §2.2, violations of functionality and policy have different observability. In this section, we aim to examine the observability of scheduler bugs.

Categories. We first classify each bug by observability; each category exhibits distinct symptoms, as listed in Table 2.

• *Functionality: Crash/Hang*. Bugs can fail-stop the kernel with a panic, oops, hard lockup, or an unrecoverable hang. Users notice them immediately as the service is unavailable.

• *Functionality: Non-fatal*. These bugs violate strict func-

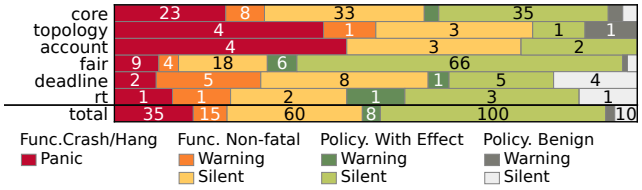

Figure 7: Observability and diagnostic logs of bugs. Bugs can span components, so component-wise counts can exceed the total.

tional guarantees (*e.g.,* affinity not honored, tasks failing to wake). While these bugs are less immediately visible, they can still be detected through explicit checks by users.

• *Policy: With Effect*. These bugs preserve functional semantics, but the implementation does not align with the intended design. They can compromise soft properties the scheduler wants to achieve, as shown in Table 2. External symptoms alone are insufficient to distinguish a policy bug from an intentional design trade-off. Determining whether a bug occurs requires examining the internal scheduler state.

• *Policy: Benign*. Policy bugs whose effects are minimal or quickly self-correcting. They have no obvious impact and are usually observable only through code review or log warnings.

Bug observability. Figure 7 shows the observability of each bug. 15% of scheduler bugs cause highly visible failures such as crashes or hangs. Silent functional violations (26%) and misalignment between policy and implementation (47%) dominate, a higher share of silent bugs than prior work [67].

Policy bugs are especially common in *Fair*: 70% of its bugs fall into this category. The reason is that CFS offers proportional sharing in a best-effort manner while balancing different goals (fairness, locality, energy, *etc.*). Policy bugs occur when these heuristics drift from the intended design. Other components also contribute to policy bugs. The *Core* layer maintains policy-critical state (runqueue statistics, task attributes, *etc.*); *Topology* defines scheduling domains to guide balancing; *RT* and *Deadline*, despite their originally functional semantics, have accumulated heuristics (*e.g.,* energy-aware scheduling) and contain a number of policy bugs.

How much do logs reveal? Figure 7 also marks whether a bug triggers any kernel panics or warnings. Scheduler warnings have narrow coverage: they guard only coarse invariants (*e.g.,* avoiding double enqueues) rather than checking whether each scheduling decision is valid or policy-consistent. As a result, 73% of bugs leave no warnings in the logs. In addition, for nearly all bugs in our study, the critical scheduler events are not recorded by default tracepoints. While powerful tracing tools exist [17, 54, 62, 69, 99, 101], fully tracing scheduler activity is expensive and disturbs time-sensitive decisions, making it impractical for production workloads. Thus, the bug-triggering event sequences are often absent in traces.

Finding 4: *Silent functionality and policy bugs dominate (73%) the scheduler bugs. Logs and traces are insufficient to reveal them or record their triggering events.*

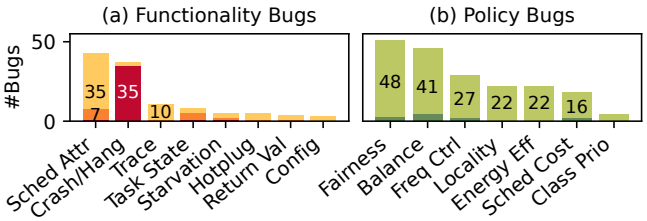

Figure 8: Bug consequences. Consequence definitions in Table 2. Colors follow Figure 7. Counts exceed 232 via consequence overlap.

3.4 Bug Consequences

In this section, we examine how scheduler bugs affect the system and applications using the categories in Table 2.

Functionality violations. Figure 8a shows that while crashes and hangs are common (35 cases), most functional bugs are silent violations. Breaking strict interface semantics is the most common scheduler failure (42 cases). The scheduler exposes many interfaces for configuring task-, cgroup-, and system-level attributes. Some have strict specifications (*e.g.,* allowed CPU sets, the CPU time a Deadline task must receive within its window). Violating them constitutes a functionality bug. Others express non-strict goals (*e.g.,* proportional share for CFS tasks, short-term work conservation) that the scheduler attempts but does not guarantee at all times; falling short of these goals does not indicate a functionality bug. The remaining cases come from breaking other strict guarantees in the scheduler skeleton. Table 2 shows a detailed breakdown.

Finding 5: *Most functionality bugs result from violating strict requirements of the scheduler-attribute interface.*

Service quality compromises. Policy bugs do not violate functional guarantees. Their symptoms are compromises of soft expectations (Table 2). For example, CFS shares express a soft expectation about the proportion of CPU time a task should receive relative to its peers. Such a share is often traded off against other goals, such as migration costs. We examine bugs by the soft expectations they compromise (Figure 8b).

Balance and fairness dominate because they sit at the center of many trade-offs. Balance can conflict with locality, energy efficiency, and scheduling cost. Fairness competes with frequency control, energy efficiency, and scheduling cost. To balance these trade-offs, the scheduler relies on numerous heuristics, making it particularly fragile. Hardware-related policies (locality, freq control, and energy-aware decisions) are frequently violated (73 cases). Modern hardware diversity forces the scheduler to grow many architecture-specific rules, making these paths especially bug-prone. Moreover, some bugs make the scheduler inefficient by slowing decision-making, increasing migration rates, or causing redundant calculations.

Finding 6: *Balance and fairness are the most fragile properties; hardware-aware policies are also hard to get right.*

3.5 Bug Discovery and Mitigation in Practice

Despite the scheduler's critical role, bug handling remains largely ad hoc. This section examines how scheduler bugs are

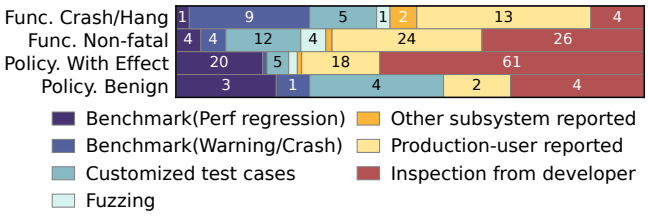

Figure 9: Discovery methods for scheduler bugs.

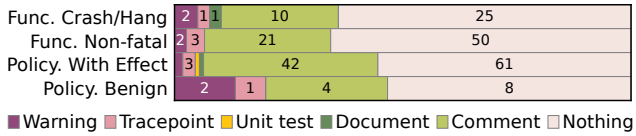

Figure 10: Prevention actions taken after fixing scheduler bugs. Prevention actions can overlap, so the total can exceed 232 bugs.

discovered, reproduced, and prevented in practice.

How are bugs discovered? Figure 9 shows how bugs in each observability level first surface: via tests (benchmark regressions, customized test cases, fuzzing tools), user reports (from either other kernel subsystems or users), or code review. Fatal errors are easiest to see, so tests and users catch 89% of them. Non-fatal functionality bugs keep the system running, but users and tests still find many of them (65%) because they can observe clear semantic violations. In contrast, users and tests only find 47% of policy bugs due to low observability. The system remains functional while service quality quietly drifts, and users cannot tell whether a performance dip is a policy bug or an intended trade-off. The remaining policy bugs are found through code review; a fragile process makes policy violations easy to miss.

> ***Finding 7:*** *Policy bugs rely heavily on code review to uncover; far fewer are reported by users or exposed by tests.*

Lack of details to reproduce bugs. Bugs are rarely reproduced during the scheduler bug-fixing process. Figure 9 shows that 61% of runtime-exposed bugs are observed by regressions or alerts from long-running workloads, with no precise triggering sequence mentioned from report to fix. More surprisingly, developers reproduce the bug and validate the patch for only 22% of user-submitted patches. Instead, patch approval relies on code inspection and the fact that "the symptom went away". The scarcity of reproducers reflects the scheduler's poor testability. §2.3 discusses the challenges that make it difficult to construct stable, repeatable bug-triggering sequences. Without reliable reproducers, validation is difficult; there are no tests to prevent reintroduction of the bug.

> ***Finding 8:*** *Bugs are rarely reproduced: 61% of runtime-exposed bugs lack a trigger sequence; only 22% of user-reported patches are explicitly reproduced and validated.*

Lack of preventive action. Mature systems typically require bug fixes to include regression tests [5, 83], which CI runs to ensure the same bug does not recur. Figure 10 shows a very different pattern: most fixes are "one-shot" patches with no preventive action. The dominant outcome is *Nothing*. The most common follow-up is a code comment, which is helpful for clarity but provides no enforcement. Unit tests and selftests are almost never added; runtime checks are rare. Once a scheduler bug is patched, little is done to prevent similar bugs from recurring (*e.g.,* `db6cc3f`). It depends on the vigilance of developers rather than regression tests.

> ***Finding 9:*** *Common practices rarely prevent bug recurrence, as fixes rarely add unit tests, warnings, or tracepoints.*

Category	Description
State	Incorrect updates or missed updates of scheduler state (*e.g.,* wrong statistics, corrupted runnable lists or rb-trees).
Logic	Scheduling decisions made from state are undesirable.
Generic	Generic semantic error (*e.g.,* wrong types, overflows, typos)
Concurrency	Race conditions or violations of locking protocols
Memory	Unsafe mem ops (*e.g.,* leak, null ptr, buffer overflow)

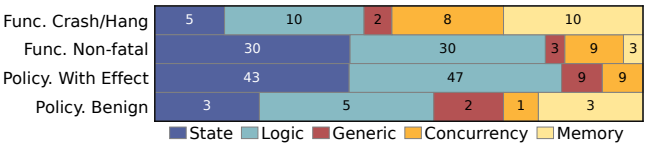

Figure 11: Categories and distribution of bug root causes.

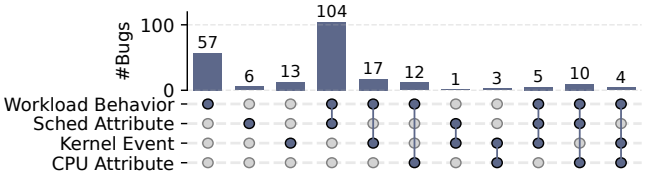

Figure 12: Triggering conditions for scheduler bugs. Each column shows a group; dots mark the combination of trigger types required.

3.6 Root Cause

Understanding why bugs arise is essential. Different root causes call for different ways to detect, expose, and fix them, so a clear taxonomy helps both developers and tool builders. We classify bugs into five categories listed in Figure 11. Overall, *state* and *logic* faults make up the vast majority (75%) of bugs. These semantic errors often demand scheduler-domain knowledge to understand, detect, and fix. General root causes common to all systems, including *concurrency* and *memory* bugs, account for 12% and 7% of cases, respectively; they are more likely to lead to crashes or hangs and are therefore easier to observe. Generic coding mistakes, such as integer overflows or typos, are relatively rare. These bugs can also lead to different levels of observability and can sometimes be difficult to expose.

> ***Finding 10:*** *75% of scheduler bugs stem from incorrect state updates or wrong logic, and likely require domain expertise to detect and resolve. These bugs often remain silent.*

3.7 Triggering Conditions

There are opportunities to improve testing by examining the types of input events required to trigger bugs. We analyze each bug's triggering events, with results shown in Figure 12.

Workload behavior. Almost all bugs (90%) require specific

userspace workload behaviors like task count, arrival patterns, CPU-usage patterns, synchronization, or sleep/wake timing.

Scheduler attributes. For 54% of the bugs, the trigger depends on how scheduler attributes are configured. Linux exposes rich interfaces for expressing performance requirements at the task, cgroup, and system levels. Among the studied bugs, 24%, 16%, and 4% rely on per-task, cgroup-level, and system-wide attributes, respectively; 8% appear only when multiple classes of tasks interact. From a testing perspective, these attributes form a rich input space, and effective testing must systematically explore these attribute combinations.

> ***Finding 11:*** *Exploring the search space for different scheduler attributes is important for 54% of bugs.*

Kernel events. Some triggers are events raised by other Linux subsystems: workqueue kthread pools, filesystem kthread activities, CPU hotplug, freezer operations, and so forth. These account for about 19% of bugs (10% hotplug, 4% kthread behavior, 5% other). These events invoke the scheduler through a large set of exported functions, and are difficult to orchestrate from userspace (*i.e.,* one cannot control the timing of filesystem kthread wakeups by issuing file operations).

Special CPU attributes. Most bugs (88%) can be triggered on a multicore machine with SMT. The rest require specialized attributes: 5% on NUMA systems, 5% on asymmetric cores, and 2% on others (*e.g.,* 4-way SMT, CPU-less NUMA nodes, or some private IBM hardware). These cases show that some failures only occur on CPUs with specific attributes that typical test environments rarely cover.

> ***Finding 12:*** *28% of bugs cannot be triggered by specific userspace behavior alone; tests must explore kernel events and varied hardware topologies at the same time.*

4 kSTEP: Kernel Scheduler Test Platform

To address the challenges of scheduler testability (§2.3), we present kSTEP[2], a framework for *controlled* and *deterministic* execution of the Linux CPU scheduler in an isolated environment. In this section, we describe the design and implementation of kSTEP. In §5, we demonstrate how kSTEP enables the development of testing tools for the Linux scheduler, such as an execution-path tracer and a coverage-guided fuzzer. We design kSTEP around the following principles:

Precise timing. Scheduler bugs are often highly sensitive to timing, posing a significant challenge for testing and reproduction (Challenge 1). kSTEP provides fine-grained control over event timing, enabling precise triggering of bugs.

Rich control. Another challenge is insufficient control over the scheduler state from userspace (Challenge 2). kSTEP exposes events for userspace tasks, kernel activities, CPU attributes, and ticks, enabling control over scheduler behaviors.

Noise-free determinism. Noisy and nondeterministic scheduler behaviors make it difficult to detect and diagnose bugs (Challenge 3). kSTEP guarantees that the same input always produces the same clean scheduler trace, enabling reliable bug reproduction and precise comparisons of scheduler behaviors.

[2]In ASCII, kSTEP is a bit flip away from KSTEP (Kernel Scheduler: Two Easy Pieces), which in turn is a single bit flip away from OSTEP [9].

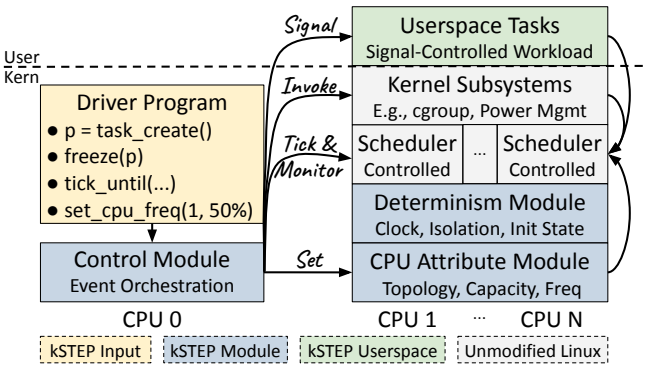

Figure 13: Architecture of kSTEP.

Fidelity. To ensure that the insights gained through kSTEP are directly applicable to real systems, kSTEP guarantees that its traces reflect real-world scheduler behavior.

Portability. To enable reliable reproduction and analysis of scheduling behaviors across different kernel versions, kSTEP does not require modification to the kernel source and is compatible with a broad range of kernel versions.

4.1 kSTEP Overview

Figure 13 illustrates the architecture of kSTEP. The input to kSTEP is a driver program that specifies a sequence of events to execute. The left side of the figure shows a dedicated CPU responsible for running both the driver program and the control module; the right side shows a controlled environment with the remaining CPUs deterministically executing the events as specified by the control module.

Controlled execution (§4.2). The driver program runs in kernel space and uses the control module to dispatch the events to the controlled environment. The events include not only actions to control processes but also kernel events (*e.g.,* kthread) and CPU attributes (*e.g.,* topology), which are otherwise impossible to control from userspace. One special event is the explicit scheduler tick. By issuing ticks manually, kSTEP advances logical time and triggers the scheduler exactly when desired. Explicit tick control enables kSTEP to order events relative to scheduler execution, allowing precise control. To preserve fidelity, the driver program cannot directly modify scheduler state; it reaches desired states only through events to exercise normal kernel code paths.

Deterministic execution (§4.3). On the remaining CPUs, userspace runs only the processes explicitly created by the control module, with nothing else permitted. These processes do not encode any workload-specific logic of their own; instead, their execution is orchestrated by the control module via signals, eliminating variability due to unpredictable execution speeds and making program behavior deterministic.

On the kernel side, the scheduler runs unmodified, but with an additional determinism module to eliminate all sources of

```
// Setup tasks: t1 runnable, t2: paused, t3 runnable
t1, t2, t3 = task_create()×3; task_wakeup({t1, t3});
// Setup cgroup hierarchy: g0: {g1: {t1}, g2: {t2, t3}}
cgroup_create({"/g0", "g0/g1", "g0/g2"});
cgroup_move_task("/g0/g1", {t1});
cgroup_move_task("/g0/g2", {t2, t3});
cgroup_set_weight({"/g0/g1", "/g0/g2"}, 15);
// Prepare scheduler state
tick_until(/* t1 eligible, but g0 and g1 ineligible */);
cgroup_move_task("/", {t1, t3});
// Trigger bug
cgroup_destroy("/g0/g1");       // Bug: overflow g0's vlag
cgroup_set_weight("/g0", 106); // Bug: overflow vruntime
// Observe task starvation
task_wakeup(t2); tick_repeat(200);
```

Figure 14: Driver pseudocode to reproduce Bug #2 in Figure 3. We discuss the driver program in more detail in Table 4.

Type	Events
Task	task_{create(), pause(p), wakeup(p), pin(p, cpumask), fork(p), set_sched(p, sched), set_prio(p, prio), freeze(p)}
Kern	cgroup_{create(g), move_task(g, p), set_weight(g, w), pin(g, cpumask), destroy(g)}, kthread_{create(), pause(p), wakeup(p)}, and any exported kernel function
Tick	tick(), tick_repeat(n), tick_until(pred)
CPU	set_freq(cpu, val), set_capacity(cpu, val), set_topo(topo)

Table 3: Selected events provided by kSTEP. In the parameters, p is a task, g is a cgroup name, and pred is a predicate function.

nondeterminism affecting scheduler execution. It controls the clock values observed by the scheduler, suppresses unintended kernel activities (*e.g.,* interrupts), and resets the initial scheduler state that may otherwise vary with the boot sequence.

Limitation. While kSTEP supports concurrent and parallel execution of tasks on multiple CPUs, the sequence of events generated by the driver program is serialized. As a result, kSTEP cannot directly expose concurrency bugs within the scheduler. As noted in §3.6, these bugs are uncommon (12%).

4.2 Controlled Execution

kSTEP operates based on a driver program that defines a sequence of events to be executed. Controlled execution means the scheduler advances exclusively through driver-issued events. The driver is a C function compiled into a kSTEP control module; it calls kSTEP's event API to orchestrate tasks, inject ticks, and configure CPU attributes on the controlled CPUs (CPUs 1–N) in the desired order. Figure 14 shows an example driver that builds a cgroup hierarchy, advances ticks until a target scheduler state is reached, then restructures the cgroups to trigger a vruntime overflow bug. Table 3 lists selected events in kSTEP.

Userspace tasks. kSTEP provides a set of events to create and control userspace tasks. For example, a driver can create tasks, pause and wake them at chosen points, pin them to CPUs, and adjust their scheduler class or priority. Most task events send signals to the userspace program, exercising the usual userspace-to-kernel code paths. When no signal is pending, the userspace program simply runs a busy loop to stay runnable. A few events, such as freezing a task, are handled by kernel-side helpers.

Kernel subsystems. kSTEP includes a set of functions that interact with other kernel subsystems, for example, to create cgroups or kthreads. Since drivers run inside a kernel module, they can also call any exported kernel function. This direct access allows fine-grained control over kernel events.

Scheduler ticks. Scheduler state evolves with every timer tick, so time-sensitive bugs require controlling when ticks occur relative to other events. kSTEP therefore provides explicit tick events to trigger scheduler execution at chosen points. It also provides a "tick until" primitive: the driver supplies a predicate, and kSTEP injects ticks until the predicate is satisfied, enabling precise waits for transient scheduler states before issuing the next event.

CPU attributes. Scheduler decisions depend on hardware properties such as topology, CPU capacity, and frequency, but these configurations are hard to control on real machines or in virtualized environments [13]. kSTEP exposes these CPU attributes as events, allowing a driver to emulate diverse hardware setups and observe how they affect scheduler decisions.

4.3 Deterministic Execution

kSTEP incorporates a determinism module to make driver execution reproducible across runs on the same kernel. Unlike traditional record-and-replay approaches that attempt to control all sources of nondeterminism [4, 14, 15, 25–27, 31, 66, 75, 80, 81, 90, 91, 106], we identify three key factors that contribute to scheduler nondeterminism: clock sources, noisy activities, and initial scheduler state.

Mock clock sources. kSTEP mocks two clock sources to ensure deterministic execution: `sched_clock`, which governs general scheduling operations (*e.g.,* time slice), and `jiffies`, which tracks timing for the next load balancing event. After each scheduler tick finishes on all controlled CPUs, both clocks are advanced, guaranteeing that time-related behaviors are fully reproducible.

Isolate noisy activities. To eliminate the noise introduced by system activities, we isolate the controlled CPUs. First, we implement a custom, minimal userspace `init` program (PID 1) to ensure that there is no other unintended process running on the controlled CPUs. We also address sources of kernel-level nondeterminism by explicitly redirecting all interrupts, RCU callbacks, and workqueue workers to CPU 0. This isolation is essential to achieving noise-free scheduler execution by ensuring the only events affecting the scheduler are those deliberately controlled by kSTEP.

Reset scheduler state. Because the kernel boot sequence is inherently nondeterministic, before driver execution we reset scheduler state to a known initial state, including zeroing runqueue load estimates, resetting per-task `vruntime` values, and clearing load-balancing cost counters on each scheduler domain. This ensures each driver run starts from the same scheduler state, independent of boot-time noise.

4.4 Implementation

The kSTEP source code is available at https://github.com/kstep-dev/kstep. The kernel module is about 1.5k LoC, complemented by a lightweight userspace program for `init` and controlled userspace tasks in about 150 LoC.

Portability. We continuously test kSTEP against long-term support kernels from the past five years (v5.15, v6.1, v6.6, v6.12, and v6.18), as well as the latest release (v7.0, at the time of writing). kSTEP is fully compatible with both `x86_64` and `arm64`, and we confirm that it produces consistent results across both architectures. As the kernel evolves, maintaining kSTEP requires little effort.

Workflow. We provide scripts to download and build a specified kernel version, then run kSTEP on the unmodified kernel in QEMU [13]. Once the kernel boots, our custom `init` loads the kernel module and executes a specified driver program. The driver emits structured JSON output to a QEMU serial console, which is used in our analysis and visualization scripts, as well as high-level tools such as the tracer and fuzzer in §5.

Driver execution. A driver defines a `name`, a `setup()` function for initialization (*e.g.,* construct test objects), a `run()` function to issue the event sequence, and optional callbacks on scheduler events (*e.g.,* on tick or load-balance). After `setup()`, kSTEP cancels the tick timer on controlled CPUs, mocks `sched_clock` and `jiffies`, and resets scheduler state. kSTEP then executes `run()` to control tasks, invoke kernel events, inject ticks, and configure CPU attributes. To implement a tick event, kSTEP advances the mocked clocks, sends IPIs [65] to invoke the tick function on each controlled CPU, and waits until all controlled CPUs finish the tick and drain pending scheduler softirqs [64]. This ensures that all CPUs reach a consistent state before the next event.

Kernel integration. kSTEP uses ftrace [98] to trace selected scheduler functions, such as load-balancing and task-group allocation paths, allowing kSTEP to observe scheduler-internal events without modifying kernel source. To call private kernel functions, kSTEP locates their address with kallsyms [63].

5 Scheduler Testing with kSTEP

kSTEP's determinism and control over scheduling events unlock a wide range of testing and analysis capabilities for kernel developers and researchers. In this section, we implement an execution-path tracer (§5.1) and a coverage-guided fuzzer (§5.2) on top of kSTEP. We then discuss additional opportunities made possible by kSTEP (§5.3).

5.1 Deterministic Scheduler Execution Tracer

Based on kSTEP, we implement a deterministic execution-path tracer that records scheduler code paths each driver event triggers. These noise-free traces help developers reproduce bugs and inspect the scheduler paths that lead to a behavior.

Event-aware tracing. For each kSTEP event, the tracer reports program counters (PCs) separately for each participating task's execution path. For example, when task A wakes task B, the tracer records the waker path executed by A and the wakee path executed by B separately. This lets users inspect each individual scheduler execution path separately and understand how each path affects scheduler state. Because kSTEP replay is deterministic, the same test generates the same trace across runs. Developers can therefore refine event sequences against stable evidence, making elusive bugs easier to reproduce than in the original nondeterministic environment.

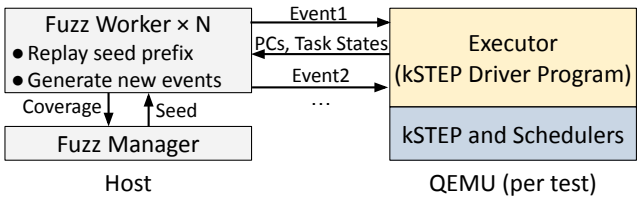

Figure 15: Overview of kSTEP fuzzer.

Implementation. We instrument the Linux kernel using LLVM SanitizerCoverage [100], which inserts PC-tracing callbacks on scheduler control-flow edges. We then symbolize PCs into source-code locations using `addr2line` [41]. To avoid noise, kSTEP records PCs mainly on the isolated test CPUs (CPUs 1–N). On CPU 0, tracing is active only while executing kSTEP events (*e.g.,* waking up a testing thread). This targeted approach ensures traces reflect test-induced scheduler behavior rather than unrelated kernel activity.

5.2 Coverage-Guided Scheduler Fuzzer

kSTEP enables noise-free coverage collection and exact event replay, making it a strong foundation for scheduler fuzzing [76]. We build a coverage-guided fuzzer on top of kSTEP to automatically explore scheduler states.

Overview. Figure 15 illustrates the kSTEP fuzzer. A host-side *manager* coordinates multiple *workers*, each running tests in a fresh QEMU instance. Each worker sends generated events to an in-guest *executor* (*i.e.,* a kSTEP driver program), which applies them to the Linux scheduler in deterministic order.

Interactive input generation. The fuzzer tracks task states (*i.e.,* running, runnable, blocked, frozen) to generate valid next events. For example, it only generates a `fork` event from a running task. After each event, the worker waits for completion and observes the updated task states. This interactive approach substantially reduces invalid inputs.

Coverage collection. The executor uses LLVM SanitizerCoverage [100] to log the program counters reached by each event. The worker converts these PCs into control-flow edge coverage and sends the result to the manager for corpus management [35]. As in §5.1, kSTEP filters PCs to avoid unrelated kernel activity. Recording coverage per event allows the fuzzer manager to pinpoint exactly which event triggers new scheduler behavior. Without kSTEP, unrelated kernel activity would pollute coverage, making fuzzing feedback unreliable.

Replay and mutation. Our mutation strategy builds on kSTEP's determinism to resume from interesting intermediate scheduler states and explore nearby behaviors. The manager marks events that yielded new coverage as split points; to

mutate a prior test, a worker replays the test up to a split point, then generates a short fresh event sequence from that point. Without deterministic replay, the same prefix could reach different states, making mutation-based fuzzing unreliable.

5.3 Potential Use Cases

In this section, we discuss additional use cases we believe can be supported by kSTEP's capabilities in the future.

Scheduler testing agents. kSTEP is well-suited for LLM-driven agents to automate scheduler testing. Such an agent can generate kSTEP driver programs to reproduce existing bugs or systematically explore scheduler behavior for new issues, testing each candidate sequence against a target kernel in seconds and iteratively improving based on results. This process depends on kSTEP's determinism: the deterministic execution trace gives the agent repeatable evidence, guiding targeted refinement of the event sequence.

Anomaly detection. kSTEP's deterministic scheduler execution produces repeatable traces that can be reliably analyzed. This provides a foundation for the development of advanced oracles to detect abnormal scheduler behavior automatically.

Policy evaluation. kSTEP 's ability to replay identical workloads deterministically enables precise comparisons across kernel versions or policy configurations. A tool built on this capability can quantify how a patch shifts scheduling decisions, expose subtle regressions, or validate that a new policy respects intended invariants.

6 kSTEP Evaluation with Case Study

Our study shows that scheduler bugs are hard to trigger and expose in practice. Thus, we propose kSTEP to execute a sequence of events deterministically, making the scheduler testable and analyzable. In this section, we evaluate kSTEP and ask the following research questions:

- §6.1: How hard is it to find kSTEP tests to trigger bugs?
- §6.2: How well can kSTEP's deterministic and noise-free trace help observe the buggy behavior and bug impacts?
- §6.3: How can kSTEP help uncover new scheduler bugs?

Case-study bug set. We sampled 7 bugs that span different components, observability, and triggers. Table 4 lists their descriptions and types (policy or functionality bug). Most bug reports lack details on how to reproduce them. These cases provide a diverse evaluation set for kSTEP.

Experiment setup. We conduct experiments on a machine with 2 Intel Xeon Silver CPUs (10 cores each) running Ubuntu 24.04. For each bug, we check out the repository immediately preceding the fix commit. We then run kSTEP on QEMU to execute our custom driver program that triggers the bug. Next, we check out the fix commit and re-run the program. Each run launches a new QEMU and shuts it down upon completion.

6.1 Trigger Bugs with kSTEP

In Table 4, we report the number of kSTEP events and LoC for each reproducer to evaluate how complex real scheduler bugs look under kSTEP 's event model. Long sequences would make kSTEP impractical. Reproducers for our studied bugs are compact: at most 20 steps and 47 LoC. Also, most studied bugs require at most five tasks to trigger, except for one case that stresses the scheduler with 20k tasks. Notably, most studied bugs were never reproduced by developers (*e.g.,* Bug #2 took a month to fix without a confirmed reproduction); kSTEP reduces them to short event sequences that run in seconds.

We also list the event types used in each reproducer. The set is diverse: task events that create, wake, pause, or freeze tasks; kernel events that control cgroups or kthreads; and CPU-frequency changes. In addition, three bugs require ticking until a specific state to hit a narrow transient window. This diversity matches our findings in §3.

Bug #1: Trigger a kernel event in a time window. This is the same bug in §2.2 (Figures 1 and 2): it only occurs when a kthread calls a sync wakeup when it is the only runnable one and the runqueue has `nr_queued` > `nr_running`.

The reproducer creates a kthread as the waker (*i.e.,* sync wakeup is an operation for kthreads only) and a userspace task that later becomes a "ghost" sleeper. Then, we tick until the userspace task becomes ineligible (*i.e.,* its runtime exceeds its share). We block it here so it remains delayed-dequeued under EEVDF policy and causes `nr_queued` > `nr_running`. With the paused task as a ghost sleeper and no other runnable tasks, both triggering conditions are satisfied. At this moment, we ask the waker to call sync wakeup. The same reproducer later showed that the upstream fix for Bug #1 was incomplete; we report the remaining bug separately as Bug #8 in §6.3.

This example shows how kSTEP lets testers reliably execute an event at a transient state. The tester advances the scheduler with "tick until," stops at the precise state, and then issues the target event at the same logical timestamp. Thus, the event is guaranteed to observe the expected transient condition, making hard-to-trigger bugs reliably reproducible.

Bug #2: cgroup hierarchy. This is the same bug in Figure 3, which remained unreproduced after a month of attempts. It requires a cgroup hierarchy and issuing an event at a transient state. Figure 14 shows the kSTEP reproducer in pseudocode.

To reproduce this bug, the driver program builds a cgroup hierarchy and places Task 1 (runnable) in cgroup 1, and Task 2 (paused) and Task 3 (runnable) in cgroup 2. The first precondition requires that cgroup 0's and cgroup 1's scheduling entities be delayed-dequeued. To reach this state, we tick the scheduler into a transient state where Task 1 is eligible but cgroup 1 and cgroup 0 are not. We then move Task 1 and Task 3 back to the root cgroup; since both tasks are currently eligible, the scheduler immediately dequeues their entities, while cgroup 0's and cgroup 1's entities remain delayed-dequeued to burn off their lag. This satisfies the first precondition.

Next, we destroy cgroup 1 so that cgroup 1's and cgroup 0's entities fully dequeue. We then reweight cgroup 0 so that the bug overflows its vruntime to a huge positive value. Finally, we wake up Task 2 and observe that Task 2 is starved because CFS avoids running cgroup 0 due to its inflated vruntime.

	ID	Description	Step	LoC	Task	CPU	T2T	Event Types	Impact
Studied Bugs	**#1** Policy	aa3ee4f: Sync-wakeup wakee not placed on waker's CPU when a delay-dequeued task exists	7	47	3	2	2.13	**Task**: create, pause, wakeup **Kernel**: kthread_{create, wakeup} **Tick until**: !eligible(tsk)	**Performance:** ~3× initial slowdown of the wakee
	#2 Func.	bbce3de: Starvation or crash due to vruntime overflow when a cgroup is dequeued under specific conditions	20	38	3	1	8.68	**Task**: create, pause, wakeup **Kernel**: cgroup_{create, set_weight} **Tick until**: eligible(tsk) && !eligible(grp)	**Correctness:** Kernel panic or tasks in the cgroup starved
	#3 Func.	cd9626e: Delay-dequeued task can still wake up after being frozen	5	28	3	1	0.02	**Task**: create, pause, wakeup, freeze **Tick until**: !eligible(tsk)	**Correctness:** Fails to capture a consistent process snapshot
	#4 Policy	6d7e478: Excessive rebalancing from multiple CPUs in the same sched group	6	28	5	2C4T	0.06	**Task**: create, pin	**Performance:** ~1 μs slowdown recurs roughly every 130 ms
	#5 Policy	17e3e88: util_avg misaccounted when the last real-time task blocks	5	26	2	1	0.49	**Task**: create, pause, set_prio **CPU**: set_freq	**Performance:** ~3× slowdown of a thread, recovers about 0.5 s later
	#6 Policy	2feab24: Pinning many tasks to one CPU makes load balancing very slow	2	21	20k	2	–	**Task**: create, pin	**Performance:** 2% CPU time is wasted for the useless rebalance
	#7 Policy	5068d84: Reweighting a running task misupdates min_vruntime	6	20	3	2	0.01	**Task**: create, set_prio **Kernel**: cgroup_{create, pin}	Benign
New Bugs	**#8** Policy	Sync-wakeup wakee not placed on the waker's CPU despite an idle sibling	7	47	3	2	0.04	**Task**: create, pause, wakeup **Kernel**: kthread_{create, wakeup} **Tick until**: !eligible(tsk)	**Performance:** ~3× initial slowdown of the wakee
	#9 Policy	Selecting the "equalize idle CPUs" balancing mode but failing to equalize idle CPUs across groups	22	44	4	4	0.27	**Task**: create, wakeup, pin **CPU**: set_capacity, set_topo	**Performance:** 1 CPU remains idle throughout execution despite pending runnable tasks
	#10 Policy	Wrong overload label on sched group prevents migration to an idle CPU	24	30	6	4	5.32	**Task**: create, wakeup, pin **CPU**: set_topo	**Performance:** 1 CPU stays idle despite pending runnable tasks
	#11 Policy	CPU's estimated utilization fluctuates sharply with an almost fully busy task	27	78	1	1	0.13	**Task**: create, wakeup, pause, set_prio **CPU**: set_capacity	**Performance:** CPU frequency may fail to ramp up

Table 4: Studied and newly found bugs. Bugs #1–#7 are studied bugs. Bugs #8 and #9 are new bugs we found using manually written kSTEP drivers. Bugs #10 and #11 are new bugs found by the kSTEP fuzzer. 2C4T: 2 cores and 4 threads. T2T: time to trigger by fuzzer in hours.

This bug has intricate triggering conditions, yet our reproducer needs only 20 events because kSTEP is able to stop the scheduler at the desired but transient state (*i.e.,* the task is eligible but its cgroup is not) with only one event, enabling reliable reproduction of bugs involving deep hierarchies.

Automated bug triggering. We use the kSTEP fuzzer (§5.2) to search for triggering event sequences. For each studied bug, we encode an invariant capturing the expected behavior; for instance, bug #4 is captured by: within a scheduling group, at most one designated core invokes the load-balancing algorithm [69]. We run the fuzzer for 24 hours, then manually inspect each violation to determine whether it reproduces the bug, is a false positive, or exposes a new anomaly.

Table 4 reports triggering times in hours. Most bugs are triggered within one hour, showing that kSTEP's deterministic, isolated execution lets the fuzzer reach buggy scheduler states effectively. Bug #2 is the hardest: it took developers 30 days to fix without a reproducer, while the fuzzer needs over 8 hours because the bug requires a condition (*i.e.,* a task must be eligible while the scheduling entities of its ancestors are not), which is reached only after exhaustive exploration. Bug #6 remains out of reach: it requires 20k threads, beyond our fuzzing scale. The fuzzer also uncovers two new bugs, Bug #10 and Bug #11, described in §6.3.

Summary. These cases demonstrate that, despite the complex triggering conditions of scheduler bugs, kSTEP enables testers to reproduce them with *simple, concise* test cases. kSTEP also enables effective automated fuzz testing of the scheduler, both to trigger the studied bugs and to uncover new anomalies.

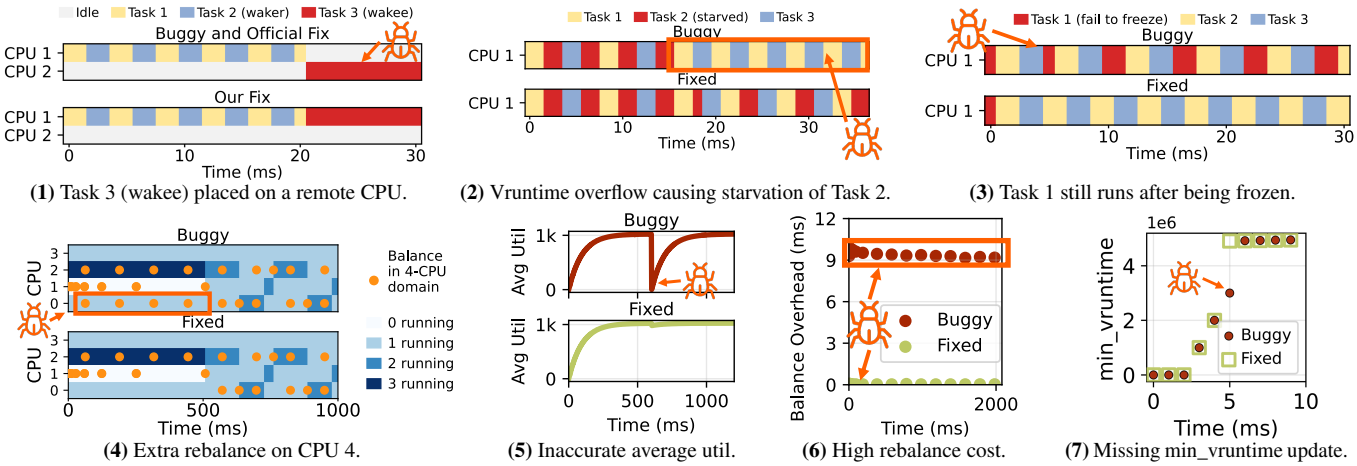
6.2 Observe Bugs with kSTEP

The output of kSTEP is a trace of the scheduler's internal states. Compared with uncontrolled systems, kSTEP traces are noise-free and deterministic. In this section, we visualize the trace generated by the reproducers of our studied bugs in Figure 16 and summarize their impact in Table 4. We first show how these traces help observe buggy behavior and support impact analysis through detailed case studies. We also evaluate the determinism of kSTEP by verifying that traces generated prior to the bug trigger are identical across runs.

Bug #1. Figure 16.1 shows a kthread calling `sync_wakeup` on CPU 1. In the buggy version, the wakee is placed on CPU 2, though CPU 1 (where the waker runs) is immediately idle; in the official fixed version (aa3ee4f), it still selects CPU 2, as the fix is incomplete. We provide a more detailed explanation in §6.3. With our patch, the wakee selects CPU 1, preserving locality. Figure 2.1 quantifies the potential impact: CPU 2 can have a low frequency as it is idle; the wakee can be 3× slower and recover after tens of milliseconds.

Bug #2. In Figure 16.2, once the bug is triggered, the vruntime of Task 2's cgroup entity overflows to a huge 64-bit value, making it effectively ineligible to run until peers catch up, so it is starved almost indefinitely. In the fixed trace, Task 2 runs normally, sharing CPU time with others.

Bug #3. In Figure 16.3, kSTEP sends a freeze to Task 1 when it is sleeping but remains on the runqueue (because of the delayed dequeue feature). In the buggy version, the task is not frozen successfully and later wakes up to run on its CPU again; in the fixed version, it remains frozen and cannot be



(1) Task 3 (wakee) placed on a remote CPU. **(2)** Vruntime overflow causing starvation of Task 2. **(3)** Task 1 still runs after being frozen.

(4) Extra rebalance on CPU 4. **(5)** Inaccurate average util. **(6)** High rebalance cost. **(7)** Missing min_vruntime update.

Figure 16: Visualization of the buggy behavior for each bug reproduced by kSTEP. In all figures, the *x*-axis shows logical time. The *y*-axis shows the CPU ID for (1)-(4); average utilization for (5); wall-time rebalance latency for (6); and minimum vruntime for (7). The colored segments show the running task on each CPU in (1)-(3), and the number of runnable tasks on each CPU in (4).

woken again. This harms correctness; applications relying on the freezer to snapshot a process can be affected.

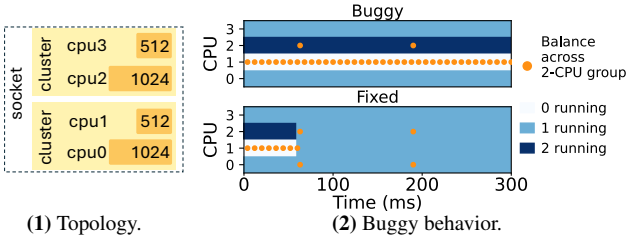
Bug #4. In Figure 16.4, we create and pin 1, 0, 3, and 1 tasks on CPUs 4–7, respectively, and examine which CPUs invoke rebalance across the 4-CPU sched domain. Ideally, only one CPU per sched group should do so; CPUs 4–5 and CPUs 6–7 form two groups. In the buggy version, both CPUs 4 and 5 attempt balancing, causing redundant calculations. In the fixed version, only one CPU per group invokes domain balancing. The impact is small (under 1 microsecond CPU time wasted per 130 ms) but can still matter for latency-critical applications. Once we remove CPU affinity for the tasks and allow migrations, the bug no longer triggers, and both versions revert to one balancing CPU per group.

Bug #5. Figure 16.5 shows that when the RT task sleeps and a CFS task takes over, the buggy scheduler drops the CPU's `util_avg` sharply and recovers after ~500 ms. A `util_avg`-driven frequency governor may lower CPU frequency and affect the task's latency (Figure 2.1). Also, the busy CPU may appear lightly loaded and attempt to pull tasks.

Bug #6. Figure 16.6 shows that pinning 20k tasks to one CPU makes load balancing on other CPUs expensive: these rebalance attempts take around 2.5 ms to finish. The fix adds a hard cap on the number of tasks to inspect, restoring normal cost (1 μs). In our setup, this bug wastes ~4 ms of CPU time every ~200 ms (the interval between affected rebalances).

Bug #7. This bug did not update the `min_vruntime` of a runqueue when reweighting a cgroup. In Figure 16.7, when triggered, the buggy version's `min_vruntime` is higher. However, this one-tick error has almost no impact on applications.

Determinism. In Figures 16.1-16.3, we see identical task switches before the trigger and clear divergence after it. In Figure 16.4, every balance attempt and task migration occurs at identical timestamps except for CPU 4. In Figures 16.5 and 16.7, buggy and fixed curves evolve identically up to the trigger. These results demonstrate kSTEP's determinism.



(1) Topology. **(2)** Buggy behavior.

Figure 17: In Bug #9, CPU 1 is idle under the specified topology.

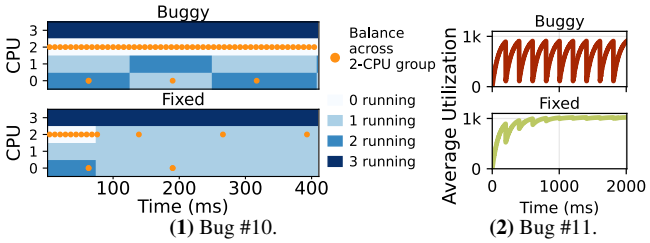
Summary. kSTEP enables deterministic and noise-free observation of scheduler bugs. It enables precise side-by-side comparison of buggy and fixed runs. The observation shows that most scheduler bugs cause noticeable disruptions across different aspects of system behavior.

6.3 New Bugs Discovered and Fixed

We also use kSTEP to uncover four new bugs in the latest Linux kernel, which we have reported to the developers. Bugs #8 and #9 are found using manually written kSTEP drivers. Bugs #10 and #11 are found by the kSTEP fuzzer.

Bug #8: Bug #1 patch does not completely fix it. Bug #8 is the remaining bug we exposed when validating Bug #1's upstream fix with our triggering program: the child still selects a remote CPU as shown in Figure 16.1. The root cause is CFS's two-phase wakeup. Phase 1 chooses a candidate CPU via heuristics such as `wake_affine_idle`; after the original fix, this phase correctly returns the local CPU. Phase 2 then decides whether to use the candidate CPU or a nearby idle CPU via `select_idle_sibling`, which still uses `nr_running` instead of the effective runnable count that excludes delayed-dequeue tasks. Thus, the patch fixed the misuse in `wake_affine_idle` but left the same issue in `select_idle_sibling`. After correcting both sites, the child selects the about-to-idle local CPU (Figure 16.1).

Bug #9: Work-conserving violation on a specific topology. Bug #9 occurs on a 2-cluster topology of varying CPU capacities (Figure 17.1). We pin 1, 0, 2, and 1 tasks on CPUs 0–3, re-



(1) Bug #10. (2) Bug #11.

Figure 18: Buggy behavior of Bug #10 and Bug #11.

spectively, then relax the affinity of tasks on CPU 2 to CPUs 1–2. The idle CPU 1 should quickly pull a task, but instead remains idle while CPU 2 stays overloaded (Figure 17.2).

The root cause is a wrong calculation. To equalize idle CPUs across the local and busiest groups, the scheduler computes the imbalance as: (local.idle_cpus - busiest.idle_cpus) / 2. In our workload, the local group has one idle CPU, and the busiest group has no idle CPU. The formula computes an imbalance of 0, so the scheduler performs no migration. This contradicts the intended policy to balance idle CPUs. To fix this bug, when the local group has one more idle CPU than the busiest group and the busiest group is overloaded, we set the imbalance to 1 instead of 0. Figure 17.2 shows that, with our fix, idle CPU 1 quickly pulls a task from busy CPU 2.

Bug #10: Work-conserving violation due to a wrong group label. We found Bug #10 on a 2-cluster topology of 4 CPUs. We pin 3 tasks to CPU 3 and 3 tasks to CPUs 0–1, then relax the affinity of the latter to CPUs 0–3. CPU 2 is idle and should quickly pull a task because there are 3 tasks eligible to run on it. However, Figure 18.1 shows CPU 2 stays idle indefinitely.

The root cause is a mislabeling: CPUs 2–3 form a cluster where CPU 3 is overloaded and CPU 2 is idle, so the cluster should be labeled *imbalanced*. Instead, the scheduler labels it *overloaded*, causing the load-balancing logic to conclude no migration is needed. With the fix, CPU 2 promptly pulls a task from CPU 1 (Figure 18.1).

Bug #11: utilization avg plunges immediately after sleep. We place a real-time task on a low-capacity CPU that runs for 200 ticks and sleeps for 1 tick, keeping the CPU nearly fully utilized. Its estimated utilization should thus stay high and stable, but Figure 18.2 shows it drops sharply when the task sleeps. The cause is that the scheduler's idle-time accounting mishandles low-capacity CPUs, overestimating how long the CPU was idle. The fix scales the idle-time estimate by the CPU capacity, keeping the estimate high for the busy task.

Summary. These results show that kSTEP uncovers new scheduler bugs with simple tests and provides a foundation for future regression and automated testing.

7 Related Work

CPU scheduler correctness. Many benchmarks have been built to evaluate schedulers: Hackbench [88] stresses message passing; Schbench [74] simulates web servers; Adrestia [34] exercises load balancing; Rt-app [10] emulates mobile tasks; and Cyclictest [40] measures wakeup latency. Another line of work focuses on verification. Ipanema [58] reimplements schedulers in a domain-specific language; Lawall *et al.* verify individual policies [56, 57]. Others simulate schedulers in userspace: LinSched and Apple's XNU scheduler test [6].

Controlled testing. Controlled testing has long been used to expose concurrency bugs [29, 33, 37, 38, 59, 72, 78, 79]. Fray [59] is a platform for performing push-button concurrency testing of JVM programs. Prior tools, such as Chess [79] and delay-bounding [33], search for bugs by bounding and exploring user-level interleavings. Controlled concurrency testing is orthogonal to kSTEP because these systems use their own schedulers to enforce interleaving rather than exercising Linux scheduler code paths.

Record and replay. Application-level record-and-replay systems record all nondeterministic inputs and internal sources of nondeterminism, such as concurrency [14, 15, 21, 25–27, 66, 75, 80, 81, 91]. Whole-machine record-and-replay techniques record every nondeterministic event along the VM boundary, allowing its entire execution to be replayed exactly [4, 22, 30–32, 86, 90, 106]. These techniques can replay previously recorded bugs but offer little help in triggering time-sensitive ones. kSTEP further lets users control scheduler state with its events, making such bugs significantly easier to expose. Also, kSTEP does not control whole-machine nondeterminism; it targets deterministic scheduler execution.

CPU scheduling policies. Many scheduling policies target different objectives [11, 20, 39, 47, 50, 55, 73, 82, 85]. We do not evaluate how these policies perform for particular workloads; instead, we check whether the implementation aligns with the intended design of the CPU scheduler.

8 Conclusion

In this paper, we characterize CPU scheduler bugs and find that they are important, yet hard to observe and trigger. We introduce kSTEP to precisely control scheduler behavior through deterministic tests, producing noise-free, repeatable traces. With kSTEP, we are able to reproduce existing bugs and uncover new ones, showing its promise as a foundation for systematic scheduler testing.

Abstract

Oversubscription is central to large-scale clouds: multiplexing virtual CPUs (vCPUs) over fewer physical CPUs (pCPUs) improves utilization and sales density, but meeting strict latency Service Level Objectives (SLOs) requires precise control over idle behavior. In 1:1 settings, idle-passthrough—especially `mwait`-passthrough—works well: by allowing guests to initiate hardware idle transitions directly, it eliminates idle-induced Virtual Machine (VM) exits and achieves near–bare-metal latency.

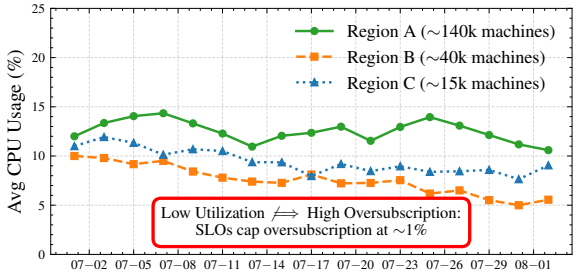
In production oversubscribed environments, however, passthrough breaks down. Because the hypervisor cannot observe `mwait` idleness, a vCPU never yields its pCPU, causing idle vCPU to monopolize cores and driving up contention, steal time ratios, live migrations, and SLO alarms across regions. Controlled experiments reproduce these production symptoms: **even an idle vCPU executing `mwait` can raise colocated tail latency by up to 3×.**

We present `mwait`-sched, a virtualization-aware redesign of `mwait` handling that reconciles bare-metal-like idle latency with predictable pCPU multiplexing. `mwait`-sched integrates deterministic timer-based emulation, fine-grained idle-interval classification, and a scalable multi-address `mwait`-proxy that restores idle visibility without frequent VM exits. Across nine representative workloads, it reduces P99 (**99$^{\text{th}}$** percentile) latency by 30–50% and reduces steal ratio by 30–40%. At hyperscale, across globally distributed production regions comprising ∼ 3.2M pCPUs, it reduces high-contention steal events by over 80%, cuts daily live migrations by 30–50%, and raises oversubscription ratio from 1.0% to 20.3%, effectively adding ∼ 600,000 vCPUs of sellable capacity.

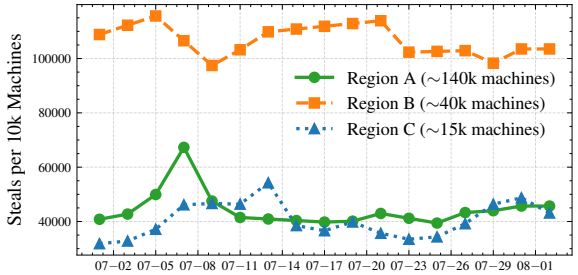
1 Introduction

Oversubscription has become a common and effective strategy in large-scale cloud platforms, allowing providers to increase resource utilization and improve overall fleet efficiency [9, 15, 16, 22, 29, 36, 38, 45, 54]. By multiplexing virtual CPUs (vCPUs) over a smaller pool of physical CPUs (pCPUs), Cloud Service Providers (CSPs) can significantly raise oversubscription ratios without impacting most workloads.

At the same time, strict latency Service Level Objectives (SLOs) remain central to cloud service guarantees. For latency-sensitive applications, even small scheduling delays can translate into SLO violations [5, 32, 40, 51]. The x86 `mwait` instruction is the standard low-latency idle path on modern CPUs: paired with `monitor`, it places a core into a



(a) Average CPU utilization across three production regions.



(b) Steal events across the region, where a VM's steal time ratio exceeds 5% in a 3-second sampling interval.

Figure 1: Cluster-level traces from three production regions. Although utilization is low, oversubscription is capped at ∼1% because higher selling would trigger contention and violate latency SLOs.

*Corresponding author.

low-power C-state and wakes on a write to a monitored memory location, avoiding the IPI round-trip that interrupt-driven idle paths like `hlt` require. In non-oversubscribed (1:1) settings, `mwait`-passthrough offers an appealing solution (details in §3): by allowing the guest to directly drive hardware idle transitions, it eliminates Virtual Machine (VM) exits on idle instructions and substantially lowers idle-exit latency, thereby improving tail performance [24].

However, when applied to oversubscribed environments, this same mechanism introduces critical problems. Instead of enabling efficient multiplexing, `mwait`-passthrough disrupts pCPU sharing and leads to escalating contention signals across production regions.

To understand contention in our production environment, we analyzed three regions representing large, medium, and small deployments. Figure 1a shows VM-level CPU utilization across these clusters. Despite uniformly low utilization, oversubscription remains limited to only about **1%**, because selling additional capacity would amplify contention and violate latency SLOs. At million-core scale, each additional percentage point of oversubscription yields roughly 10,000 vCPUs of additional sellable capacity.

To quantify contention, we use the steal-time ratio, the fraction of time a vCPU is ready to run but cannot obtain pCPU resources, and treat 5% as the operational threshold for noticeable interference [34].

Figure 1b shows that, even under similarly low utilization, regions differ by more than an order of magnitude in the fraction of VMs exceeding this threshold. Unlike utilization, rising steal-time ratios directly indicate performance degradation. This divergence demonstrates that utilization is decoupled from interference, making it an unreliable signal for safe vCPU placement.

A deeper investigation revealed the root cause. Despite its excellent latency characteristics, `mwait`-passthrough is fundamentally incompatible with pCPU sharing because its **native semantics do not translate into virtualization.** On bare metal, `mwait` is a true blocking primitive: the processor enters a deep C-state and relinquishes execution until a microarchitectural wake event occurs. In virtualization, however, this hardware-level blocking cannot be observed or mediated by the hypervisor. As a result, a passthrough vCPU never performs a schedulable yield. From the host scheduler's viewpoint, it remains continuously runnable and is therefore accounted as 100% busy. This semantic gap—between hardware-defined idleness and software-visible runnability—causes passthrough vCPUs to monopolize their pCPUs under oversubscription, amplifying contention, delaying colocated vCPUs, and destabilizing latency-sensitive workloads. This leaves us with a simple goal: keep `mwait`'s low wake-up latency, but make idle vCPUs visible to the host scheduler when pCPUs are shared. We introduce `mwait`-sched to meet this goal through three mechanisms:

1. **Profile-guided timer-based `mwait` emulation.** A hypervisor timer regains control from idle vCPUs at slice intervals tuned per workload from PMU counters (short slices of 20–50 µs for I/O-heavy services, longer for CPU-bound), restoring idle visibility to the host scheduler without per-instruction trap-and-emulate cost.

2. **Bimodal-idle vCPU aggregation.** `mwait` idle durations follow a bimodal distribution—transient (μs-scale spinlock backoff) versus stable (ms-scale quiescence); `mwait`-sched aggregates only stable-idle vCPUs onto shared pCPUs, raising density without making transient-idle interference worse.

3. **Multi-address `mwait`-proxy.** A hypervisor-side linked list of monitored addresses, scanned on every hypervisor entry, replaces per-vCPU timers when several vCPUs share a pCPU; this variant scales beyond two-vCPU colocation and is deployed on the burst-instance fleet.

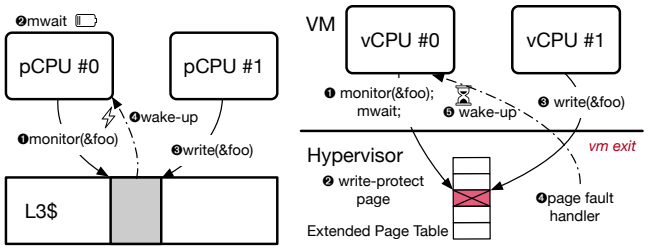
We deployed `mwait`-sched in the production fleet of a leading global cloud provider, covering $\sim 3.2M$ pCPU cores. In production, it reduces average daily alarms by 61.5%. In targeted workloads that match our main deployment scenarios, it reduces latency by 60% on average. To our knowledge, this is the first work to systematically study and optimize idle instructions in large-scale cloud environments.

2 Background

2.1 vCPU Scheduling

Colocation for Latency-intensive Workloads. Cloud workloads exhibit substantial variability in CPU demand, prompting cloud providers to increase pCPU utilization by multiplexing multiple vCPUs on fewer physical cores. Prior studies examine how to pack heterogeneous tasks while balancing contention, latency, and utilization [4, 9, 14, 21, 31]. A long line of work explores colocating latency-critical (LC) and best-effort tasks to increase aggregate efficiency [13, 17, 29, 33, 48]. In production, however, even colocating idle vCPUs with LC workloads can violate SLOs: idle vCPUs create unpredictable wake-up interference that breaks LC latency. Consequently, CSPs adopt *exclusive core allocation* for LC workloads, avoiding any form of colocation.

A key mechanism enabling safe oversubscription is the use of idle instructions as cross-layer scheduling signals. Unlike bare-metal systems, where idle instructions serve solely as power-management hints, virtualized environments reinterpret them as opportunities for vCPU descheduling: the hypervisor treats a guest idle event as an explicit yield, reclaiming pCPU cycles for runnable vCPUs [5, 33, 54]. Thus, accurate idle detection is fundamental to high-density multiplexing.



(a) Bare-metal `mwait` (b) Virtualized `mwait`

Figure 2: Bare-metal vs. virtualized `mwait`. Hardware monitoring enables fast, cache-line–granular wake-up. Virtualization must use coarse, high-overhead mechanisms such as page-protected emulation.

2.2 Idle Instructions

Modern CPUs provide `hlt` and `mwait` to enter idle states with varying power and latency characteristics [41, 50]. `hlt` halts execution until an interrupt arrives, whereas `mwait` waits on monitored memory events and enables deeper C-states with lower exit latency [23, 55]. These properties make `mwait` an appealing candidate for latency-sensitive workloads.

However, `mwait` semantics fundamentally conflict with virtualization. The instruction depends on microarchitectural monitoring and cache-line–granularity wake-up signals that software-based hypervisors cannot observe or emulate [42]. Virtualized clouds rely on idle events to detect quiescent vCPUs and reassign their pCPUs; `hlt` supports this by triggering a VM exit and allowing the hypervisor to suspend the vCPU. But these VM exits impose substantial overhead that inflates tail latency [6, 25, 28].

`mwait` creates even deeper challenges. Upstream KVM, lacking hardware visibility, treats intercepted `monitor`/`mwait` as no-ops, forcing the vCPU to spin and preventing the hypervisor from recognizing idleness [26, 27]. Passthrough allows the guest to execute native `mwait` and enter hardware C-states, but because the vCPU thread remains bound to the pCPU, guest idleness becomes host-level busywait, causing large and unpredictable delays for colocated vCPUs [47]. In short, both no-op emulation and passthrough destroy the scheduling semantics required for efficient pCPU sharing.

Virtualizing `mwait`: Monitoring vs. Software Simulation. Figure 2 illustrates the semantic gap. On bare metal, `monitor` tracks writes to a cache line and wakes the CPU through a microarchitectural event. In virtualization, issuing `monitor`/`mwait` causes a VM exit. The hypervisor must either poll the monitored address—wasting pCPU cycles—or rely on page-protected emulation, where writes trigger page faults or EPT (Extended Page Tables) violations [18]. This emulation incurs thousands of cycles and operates at page granularity, far coarser than `mwait`'s intended semantics.

Host vs. Guest Semantic Gap. Passthrough further exposes a scheduling mismatch: the guest expects `mwait` to place the CPU in a deep C-state, while the host scheduler expects runnable vCPU threads. When the pCPU enters deep idle, the host loses visibility into the vCPU's status, preventing safe time-slice reallocation and introducing long wake latencies that affect other tenants [47]. These effects directly conflict with oversubscription and predictable tail-latency guarantees.

Security Considerations. Allowing unregulated passthrough of `mwait` in multi-tenant settings introduces denial-of-service and timing-side-channel risks [52]. A malicious VM could force pCPUs into deep C-states, delaying colocated workloads and amplifying latency variance.

Existing Mechanisms and Limitations. Prior mechanisms attempt to reconcile `mwait` with virtualization, but all introduce severe trade-offs:

1. **NOP Simulation**: Trap-and-resume converts guest idle loops into rapid VM exits, preserving wake-up latency but imposing high exit overhead.

2. **`mwait`-Passthrough (non-oversubscribe)**: Allows native C-state transitions but prevents the hypervisor from detecting idleness, making oversubscription unsafe.

3. **`hlt`-Passthrough**: Avoids the trap on `hlt` itself, but every wake-up still arrives as an IPI that traps for emulation and injection, so the hypervisor pays an exit-and-reentry per idle-active transition.

4. **Paravirtualization**: Requires intrusive guest changes and is unsuitable for public clouds.

Across these methods, none preserve low-latency `mwait` semantics while enabling scalable, high-density vCPU aggregation. Existing approaches either abandon hardware behavior, incur prohibitive overheads, or break core-sharing safety.

Summary. Efficiently supporting `mwait` in production-scale virtualized environments remains a challenging and high-impact problem. The instruction's reliance on microarchitectural memory events is fundamentally misaligned with software-based hypervisor control, and both existing emulation and passthrough fail to provide accurate idle detection or safe pCPU sharing. Overcoming this semantic conflict is essential for enabling low-latency workloads and high oversubscription in modern multi-tenant clouds.

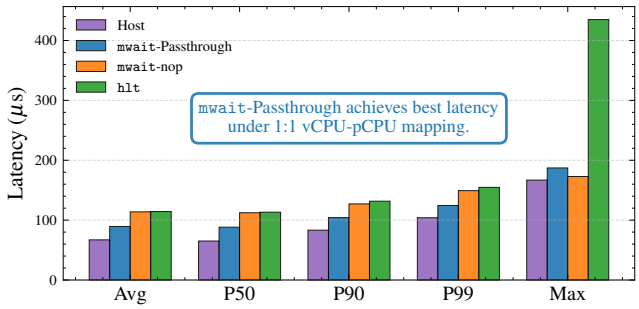


Figure 3: YCSB request latency under four execution configurations (Redis). Among all VM setups, the VM with `mwait` passthrough achieves the lowest latency, while the `hlt`-based VM and the VM using trapped `mwait` both suffer higher latency due to the overhead of trap-and-emulation on idle instructions.

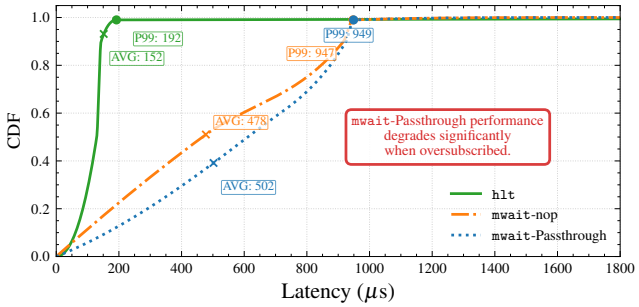

Figure 4: YCSB latency CDF on a latency-critical VM colocated on the same pCPU with an otherwise-idle VM. Three curves vary the idle instruction the colocated VM uses: `hlt`, `mwait`-nop (KVM treats `mwait` as a no-op), and `mwait`-passthrough. Both `mwait` variants degrade the latency-critical VM substantially relative to `hlt`, even though the colocated VM is doing no work, because under both the idle vCPU never yields the pCPU back to the latency-critical workload.

3 Characterization

3.1 Symptoms: Latency Benefits but Severe Colocation Interference

We conducted YCSB (Yahoo! Cloud Serving Benchmark [8]) experiments with four different configurations: (1) Bare-metal, where the system runs directly on physical hardware without any virtualization; (2) VM with `hlt`, where the virtual machine (VM) uses the `hlt` instruction to enter an idle state; (3) VM with `mwait`, where the VM uses the `mwait` instruction to enter a low-power state; and (4) VM with `mwait` passthrough, where `mwait` is passed directly to the guest without any intervention. In configurations 2 and 3, both `hlt` and `mwait` are privileged instructions, so they trigger a **trap and emulation** process. As a result, both setups involve VM exits when the instructions are executed.

Table 1: Comparison of vm exits (exits/s)

	mwait-passthrough	**mwait-nop**	**hlt**
Total	9,953	1,835,258	6,161
Idle-induced	0	1,826,602	1,773

As shown in Figure 3, we observed the impact of different configurations on average read and write latencies, as well as P99 (**99th** percentile) latencies. The Bare-metal configuration, representing the host system, provides the highest performance and serves as the ideal performance for latency.

Among the virtualized configurations, the `mwait`-passthrough VM delivers the lowest latency: its average read and write latencies are roughly 20% lower than those of both the `hlt`-based VM and the `mwait`-nop VM. The improvement also appears in the tail, where passthrough achieves lower P99 latency.

The key difference is that `mwait`-passthrough avoids all idle-induced exits, while `mwait`-nop triggers more than 1.8M and `hlt` incurs 1,773 (Table 1). By allowing the guest to change the hardware idle state without involving the hypervisor, passthrough eliminates the trap–and–resume cycles that dominate exit overhead. This directly accounts for both the roughly 20% reduction in average latency and the improvement in P99 latency.

While `mwait`-passthrough allows the guest to directly issue hardware `mwait`, it becomes problematic once the host CPU is shared. To quantify this effect, we colocate a latency-critical VM with an otherwise-idle VM on the same pCPU and vary the idle instruction the colocated VM uses: `hlt` (the standard, hypervisor-trapped path), `mwait`-nop (KVM's current treatment of guest `mwait`), and `mwait`-passthrough. We then run a YCSB latency test on the loaded VM. As shown in Figure 4, both `mwait` variants cause substantial performance degradation relative to `hlt`, even though the second VM is completely idle. This result highlights a fundamental problem: once a vCPU executing `mwait` occupies a shared pCPU without yielding, any co-located vCPUs can experience severe and unpredictable latency inflation.

3.2 Root Cause: Missing Idle-Exit Signals under Passthrough

Although `mwait`-passthrough substantially reduces VM exits, it also prevents an idle vCPU from yielding control back to the hypervisor. This limitation becomes harmful under oversubscription—the common case in production—where multiple vCPUs share a single pCPU. In such settings, enabling `mwait` passthrough can unintentionally amplify contention and increase latency.

As shown in Figure 5, when there is no oversubscription and each vCPU is pinned to its own pCPU, `mwait`-

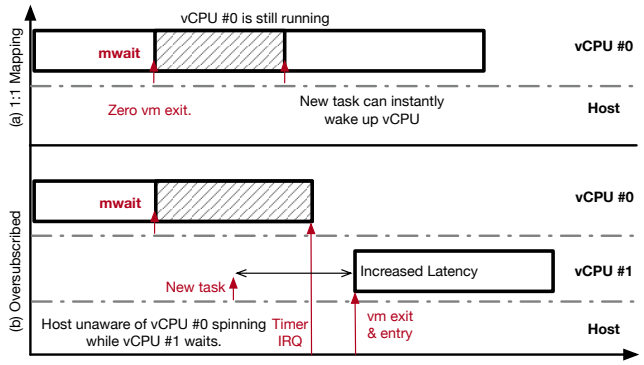

Figure 5: Behavior of `mwait` under passthrough in non-oversubscribed (top) and oversubscribed (bottom) settings. Passthrough preserves low latency when each vCPU owns a dedicated pCPU, but prevents timely yielding under oversubscription, inflating latency for colocated vCPUs.

passthrough behaves benignly. Even if the guest enters an idle loop, no other vCPU competes for the core, and the vCPU will simply resume execution without incurring additional VM exits. This is why passthrough delivers the best latency in 1:1 vCPU–pCPU environments.

The behavior changes fundamentally under oversubscription. Consider the scenario in which vCPU 0 executes `mwait` intending to yield. Because passthrough treats `mwait` as a hardware instruction, the hypervisor receives no signal that the vCPU has become idle. Consequently, the pCPU continues to be "owned" by vCPU 0—even though it is idle—until an unrelated event such as a timer interrupt triggers a scheduling opportunity. Meanwhile, vCPU 1, which is runnable and waiting on the same pCPU, experiences inflated queuing delays. The resulting latency inflation is especially severe for latency-critical workloads colocated with a passthrough-`mwait` VM.

In contrast, if `mwait` is trapped, the hypervisor can immediately reassign the pCPU to vCPU 1, restoring expected scheduling behavior and significantly improving tail latency. This divergence in behavior makes it necessary to handle idle instructions differently depending on whether the system is oversubscribed. In short, while passthrough is ideal for 1:1 mappings, it is detrimental in shared-core settings where timely yielding is essential for maintaining low latency.

4 `mwait`-sched Design

`mwait`-sched is designed to make `mwait` usable in oversubscribed, multi-tenant cloud environments, where naïve passthrough causes uncontrolled contention and existing trap-and-emulate approaches fail to preserve low-latency behavior. The scheduler must protect latency-sensitive workloads, support high consolidation to improve resource utilization, and mitigate interference under colocation. To meet these requirements, we design `mwait`-sched as a hypervisor-level mechanism that preserves the low-exit semantics of `mwait` while giving the hypervisor sufficient visibility to safely multiplex vCPUs on shared pCPUs. We have deployed `mwait`-sched across production regions, where it operates at cloud scale and serves diverse tenant workloads. The remainder of this section describes its core components: profile-guided `mwait` emulation, contention-aware wake-up, `mwait`-based vCPU aggregation, and a scalable multi-address `mwait`-proxy for high-density consolidation.

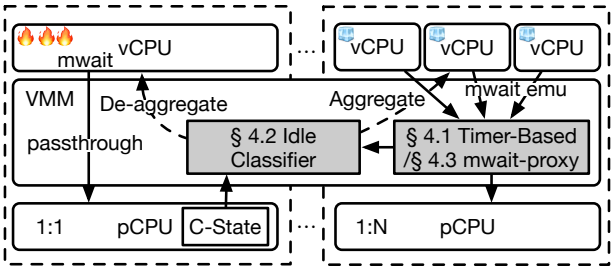

Figure 6: Overview of `mwait`-sched. Active vCPUs run 1:1 with passthrough `mwait` (left); the §4.2 idle classifier aggregates stable-idle vCPUs onto a shared 1:*N* pCPU (right), where `mwait` is emulated by either the §4.1 hypervisor timer or the §4.3 multi-address linked-list proxy.

Figure 6 illustrates the core idea of `mwait`-sched. The hypervisor handles vCPUs in two modes based on how often they idle. Active vCPUs run 1:1 with passthrough `mwait`, which lets the core enter a hardware C-state directly and gives the lowest exit latency. Once a vCPU's idle pattern is classified as *stable* by idle classifier in §4.2, it is aggregated onto a shared 1:*N* pCPU where `mwait` is emulated either by §4.1's periodic hypervisor timer (used for low-density colocation, e.g., dedicated instances at $\leq$1:2) or by §4.3's multi-address linked-list proxy (used at higher density on burst instances, typically $\sim$1:4). When a previously stable vCPU resumes activity, the classifier de-aggregates it back to a dedicated pCPU. Together these mechanisms close the visibility gap of `mwait` under virtualization without sacrificing the low-latency idle path for active workloads.

4.1 Profile-guided `mwait` emulation

As §3 shows, `mwait` passthrough works well only when a vCPU exclusively owns a pCPU, while enabling `mwait` exits is necessary under colocation to avoid uncontrolled contention. A natural first step is therefore to enable passthrough only for exclusive vCPUs. However, this immediately raises a key challenge: how to emulate `mwait` correctly when multiple vCPUs share a pCPU.

As discussed in §2.2, the special semantics of `mwait` make simple trap-and-simulate infeasible. The hypervisor cannot reliably observe the memory writes that should wake a sleeping vCPU, and therefore cannot emulate the hardware monitor-

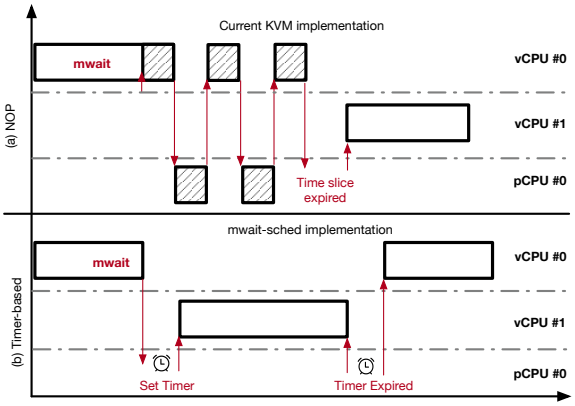

Figure 7: Profile-Guided `mwait` emulation allows vCPUs to yield in a controlled interval, preventing pCPU monopolization and reducing contention under colocation.

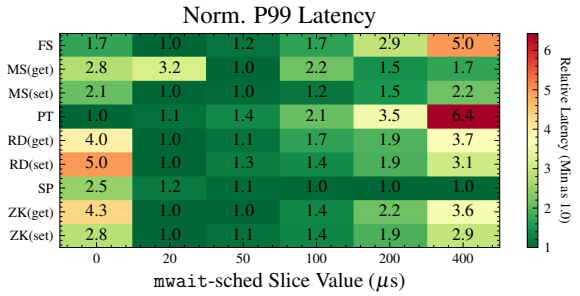

Figure 8: Normalized P99 latency across nine representative workloads (definitions in Table 3) as we vary the `mwait`-sched slice length. Each row is normalized to the minimum P99 observed for that workload (greener is better). All measurements were collected under a 2 vCPU : 1 pCPU colocation setting. Short slices (0–50 µs) favor I/O- and synchronization-heavy services, whereas CPU-bound compute prefers longer slices.

ing behavior. To address this, we introduce a periodic timer that forces control back to the vCPU at fixed intervals. At each timer tick, the vCPU checks whether its wake-up conditions are met, allowing us to provide deterministic `mwait`-like behavior even when vCPUs are colocated.

Figure 7 illustrates the effect of KVM's current no-op implementation. When `mwait` is treated as a NOP, a vCPU never yields and effectively monopolizes the pCPU time slice, causing severe interference for colocated vCPUs.

In `mwait`-sched, we replace the NOP with a timer-based emulation. The timer guarantees that a vCPU regains control within a bounded time window, while allowing the scheduler to allocate the pCPU to other vCPUs between ticks. The length of this window determines the tradeoff between latency and throughput: short slices allow latency-sensitive workloads to regain execution quickly, while overly short slices introduce excessive VM switching overhead and waste CPU cycles in context switching.

To balance this tradeoff, a number of approaches could in principle be adopted—ranging from offline profiling with per-VM tuning, to online machine-learning classifiers, to fine-grained instruction-level instrumentation. However, these techniques introduce nontrivial complexity, operational burden, or deployment risks at hyperscale. For production stability, we adopt a simple and robust solution: a profile-guided `mwait` emulation.

As shown in Figure 8, most latency-sensitive, I/O-heavy workloads (FS, MySQL, Redis, ZooKeeper, and PT) achieve their lowest P99 latency when the `mwait`-sched slice is short, typically in the 20–50 µs range: for example, Redis get/set improve by roughly 4–5× when moving from a 0 µs slice to 20 µs. In contrast, the CPU-intensive `super-pi` benchmark benefits from longer slices, with P99 latency steadily decreasing by about 2.5× as we extend the slice from 0 µs to 400 µs. The mechanism is direct: I/O- and synchronization-heavy workloads idle frequently and are sensitive to wake-up latency, so a shorter slice that resumes them quickly when the wake event arrives reduces queuing delay; `super-pi` rarely idles, so any short-slice timer overhead pays for nothing and just wastes cycles.

eBPF traces of representative vCPUs make this concrete: an I/O-bound vCPU enters `mwait` only ∼19 times/sec but stays idle ∼53 ms each time (∼96% of episodes longer than 1 ms), while a CPU-bound vCPU enters ∼6,900 times/sec with each idle averaging only ∼110 µs (∼95% under 200 µs). The I/O-bound vCPU spends most of its time idle waiting for a request, so each wake aligns with a real I/O or synchronization event and a short slice cuts directly into the request tail. The CPU-bound vCPU's idles are short scheduler-sync gaps with no external wake to align with, so a short slice just adds a timer interrupt per gap without any latency upside.

Because we cannot inspect applications inside customer VMs, we infer workload type by sampling PMU (Performance Monitor Unit [20]) counters and using the ratio of IOPS (Input/Output Operations Per Second) to vCPU utilization as a simple, deployable indicator: high ratios correlate with latency-sensitive workloads, while low ratios correspond to CPU-intensive jobs. Based on this signal, `mwait`-sched dynamically steers such workloads toward shorter or longer slices, balancing latency and throughput across diverse tenants.

As shown in Figure 9, the guest-reported VM utilization stays nearly flat (around 6–9%) across all slice lengths, but the host CPU utilization jumps from about 8–10% at 400 µs to over 50–60% at 0–20 µs. These extra host cycles are spent on more frequent timer interrupts, VM exits, and rescheduling rather than useful work, effectively increasing the cost of idleness and capping the workload's maximum sustainable throughput. Thus, blindly choosing the smallest slice is counterproductive: `mwait`-sched must trade off tail-latency gains against the additional host CPU consumption of overly

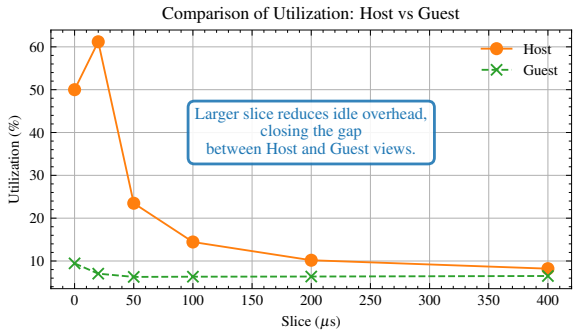

Figure 9: Average host/guest CPU utilization of the nine representative workloads under different `mwait`-sched slice lengths (2 vCPU : 1 pCPU). Short slices inflate host usage due to timer and scheduling overhead, while guest-reported utilization remains almost unchanged.

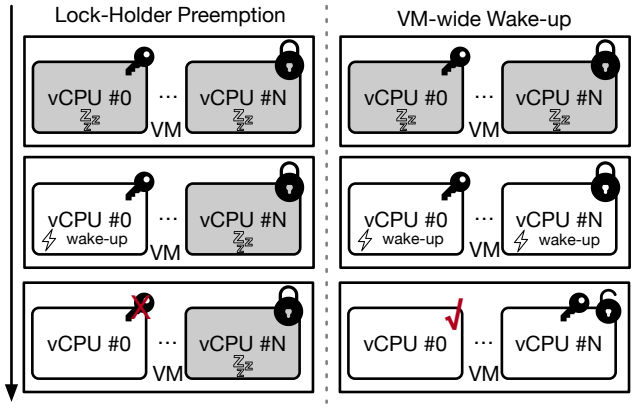

Figure 10: Naïve `mwait` emulation wakes only the waiter, leaving the lock holder descheduled and causing lock-holder preemption. `mwait`-sched instead performs VM-wide wake-ups, ensuring lock holders and waiters are co-scheduled to restore forward progress under oversubscription.

fine-grained slices.

Avoiding Lock-Holder Preemption in `mwait` Emulation. A naïve implementation of profile-guided `mwait` emulation wakes only the vCPU that issued the simulated `mwait` exit. However, this approach suffers from the classic *lock-holder preemption* problem: the awakened vCPU often depends on another vCPU—typically the lock holder or a synchronization partner—that has been descheduled by the hypervisor. As a result, the awakened vCPU immediately stalls on the same contended memory location, wasting its entire time slice and amplifying tail latency. In oversubscribed environments, where such dependency chains are common, this can lead to severe head-of-line blocking and cascading delays across the VM.

To address this issue, we treat `mwait`-driven wake-ups as VM-local synchronization events and wake *all* runnable vCPUs belonging to the same VM. When the periodic timer re-evaluates simulated `mwait` states and determines that a vCPU should be woken, we activate not only the vCPU that originally issued the simulated `mwait` but also other vCPUs in the same VM that may lie on its critical path. This optimization addresses the classic *lock-holder preemption* problem: by waking all runnable vCPUs that may participate in the upcoming synchronization step—including lock holders, I/O threads, and application threads likely to release or propagate the event—we ensure immediate forward progress and avoid pathological latency spikes under oversubscription.

The overhead of this design is low in practice: VMs typically have only a small number of runnable vCPUs near idle boundaries, and waking them merely marks the vCPUs as eligible for scheduling rather than forcing context switches. Figure 11 confirms this even in the worst case where all 48 vCPUs of a VM are woken at once. The hypervisor cost to mark all 48 runnable stays at $\sim$20 µs across oversubscription ratios $R \in \{1.0, 1.1, 1.2, 1.5\}$, since the work scales with the vCPU count, not the level of oversubscription. The time until every vCPU is actually on-CPU climbs to $\sim$240 µs at R=1.5, but that gap is just the queue waiting for a pCPU to free up; any wake mechanism inherits it under oversubscription. In contrast, the latency benefits are substantial. By aligning wake-up semantics with VM-level synchronization behavior, the scheduler ensures that lock holders and waiters are co-scheduled, reducing wake-up jitter and improving end-to-end performance under oversubscription.

Figure 10 illustrates the difference between naïve single-vCPU wake-up and our VM-wide wake-up strategy. In the naïve case, the waiter is awakened while the lock holder remains descheduled, causing the waiter to spin unproductively until the next scheduling opportunity. In contrast, our approach wakes both the waiter and the lock holder, restoring forward progress immediately.

4.2 `mwait`-based vCPU Aggregation

A central insight of `mwait`-sched is that `mwait` provides a fine-grained, guest-generated signal of short-term idleness that can be formalized and exploited for safe vCPU aggregation. To distinguish meaningful slack from brief synchronization stalls, `mwait`-sched maintains a lightweight profile of idle intervals. Let Δt_i denote the duration of the i-th idle episode, measured as the time between two consecutive `mwait` entries or between `mwait` entry and the next activity-indicating timer tick. Empirically, idle durations form a bimodal distribution: one cluster corresponding to microsecond-scale *transient idle* caused by spinlock backoff or retry loops, and another corresponding to millisecond-scale *stable idle* produced by genuine quiescence such as thread sleep or queue emptiness. Figure 12 confirms this on production hosts: in eBPF-sampled traces, 99.6% of `mwait` episodes on busy vCPUs finish within 200 µs, while

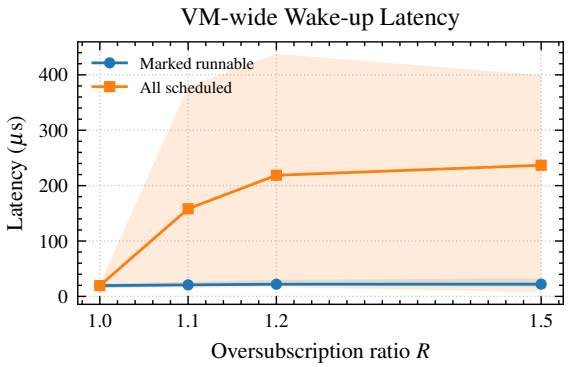

Figure 11: VM-wide wake-up latency on a 48-vCPU VM at oversubscription ratio R (vCPUs per pCPU). *Marked runnable* is the hypervisor's cost to mark all 48 vCPUs eligible to run; *All scheduled* is the time until every vCPU has been picked up by a pCPU. Shaded bands span per-trial min/max over a 30 s window; markers show the mean.

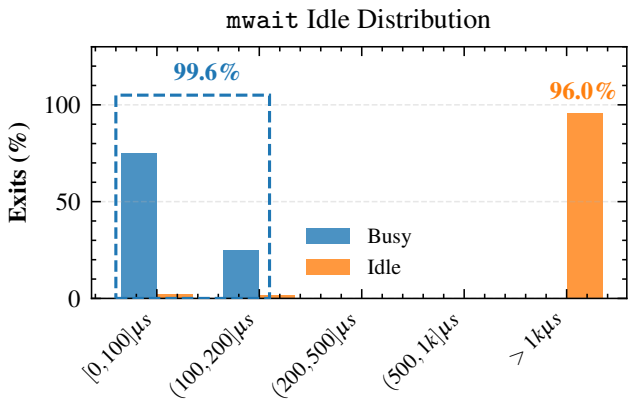

Figure 12: Distribution of `mwait` idle durations sampled with eBPF on randomly chosen production hosts. 99.6% of episodes on busy vCPUs end within 200 µs; 96.0% of episodes on idle vCPUs last beyond 1 ms. The two populations are essentially disjoint, justifying the binary stable/transient classifier.

96.0% of episodes on idle vCPUs last beyond 1 ms. Almost nothing lands between 200 µs and 1 ms, so a single threshold cleanly separates the two populations.

We formalize this distinction using a classifier $C(\Delta t_i)$:

$$C(\Delta t_i) = \begin{cases} \text{transient}, & \Delta t_i < \theta \text{ or } \Delta t_i \in \text{HighVar}(W), \\ \text{stable}, & \Delta t_i \geq \theta \text{ and } \Delta t_i \in \text{LowVar}(W), \end{cases}$$

where θ is a latency-safe aggregation threshold, and $\text{Var}(W)$ measures the variance of idle intervals over a sliding window $W = \{\Delta t_{i-k}, \ldots, \Delta t_i\}$. Transient idle thus corresponds to short, bursty intervals with high variance, indicating imminent forward progress and making aggregation unsafe. Stable idle corresponds to long, low-variance intervals, signaling that the vCPU is quiescent and eligible for aggregation.

Only vCPUs for which $C(\Delta t_i) = \text{stable}$ are considered for packing. When spare capacity is available, the scheduler aggregates these stable-idle vCPUs onto shared pCPUs, increasing consolidation density while avoiding interference with active workloads.

To preserve latency guarantees, aggregation is tightly coupled with deterministic de-aggregation. When a vCPU exhibits transient idleness, exiting `mwait` quickly, it is immediately separated from its siblings and restored to dedicated execution. This rapid de-aggregation prevents bursty workloads from incurring queuing delays while still allowing deep consolidation during idle phases.

Compared to traditional consolidation mechanisms that rely on coarse reactive signals such as CPU utilization or run-queue length, `mwait`-based aggregation is predictive: the guest explicitly informs the hypervisor of current idleness, enabling fine-grained packing opportunities without incurring unnecessary interference. This design improves consolidation density, supports higher oversubscription ratios, and reduces pCPU fragmentation while keeping tail latency close to the non-overcommitted baseline.

Architectural C-state reporting does not solve this visibility problem. Although x86 processors expose MWAIT-hint-driven C-state residency fields through power-management registers [19], these counters are too coarse and asynchronous for scheduling. They can show that a core spent time in an idle state, but they do not provide the timely per-vCPU yield signal needed to multiplex pCPUs safely.

4.3 Multi-Address `mwait`-Proxy

The profile-guided, timer-based approach works well when only two vCPUs share a pCPU, but it fails to scale as more vCPUs are colocated. Assigning a dedicated timer to each vCPU triggers excessive VM switches, consuming substantial pCPU cycles in context switching. Moreover, for workloads such as database systems that rely heavily on bare-metal `mwait` on the `NEED_RESCHED` flag to bypass IPIs [46], timer-based emulation becomes fundamentally inadequate: the guest must wait until the next timer tick, even when the `NEED_RESCHED` flag is already set.

To support high vCPU aggregation while avoiding these delays, we introduce a multi-address, linked-list–based `mwait`-proxy design that tracks multiple watched locations and promptly boosts these workloads without relying on periodic timers. Each time a vCPU executes `mwait` and exits, we insert its monitored address into a shared linked list maintained by the hypervisor. Whenever control returns to the hypervisor, we scan this list and check all monitored addresses to determine whether any vCPU should be woken up. Unlike the timer-based approach, this method allows multiple vCPUs to

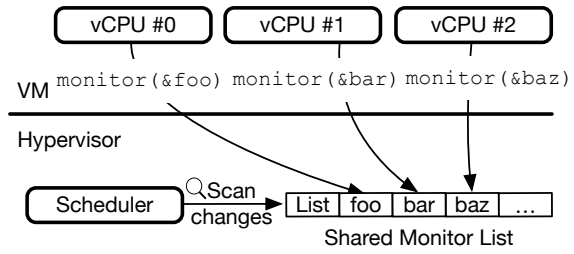

Figure 13: `mwait`-proxy replaces per-vCPU timer polling with a shared multi-address monitor. By tracking all `mwait` addresses in the hypervisor, it supports many colocated vCPUs without incurring excessive VM exits.

share a pCPU efficiently without installing multiple periodic timers, eliminating unnecessary VM switches and reducing wasted cycles.

We believe this multi-address proxy is the most practical way to emulate multi-address `mwait` using today's x86 hardware. Supporting true multi-address monitoring would likely require ISA support—such as a new vectorized monitor instruction—to allow the hardware to track multiple addresses natively.

Wake-up correctness. Native x86 `mwait` wakes on any store to the monitored address, not on a value change, so a same-value write or a write-then-revert can in principle defeat a value-comparison check. `mwait`-sched is unaffected: the timer just delays the vCPU between checks, and the wake check runs at every tick, so no event in the steady state goes unchecked. The question applies to `mwait`-proxy, which checks the monitored value (not the coherence event) when it scans the watch list. We accept this simplification because, in current Linux guests, only the idle path uses `mwait`, and its wake signal is the kernel's `need_resched` flag going from 0 to 1. Only the idle vCPU itself clears the flag, so a same-value write by another vCPU does not occur in practice; even if it did, native `mwait` would just wake the vCPU, re-check, and re-enter `mwait`—indistinguishable from our skipping the spurious wake. No kernel logic we surveyed depends on observing every store as a discrete pulse: a software flag that is set and then cleared between observation points is already an inherently missable event, so guests do not build protocols around it. Moreover, KVM's upstream `mwait`-nop has the same limitation: with `mwait` NOPed, the guest's idle loop polls the wake flag itself, and a same-value write or write-then-revert between two polls is equally missed. `mwait`-proxy therefore introduces no regression relative to current production behavior.

Security. Pure `mwait`-passthrough lets an idle vCPU monopolize a shared pCPU, which §2.2 flagged as a denial-of-service vector. Both `mwait`-sched and `mwait`-proxy close this gap: a malicious or buggy guest cannot withhold the pCPU beyond one timer slice (`mwait`-sched) or until the next hypervisor entry (`mwait`-proxy), so the worst-case interference one tenant can impose on its colocated neighbors is small and predictable. The hypervisor stays the trust boundary, and these paths use only state already available from VM exits, so they do not add any new attacker capability.

Table 2: Environment Configuration

Type	Hardware / Software Configuration
Host	Intel Xeon CPU Platinum 8269CY 52C/104T @ 2.50GHz (2 sockets) 12 × 16GB DRAM DDR4 2666 MT/s Linux 4.9.168 QEMU 8.2.2
Guest VM	4 vCPUs, 8GB RAM Linux 5.10.134 NIC: dual-queue virtio-net ×1 10Gb/s max throughput, 190,000 PPS
Production	37 regions, 92,000 nodes Same generation as host

Table 3: Representative Workloads Used in the `mwait`-sched Evaluation

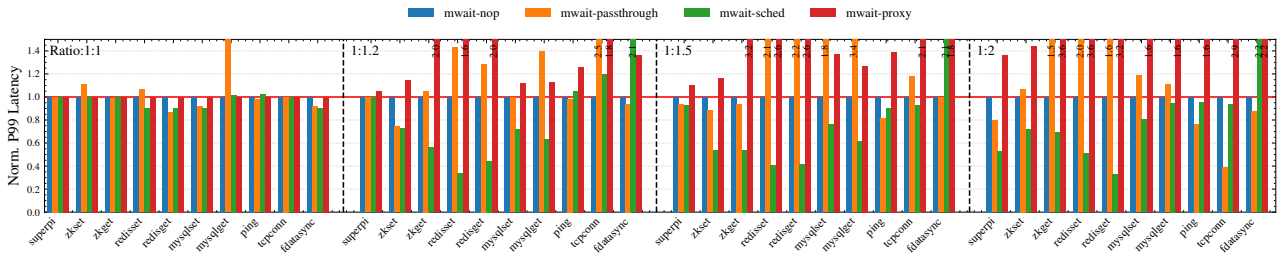
Workload	**Type**	**Description**
FS [2]	Disk I/O	File I/O with `fdatasync`
MS [3]	Disk I/O	MySQL: Random get/set
PT	Network	Ping Gateway
RD [35]	Network	Redis: Random get/set
SP [12]	Computation	Calculates π
TC	Network	TCP connection loop
ZK [1]	Network	ZooKeeper service

5 Evaluation

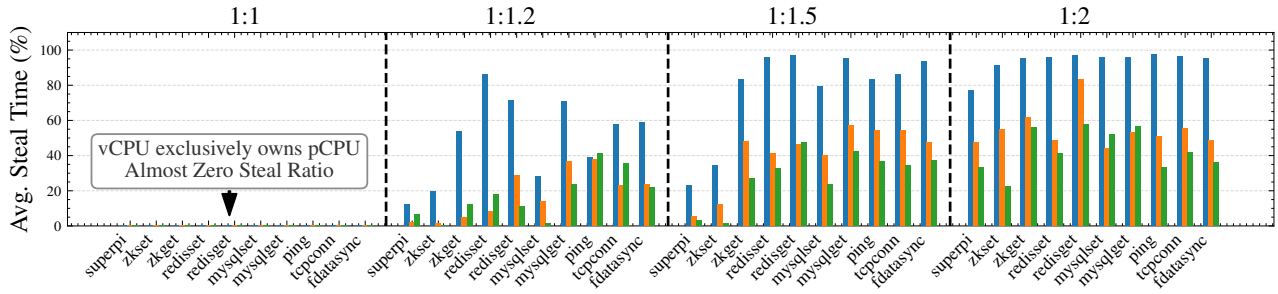
We evaluate `mwait`-sched through a comprehensive set of experiments. First, we examine end-to-end latency and preemption behavior across diverse workloads to characterize its scheduling impact. Second, we assess the effectiveness of `mwait`-proxy under high oversubscription ratios and quantify its ability to sustain performance at scale. Third, we analyze multi-region deployment data to demonstrate the improvements `mwait`-sched delivers in real production environments.

Experimental Setup. We evaluate `mwait`-sched through controlled experiments and production deployments. Our study compares four configurations:

- **`mwait`-nop (Baseline)**: Upstream KVM implements `mwait` as a no-op, causing the vCPU to remain runnable



(a) **Normalized P99 Latency (Lower is better).** Values are normalized to the `mwait-nop` baseline at the same ratio. `mwait`-sched effectively mitigates tail latency degradation under high oversubscription (1:1.5/1:2), particularly for latency-sensitive workloads like Redis and ZooKeeper. `mwait`-proxy is benign at 1:1 and scales smoothly through the low-density regime, with the synchronization-heavy workloads (RD, ZK Get, TC) climbing fastest—consistent with the higher-density picture in Figure 15.



(b) **vCPU Steal Time Analysis (Lower is better).** The breakdown of steal time across different oversubscription ratios. `mwait`-sched significantly suppresses steal time in oversubscribed scenarios (e.g., 1:2), explaining the latency improvements observed in (a). The 1:1 base case shows negligible contention.

Figure 14: **Performance and Interference Analysis.** Comparison of `mwait-nop`, `mwait-passthrough`, and the proposed `mwait`-sched and `mwait`-proxy mechanisms. Simple benchmarks such as Ping remain stable, while `mwait`-sched reduces preemption overhead for synchronization-heavy workloads.

and always accounted as 100% busy. This reflects the default behavior in today's virtualized clouds.

- **`mwait-passthrough`**: `mwait` executes directly without triggering VM exits, offering the lowest exit latency but preventing pCPU sharing because the vCPU never yields to the hypervisor.

- **`mwait-sched`**: Our timer-based emulation of `mwait`, which exposes idle signals to the hypervisor while avoiding the high overhead of trap-and-emulation. This enables predictable pCPU sharing under oversubscription.

- **`mwait-proxy`**: A linked-list–based multi-address monitor that extends `mwait`-sched to track many vCPUs concurrently, improving aggregation density under high oversubscription.

All configurations are shown in Table 2. Experiments constrain guest VMs to a single NUMA node to avoid cross-node interference. Our production evaluation spans multiple regions and heterogeneous workloads, enabling characterization across diverse usage patterns and deployment scales.

Workload. Due to privacy and isolation requirements, our microbenchmarks were conducted in a controlled testbed rather than on production VMs. The testbed evaluation spans 24 representative workload categories and 220 *scenarios*. A scenario pairs a workload category with a traffic profile, including request mix, rate, and key/payload distribution. These scenarios are derived from production traffic patterns, user reports, and performance incidents. Table 3 lists the subset we highlight in figures throughout this paper. In each experiment round, multiple VMs were randomly assigned scenarios and executed concurrently to capture contention, preemption behavior, and end-to-end latency under oversubscription.

5.1 Stand-Alone Classifier Evaluation

§4.1 uses the IOPS-to-utilization ratio from PMU counters to choose short or long timer slices. We test this classifier on PMU telemetry from 1,000 production VMs whose workload type is known from the VM image. The two classes are well separated: I/O-bound VMs have a median ratio of 840, while CPU-bound VMs have a median ratio of 20, a 42× gap. We set $T = 100$ between the two groups. This gives a 0.21% overall misclassification rate: 0.07% of I/O-bound VMs are

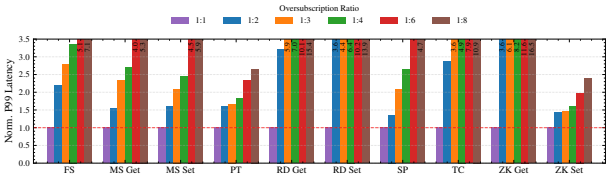


Figure 15: Normalized P99 latency of `mwait`-proxy across ten workloads (FS, MS Get/Set, PT, RD Get/Set, SP, TC, ZK Get/Set) at oversubscription ratios from 1:1 to 1:8. The y-axis is capped at 3.5×; bars over the cap show their value as a label. 1:4 is the burst tier's typical production density and 1:6 its peak; 1:8 is included as a stress point beyond production.

classified as CPU-bound, and 0.36% of CPU-bound VMs are classified as I/O-bound. The harmful error is the first one because it can hurt tail latency; the second mainly wastes a few timer ticks. The result is not sensitive to the exact threshold: any $T \in [50, 150]$ keeps misclassification below 0.7%.

5.2 End-to-End Tail Latency

Mitigating Contention. Figure 14a shows the impact of our mechanism on tail latency under different oversubscription ratios. When contention is low (1:1 mapping), all configurations behave similarly. As the oversubscription ratio increases, however, `mwait`-sched scales more effectively. At high oversubscription levels, it reduces the P99 latency of latency-sensitive workloads such as ZooKeeper and Redis by 30–50% compared to the `mwait`-nop baseline. This improvement aligns with the steal-time analysis in Figure 14b. Under `mwait`-nop, vCPUs suffer severe starvation—steal time exceeds 90% for synchronization-heavy workloads—indicating frequent lock-holder preemption. In contrast, `mwait`-sched leverages the semantic gap to convert unproductive spin-wait loops into cooperative yields, reducing steal time to below 60% and allowing critical sections to make forward progress even under heavy interference.

Two outliers need explanation. First, `mwait`-passthrough spikes for `mysqlset` at 1:1 because the pCPU enters deep C-states between requests, and waking from them adds latency to each MySQL write. Second, `fdatasync` stays high under `mwait`-sched at every ratio because the timer can add up to one slice of delay per fsync, and `fdatasync` issues many fsyncs back-to-back.

5.3 `mwait`-Proxy

Figure 15 shows normalized P99 latency for ten representative workloads at oversubscription ratios 1:1, 1:2, 1:3, 1:4, 1:6, and 1:8. The 1:2–1:4 range covers the densities used in production, with 1:4 the burst tier's typical density and 1:6 its peak; 1:8 is a stress point beyond production. At 1:2 most workloads stay within ∼2.2× (FS 2.2×, MS 1.6×, PT 1.6×, SP 1.4×), and the synchronization-heavy ones (TC, RD Get/Set, ZK Get) sit at 2.9–3.7×. At 1:4 the workloads split further: CPU- and I/O-bound ones scale moderately (1.8–3.4×), while synchronization-heavy ones reach TC 4.9×, RD Set 6.4×, RD Get 7.0×, and ZK Get 8.2×. ZK Set, dominated by write batching rather than per-request synchronization, stays close to baseline (1.4–1.6×). The 5–8× inflation on the synchronization-heavy group fits within the burst tier's variance budget, which is what makes `mwait`-proxy a viable production scheme at this density.

Beyond 1:4 the proxy's monitor-list traversal cost dominates: each entry into the hypervisor scans a longer list, and per-vCPU wake events compete for service. At 1:6 (burst peak) RD Get/Set and ZK Get reach 10–12× and TC reaches 7.9×, while CPU- and I/O-bound jobs sit at 2–5×. At 1:8 the worst cases land at 11–16× (TC 11×, RD Set 14×, RD Get 15×, ZK Get 16×), exposing the scaling limit of software multi-address emulation and motivating the hardware-level vectorized monitor support discussed in §6.

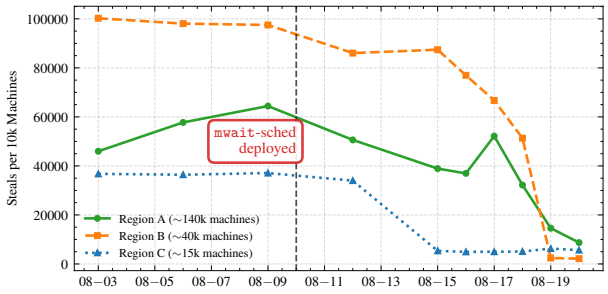
5.4 Production Rollout

Our production fleet has two instance classes with different SLO requirements, and we pick `mwait`-sched vs. `mwait`-proxy by class at deployment rather than auto-switching per VM. *Dedicated* instances have strict latency SLOs and stay at ≤1:2 oversubscription, since putting more than two vCPUs on a pCPU easily causes SLO violations at this tier; this fleet runs `mwait`-sched, which is what we report below. *Burst* instances tolerate higher latency variance and typically run at ∼1:4 (peaking at 1:6), where `mwait`-proxy handles the longer monitor list. The numbers in this section therefore come from the dedicated fleet under `mwait`-sched.

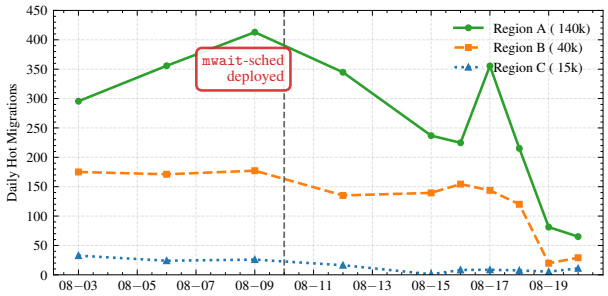
We selected three representative regions with distinct machine scales and baseline contention levels to evaluate the cross-region effects of `mwait`-sched. Before deployment, the frequency of high-contention steal events (steal ratio > 5%) differed significantly across regions: Region B was under the most pressure (around 95,000–100,000 steals per 10k machines); Region A was moderate (rising from 45,000 to 65,000); and Region C was flatter (around 36,000–37,000).

As shown in Figure 16a, all three regions experience a substantial drop after the rollout of `mwait`-sched. Within about ten days, Region B drops by ∼97% (from a ∼100,000 peak to under 5,000), Region A by ∼85% (from a ∼65,000 peak to under 10,000), and Region C by ∼86% (from ∼37,000 to ∼5,000). Despite their disparate starting points, the post-deployment curves converge to a significantly lower and tightly clustered band, indicating that `mwait`-sched consistently suppresses oversubscription-induced contention across heterogeneous environments.

Hot migration activity provides an independent validation of this effect. When enough VMs exceed the 5% steal time



(a) Normalized steal events.



(b) Daily live migrations.

Figure 16: Cross-region production signals before and after `mwait`-sched rollout. (a) Steal events drop sharply and converge to a consistently low band across heterogeneous regions. (b) Hot migrations also decline immediately after deployment, independently confirming that reduced contention improves VM stability and mitigates scheduler-driven relocations.

threshold, the platform initiates VM hot migrations to avoid SLO violations. As shown in Figure 16b, all three regions exhibit a clear decline in daily hot migrations immediately following deployment. Since hot migrations are triggered primarily by severe CPU contention and imbalance, their consistent decline corroborates the steal-ratio reductions and highlights the improved runtime stability brought by `mwait`-sched.

Figure 17 shows the global effects of deploying `mwait`-sched across multiple production regions covering 3.2M physical CPU cores. After rollout, the oversubscription ratio increased from 1.0% to 20.3%, effectively adding roughly 600,000 vCPUs of sellable capacity. Despite this substantial increase in utilization, system reliability improved: the normalized daily alarm rate dropped from 512 to 197 per 10k machines across regions. These results demonstrate that precise idle-state handling allows the platform to safely operate at much higher density while simultaneously reducing QoS-related incidents at hyperscale.

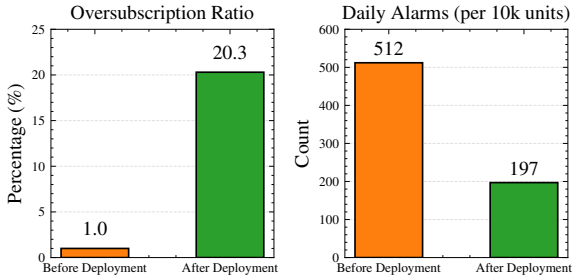


Figure 17: Global deployment impact of `mwait`-sched across multiple regions covering 3.2M physical CPU cores. The rollout increased oversubscription ratio (1.0%→20.3%) while reducing daily alarms (512→197 per 10k machines), demonstrating higher utilization without compromising stability.

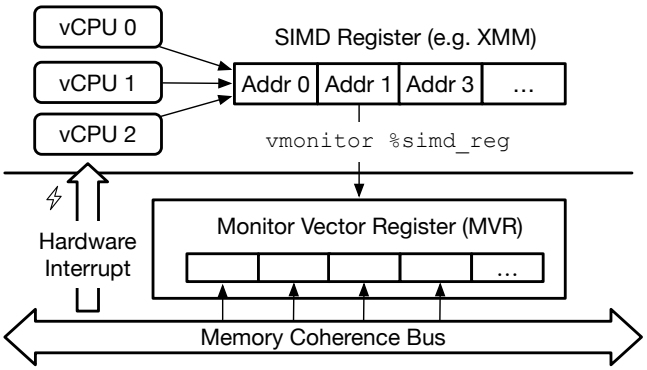

Figure 18: Conceptual design of a vectorized `vmonitor` instruction. Software supplies a SIMD-packed list of addresses, which hardware loads into a Monitor Vector Register (MVR) and checks in parallel against coherence-bus writes.

6 Recommendations for Future Hardware

Based on our experience deploying `mwait` at scale in virtualized clusters, we believe future ISAs (including x86, Arm, and RISC-V) should treat idle instructions not merely as power-management hints, but as first-class scheduling primitives. Below we outline several directions for hardware designers; these proposals are conceptual and intended to guide future architectural support rather than describe implemented mechanisms.

Multi-address monitoring. Current `monitor/mwait` instructions bind a thread to a single watched location, yet virtualized workloads often need to observe the quiescent state of many vCPUs simultaneously (e.g., runnable flags or per-thread wake tokens). We recommend exploring vectorized forms of the instruction that accept a small array of virtual addresses and a validity mask, allowing software to arm or update a set of watchpoints with a single operation.

Conceptually, such an extension could take the form of

a new vmonitor interface (Figure 18) in which software supplies a vector of addresses using SIMD registers. Hardware would load these addresses into a Monitor Vector Register (MVR) and compare coherence-bus writes against all entries in parallel, triggering an interrupt whenever any monitored location changes. This generalizes mwait from a single-address primitive into a hardware-level multi-way event monitor—akin to providing select/epoll semantics within the CPU. While we do not implement this design, it illustrates a promising direction for reducing polling overhead, eliminating unnecessary context switches, and enabling a host thread to efficiently wait on many vCPU idle signals. Such support would make multi-address mwait semantics practical for virtualization and allow denser vCPU aggregation in oversubscribed cloud deployments.

Virtualization-aware semantics. Future ISAs should also define how idle instructions interact with hypervisors explicitly: which state transitions are visible to the guest, which are owned by the host, and which events must be delivered as exits. A "virtualizable wait" variant, for example, could guarantee that entering the wait state always notifies the hypervisor, while wakeups may be signaled either through a watched-memory write or via a host-injected event. Clear semantics of this kind would enable safe pCPU sharing while still providing the low exit latencies expected by modern guests.

7 Related Work

7.1 Idle in Virtualization

Idle instructions are a fundamental but often overlooked component of virtualized execution. Prior measurements show that idleness can dominate context-switch overhead: Liu et al. [28] observe that idle periods account for up to 66.7% of context-switch costs in GaaS (GPU as a Service) clouds, and similar effects appear in nested virtualization where idle loops amplify VM–VMM interaction overheads [25]. Most existing work identifies VM idleness via VM introspection [10, 11, 41], inferring quiescence by sampling guest states or events, but such approaches are infeasible at hyperscale due to overhead, isolation concerns, and operational complexity. To our knowledge, mwait-sched is the first production-scale system that directly leverages hardware idle instructions as a scheduling signal, avoiding introspection while enabling sub-microsecond reactivity.

7.2 Oversubscription Optimization

A large body of work aims to improve vCPU colocation under oversubscription [5, 37, 44, 48, 53, 54]. Hardware-assisted techniques isolate interference through cache partitioning or memory-bandwidth control [29], and in-hardware request schedulers prioritize latency-critical VMs [7, 39, 43, 49]. Coordination-based designs further reduce double scheduling (e.g., UFO [33]) or exploit fine-grained time windows to identify transient opportunities for packing (e.g., SmartHarvest [48]). A separate line of work targets high CPU efficiency for latency-sensitive workloads through user-space scheduling and core reallocation, most notably Shenango [30]. These designs deliver impressive efficiency on dedicated workloads but require application-level integration with their runtime, which is incompatible with our public-cloud setting where guests run unmodified images. However, two limitations persist in public clouds: QoS signals are generally unavailable, and even nominally idle VMs can introduce interference because the hypervisor cannot estimate the stability of idle periods. mwait-sched addresses both challenges by exploiting the semantics of idle instructions: the guest-generated idle signal reveals short-term quiescence without application-level hints, allowing the hypervisor to dynamically adjust colocation decisions. By aggregating vCPUs with stable idle patterns and separating those exhibiting only transient waits, mwait-sched achieves a practical balance between reducing exit latency and improving CPU utilization.

8 Conclusion

mwait-passthrough provides low wake-up latency, but hides idle vCPUs from the host scheduler and prevents safe pCPU sharing. mwait-sched restores this visibility through timer-based emulation and idle-interval classification, while mwait-proxy supports denser colocation. This lets idle vCPUs yield their cores while preserving the low-latency behavior needed by guests. Across nine workloads, mwait-sched reduces P99 latency by 30–50% and steal ratio by 30–40%. Its deployment across $\sim$ 3.2M pCPUs reduced high-contention steal events by over 80% and raised the oversubscription ratio from 1.0% to 20.3%.

Acknowledgments

We thank our shepherd and the anonymous reviewers for their insightful comments that improved the quality of this paper. We also thank our colleagues for their feedback during the design and deployment. Their engineering support was essential to the production rollout and large-scale evaluation. Abstract

The Linux kernel is permeated with constant values that are critical to system performance. Many of these constants, referred to as *perf-consts*, are magic numbers with brittle assumptions on hardware and workloads. Unfortunately, there is no capability of *in-situ* tuning of perf-const values on deployed kernels. This paper rethinks OS performance tunability. We present Xkernel, a system that offers a safe, efficient, and programmable interface for *in-situ* tuning of any perf-consts directly on a running kernel. Xkernel transforms any perf-const into a tunable knob on demand using a novel approach called Scoped Indirect Execution (SIE). SIE captures precise binary boundaries where a perf-const enters system state and redirects control to synthesized instructions that update the state as if new values were used. Xkernel goes beyond version atomicity when updating perf-consts to guarantee side-effect safety, a property notably absent in existing kernel update mechanisms. Case studies on various OS subsystems demonstrate significant performance benefits of tuning perf-consts which is made possible by Xkernel.

1 Introduction

Modern operating systems like Linux are permeated with constant values that shape system performance. These constants, referred to as *performance-critical constants* or *perf-consts*, appear in various source-code forms (e.g., macros, literals, and static integers); they govern thresholds, time intervals, batch sizes, scaling factors, etc. Whether to balance latency and throughput or to match batching behavior to device parallelism, perf-consts embed design trade-offs and workload/hardware semantics directly into kernel behavior, forming the kernel's implicit performance policy.

Perf-consts are not tunable in deployed systems without recompiling and rebooting the OS kernels. Unfortunately, their values are often "*arbitrarily chosen* [40]" by developers based on brittle heuristics, limited testing, or assumptions on dated hardware, which "*just happen(ed) to work well* [38]." However, static magic numbers can hardly serve dynamic workloads or diverse hardware configurations, especially emerging ones that significantly deviate from the time those values were chosen (see [14,16,20,39,56,75,76]).

Ideally, perf-consts should be decided at runtime, dynamically adapting to workload patterns, hardware characteristics, and service-level objectives. In practice, the benefits of tuning perf-consts are substantial. In one of our case studies (§2.1), tuning a perf-const yields 50× throughput improvement. Yet such benefits are completely missed as modern OSes provide no mechanism for tuning perf-consts.

Today, tuning a perf-const typically involves converting it into a runtime knob via interfaces such as `sysctl` [77] and `sysfs` [54], or changing its value in kernel source and updating the deployed kernel through live patching [1,7,10,22,23]. However, neither satisfies the needs of performance tuning. The former (`sysctl`/`sysfs`) is limited to a small subset of predefined constants with fixed granularity, often system-wide, and provides no safety guarantees—the correctness of an update depends on manual reasoning. The latter needs to recompile kernel code and apply binary diffs, incurring minutes-level delays, which is fundamentally incompatible with fast policy adaptation and online tuning.

In this paper, we advocate for *principled OS performance tunability*—a general machinery that enables safe, fast value updates for *in-situ* performance tuning of *any* perf-consts in deployed OS kernels, *without* kernel recompilation or rebooting. Such tunability must support expressive, programmable policies, ensure correctness and safety, as well as allow millisecond-scale value updates.

Achieving this goal is challenging. First, the system must precisely identify all instructions that consume the original constant, in the presence of sophisticated compiler transformations such as constant folding and strength reduction. Any missed or incorrectly replaced instructions may leave unsafe remnants in the running kernel. Second, the system must generate the instructions based on the new value, as well as the tuning policies, without recompilation. Finally, the kernel execution may have already produced side effects on runtime state, and any update must not cause conflicts on them.

We introduce *Scoped Indirect Execution (SIE)*, a novel mechanism that addresses the aforementioned challenges. Our key insight is that a constant—unlike arbitrary code—has structural semantics: its influence enters the machine state (registers or memory) at a specific point and manifests through a small instruction sequence, enabling safe, in-situ tuning of the perf-const without recompilation or rebooting. For a perf-const, the point where its value enters registers or memory, is *well-scoped*: it can be identified by static analysis and be represented by a symbolic state expression agnostic to compiler optimizations; moreover, it is small enough (typically several instructions) to analyze for side effects.

SIE leverages this structure to identify the precise binary region where the perf-const affects runtime machine state termed a *critical span*, by deriving the symbolic relationship between the perf-const and the affected registers or memory. Within this span, SIE inserts a set of *indirections*: small code snippets tied to specific kernel address locations. When execution reaches these locations, the indirections update the machine state to reflect the new value as per policy. Once execution leaves the critical span, the resulting state matches what would have occurred had the perf-const been changed directly in the binary. The kernel binary remains untouched; all modification occurs indirectly and locally.

To ensure safety, SIE analyzes how effects from the critical span propagate to derive a second region, the *safety span*, which encapsulates all consumption of constant-dependent state. At runtime, indirections are enabled only when the execution is outside the safety span, ensuring that updates never occur while the original effects are still in flight.

We build Xkernel atop Linux as the first system to realize principled performance tunability for OS kernels. Xkernel implements SIE, reducing update latency from minutes to milliseconds and supporting programmable tuning policies written in eBPF. Xkernel does not change the kernel source or require reboots. It seamlessly integrates with deployed kernels as its implementation depends on stable kernel features like Kprobe, kernel modules, and eBPF.

We evaluate Xkernel across core Linux subsystems, including CPU scheduling, memory management, storage, and network. Xkernel unlocks previously inaccessible tuning opportunities, achieving up to 50× microbenchmark improvement and boosting real-world application performance, e.g., 1.2× throughput in RocksDB and 81% latency reduction in NGINX. Xkernel enables new capabilities: online exploration of design trade-offs, adaptation to hardware and workload patterns, control of OS-internal maintenance behavior, and coordinated tuning across multiple perf-consts.

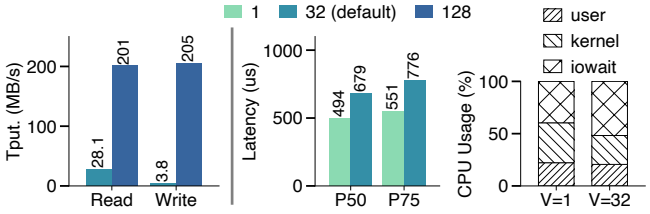
We extensively evaluate Xkernel on 140 perf-consts (comparable in scale to the 145 performance knobs exposed by `sysctl`). We show that SIE applies broadly, introduces negligible runtime overhead (a few hundred cycles per perf-const update), and achieves millisecond-scale policy updates.

In summary, this paper makes the following contributions:

- Principled OS performance tunability that exposes the unexplored performance benefits of pervasive perf-consts;
- Scoped Indirect Execution (SIE), a new approach that enables safe, fast performance tuning of any perf-consts with programmable policies;
- Xkernel, a practical implementation on Linux, which can directly benefit deployed kernels;
- Case studies and extensive evaluation demonstrating new opportunities and inspiring new tuning techniques;
- Xkernel is open-sourced at `https://github.com/xkernel-org/Xkernel/`.

Table 1: Performance regimes of perf-consts.

Category	Explanation and Examples
Threshold	Triggering a behavior change as a limit or boundary `#define MAX_SOFTIRQ_RESTART 10`
Interval	Controlling deferred or periodic actions `#define IPVS_SYNC_SEND_DELAY (HZ/50)`
Batch Size	Work processed together per operation to amortize cost `#define BLK_MAX_REQUEST_COUNT 32`
Scaling Factor	A multiplier that adjusts the magnitude or intensity `delta *= 4;`



(a) FIO on HDD (b) RocksDB on NVMe SSD

Figure 1: Performance benefits of changing the value of a perf-const `BLK_MAX_REQUEST_COUNT` based on hardware devices and workloads. The default value is 32.

2 Background and Motivation

2.1 Perf-Consts in Linux

A perf-const is a fixed numeric value used by kernel code to control the *magnitude* of OS behavior, without altering correctness or existence of that behavior. Table 1 shows four common types. Perf-consts are pervasive in Linux, appearing in every kernel subsystem. Typical perf-const representations include macros, literal immediates, and `static const` variables. Perf-consts govern core trade-offs (e.g., latency vs. throughput, responsiveness vs. utilization); they also shape how workloads interact with hardware. There are strong needs to customize their values based on application SLOs, workload behavior, and device characteristics.

A motivating example. We take `BLK_MAX_REQUEST_COUNT`, a perf-const in Linux's storage subsystem, as an example. Introduced in 2011 [40], this perf-const controls block I/O's plug behavior [4] by delaying request submission to merge adjacent requests and reduce device contention. Once buffered requests reach the threshold specified by this perf-const, they are flushed to the device. The original commit shows the value was arbitrary: "16 *works efficiently to reduce lock contention...* 32 *also works in my tests.*" The choice implicitly reflects then-current hardware—CPU speed, storage performance, and lock overhead. A decade later, in 2021, the value was raised to 32 [6], justified by observed benefits on NVMe devices. However, with the wide variety of hardware (HDD, SSD, and NVMe devices) and workload access patterns, a single magic number is inevitably suboptimal.

Figure 1(a) shows the performance benefits of tuning the perf-const. Running a sequential FIO workload [5] with intra-segment shuffling (4 KB requests randomly shuffled

within each 128 KB segment) on a 7200-RPM SAS HDD, the default value (32) causes the plug to flush too frequently, missing many opportunities to merge adjacent requests. Increasing the value to 128 allows most requests to be merged, maximizing sequential disk access. This improves read and write performance by 7× and 54×, respectively.

By contrast, a large value of `BLK_MAX_REQUEST_COUNT` may not always benefit NVMe SSDs—sometimes request merging has little benefit but adds overhead. We deploy RocksDB on a 256GB Toshiba XG3 NVMe SSD, and run the *multiread-random* workload from DBbench [21] with 32GB dataset (16B keys; 2048B values). We use RocksDB's `io_uring`-backed MultiGet API for asynchronous parallelism and use Direct I/O for data transfer between the storage device and user memory. As shown in Figure 1(b), reducing `BLK_MAX_REQUEST_COUNT` from 32 to 1 reduces CPU time spent on I/O wait by 12%, yielding an end-to-end 1.2× throughput improvement, while reducing P50 and P75 latency by 1.37× and 1.41×, respectively.

2.2 Limitations of Existing Mechanisms

Despite the strong benefits of tuning perf-consts, modern OSes like Linux provide little support or interface—perf-consts are hardwired into kernel binary once compiled and cannot be changed at runtime once deployed in production.

Existing mechanisms are inflexible and unsafe. One way to tune a perf-const is to convert a perf-const into a runtime variable and expose it through kernel interfaces like `sysctl` [77], `sysfs` [54] or system calls. However, this is not a general mechanism—it requires modifying source code on a per perf-const basis and results in rigid, narrow interfaces.

One fundamental difficulty is to predefine a complete set of perf-consts *a priori* before deployment; only a very small subset of perf-consts are currently exposed. Linux interfaces like `sysctl` and `sysfs` are treated as kernel ABIs and therefore prioritize stability over flexibility [44]. For example, our analysis shows that `sysctl` knobs change slowly—among 145 `sysctl` knobs, 96 of them have remained unchanged since 2005. Moreover, decisions to expose perf-consts as `sysctl` knobs have been largely *ad hoc*, driven by developers' preference and experience (Appendix A).

Besides the difficulty of upstreaming, source-code conversion is fundamentally inflexible: changing the granularity of a tuning policy from global (the `sysctl` default) to per-process or per-cgroup requires modifying source code again, which in turn requires recompilation and rebooting.

In addition, `sysctl` and `sysfs` conversions are known to risk safety [12, 72]. In our study, 20 of 145 conversions led to bugs, largely due to concurrency: for example, the `sysctl` setter writes to a shared global variable from a separate context while core kernel logic reads it concurrently, easily causing races in practice. Our inspection shows that 43 `sysctl` knobs are potentially buggy and lead to races or inconsistent states (see Appendix A).

Kernel live patching offers no rescue. A relevant mechanism is Kernel Live Patching (KLP) [1, 50, 60, 67, 74] which enables patching deployed kernels without rebooting. KLP modifies kernel source, recompiles it, and applies the resulting binary diff to replace selected regions of the kernel image. However, KLP is not suited for perf-consts tuning.

First, KLP is too slow. It takes minutes per patch. Updating a perf-const value would require recompiling the kernel (with the new value) and patching the binary diff. By the time a patch is applied, the workload may have changed.

Second, KLP uses functions as the patching unit. When tuning spans multiple functions (e.g., due to compiler inlining or multiple affected perf-consts), finding safe quiescent points becomes difficult and fragile [13]. KLP offers no side-effect safety and struggles to support consistent states under multi-threading [60, 67].

2.3 Our Goal: Principled OS Tunability

Our goal is to address the limitations of existing mechanisms and enable safe and fast tuning of any perf-consts in a running OS kernel with *principled OS tunability*:

Transparent in-situ tuning on deployed systems. Tuning a perf-const should not require the slow process of recompilation, redeployment, or rebooting the OS kernel.

Programmability and flexible granularity. Effective tuning requires programmable policies that can encode sophisticated algorithms and heuristics through fine-grained control (e.g., TCP flow awareness [80]). Policies should apply at flexible granularities (e.g., selected cgroups, selected devices, or their combinations) instead of fixed ones.

Out-of-box tuning for all perf-consts. A general tuning mechanism must support *any* perf-consts in the kernel and be fully compatible with standard OS kernel distributions.

Millisecond-scale policy updates with low overhead. Performance tuning must be fast and not cause interference on the target OS. We aim at *millisecond*-scale policy updates.

System safety during tuning. Tuning must be safe at runtime and must not result in inconsistent system states. Arbitrarily changing a perf-const value at runtime can be unsafe.

2.4 Challenges

Principled tunability introduces new challenges, stemming from the requirement to avoid recompilation and rebooting.

Precisely locating instructions for the perf-const. The compiler materializes each perf-const into instructions in the kernel binary. However, compiler optimizations can fold constants, merge lines, or reorder nearby instructions. A missed instruction leaves part of the original value in the system state; a misidentified one may overwrite unrelated computation and corrupt the system state.

Generating instructions for new values and policies. When users express new values and policies in a high-level language, we must generate the required instructions directly. KLP systems achieve this by recompiling the ker-

nel, which introduces minutes of delay. This is challenging because the generated code must interact correctly with existing kernel instructions and avoid conflicts such as register clobbering near the original sites.

Side-effects of the original value. The original value may have already propagated, producing side effects that kernel execution still depends on. A reboot clears these effects but is incompatible with our goal. We therefore must identify and detect when these side effects have dissipated so the new perf-const value can be applied safely at runtime.

3 Xkernel

Xkernel is the first system to provide a safe, fast, and expressive interface for *in-situ* tuning of any perf-const on a deployed Linux kernel. We present the design of Xkernel, beginning with *Scoped Indirect Execution* (SIE), a novel mechanism for principled tunability that addresses the challenges outlined above (§2.4). We then describe the design principles and the key techniques that realize SIE and provide programmability in Xkernel.

3.1 Scoped Indirect Execution (SIE)

The insight is that perf-consts exhibit intrinsic instruction-level semantics. For a perf-const, the point where its value enters the machine state (registers/memory) forms a *well-scoped region*. This region—a *critical span*—has three properties: (1) it can be localized by static analysis, (2) it corresponds to a *symbolic state expression* that captures the relation between the machine state and the perf-const, (3) the region is *small*, involving only a few instructions, which keeps correctness reasoning narrow and makes safe runtime updates tractable.

SIE identifies the critical span based on the symbolic state expression and safely redirects execution, at runtime, to a short JIT-compiled instruction sequence. These instructions execute next to the original code and, when combined, produce the same effects as if the perf-const were changed directly. The original binary remains intact; all modifications occur indirectly, within scoped regions.

SIE ensures side-effect safety by defining a second scope, *safe span*, within which the effects of the perf-const are encapsulated. Transitioning occurs only when execution is outside this span, converting a temporal coordination problem into a spatial one that can be analyzed statically.

SIE in Xkernel. Xkernel implements SIE on Linux. Figure 2 gives an overview of Xkernel and its user-facing workflow. Xkernel performs *offline* static analysis on kernel code to understand the symbolic state expression, critical span (CS), and safe span (SS) of each perf-const, and maintains them in a global *scope table*. The offline analysis is a one-time effort. The scope table only needs to be updated when the deployed kernel is updated.

To tune a perf-const, users (or agents) specify the perf-const in source code (by source file, line number, and token

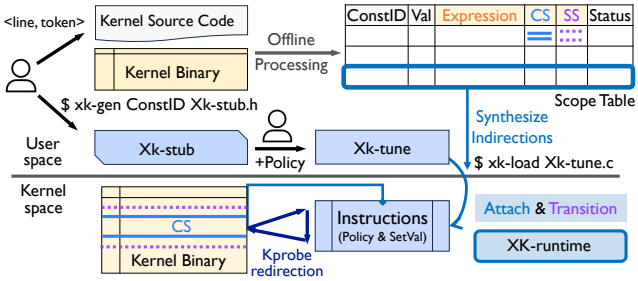


Figure 2: Overview of Xkernel.

index) and implement tuning policies in eBPF, called *Xk-tune*. An Xk-tune can be loaded at any time in the OS. A lightweight Xk-runtime handles attachment and transitions.

3.2 Design Principles

Separating value updates from tuning policies. Xkernel separates mechanism from policy: SIE provides a general mechanism for safe in-situ value updates, while programmability is delegated to safe kernel extensions (e.g., eBPF).

Synthesizing state update code, not patch instructions. Directly creating replacement instructions without recompilation is untenable. Instead, Xkernel synthesizes code that updates the system state described by symbolic state expressions of the perf-const, turning instruction replacement into a general state-update function.

Reusable static processing for fast policy update. Xkernel incurs a one-time offline cost per perf-const for kernel build, symbolic execution, and analysis. The resulting artifact (scope table) enables millisecond-scale *in-situ* updates and is reusable across all future values and policies. In contrast, live patching or source-code modification requires kernel rebuilding and rebooting for every change.

Decoupling version atomicity and side-effect safety. Xkernel ensures version atomicity with correctness guaranteed by symbolic state expressions, when transitioning from the original value to a new one. Xkernel also offers side-effect safety based on safe spans that encapsulate all effects of the original value. The safety of transition is supported for both per-thread and multi-threading.

Encapsulated kernel writes; free reads. To allow user-written policy programs (Xk-tunes) to update perf-const values, Xkernel provides a simple, safe API. Writes to kernel state are protected and only done by Xk-runtime.

3.3 Capturing Instruction-level Effect of Perf-Consts

Conceptually, Xkernel must replace the effect of instructions tied to the original perf-const value with the updated effect based on the new value, while preserving other runtime state. A key challenge is to precisely capture the effect, as reversing kernel binaries to original source code is difficult and costly. Our insight is that the state affected by perf-consts is tractable to capture. A perf-const manifests as a numeric value chosen by the compiler and becomes part of runtime state by instructions that produce a local numeric effect. De-

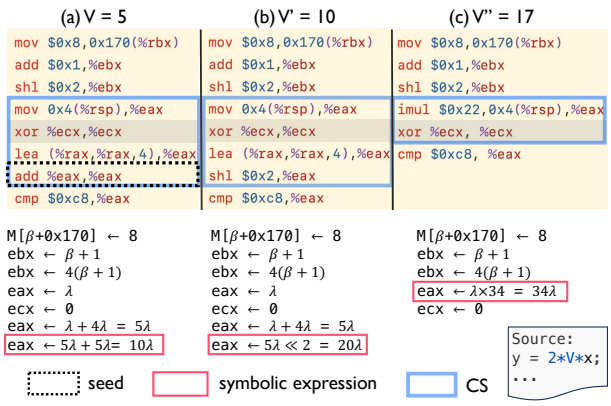

Figure 3: Symbolic expression derived from a perf-const (V)'s seed instructions and its critical span. (a) and (b) show instructions from binaries rebuilt with $V' = 10$ and $V'' = 17$. The seed is obtained by diffing (a) and (b). The IV values in the symbolic expression are 10, 20, and 34.

spite compiler optimizations that obscure its representation, we find that *symbolic state expression* provides a clean, precise way to express how a perf-const affects runtime state.

3.3.1 How Does a Perf-Const Affect Runtime State?

If a value is a constant and ultimately affects system state, there must be a well-defined point where it enters machine state. This boundary reflects the compiler's decision to materialize the constant and is determined statically. Since a constant carries no state before its introduction (unlike a variable), this entry point is identifiable in principle and is the semantic boundary we must capture.

A key challenge is to handle complications due to compiler optimizations. A perf-const may be folded, propagated, or merged with other expressions. Backend optimizations may further rewrite it for strength reduction or interleave unrelated instructions. As shown in Figure 3(a), the instruction sequence for a source-level perf-const of value 5 contains no immediate value 5 in the binary. Recompiling the same source with values 10 and 17 produces distinct instruction sequences (e.g., transforming `add` into `shl`, and reducing three instructions to one). Thus, the perf-const often appears in transformed form, denoted as IV, not its source value V.

Despite these transformations, IV can only influence machine state by becoming part of register or memory states, denoted as R/M. All effects must arise through instructions expressible in arithmetic and bitwise operations. Even source-level logical expressions reduce to comparisons such as "`cmp eax, edx`", which update condition flags as the arithmetic result of "`eax - edx`". Thus, regardless of source syntax, the effect of a perf-const in the binary always reduces to a mathematical relation in the form: $R/M \leftarrow f(R/M, IV)$.

Once expressed symbolically, this relation becomes explicit. As shown in Figure 3, the same source code with IV equal to 10, 20, and 34 produces drastically different binary code, yet their symbolic state expressions all reduce to `eax` $\leftarrow IV \times$ `eax`. Intuitively, compiler transformations preserve the numeric semantics of the constant, and those semantics are directly reflected in this symbolic form.

We use symbolic execution to derive a *symbolic state expression* that precisely captures how a perf-const affects runtime state. Symbolic execution naturally isolates relevant instructions from noise introduced by optimizations and yields the mathematical relationship between IV and architectural state R/M. Resolving IV back to V yields the final expression relating V to runtime machine state.

3.3.2 Deriving Symbolic State Expressions

The first issue is locating the instructions that consume a perf-const. Debug information (e.g., line number) is too coarse-grained—one source line can be compiled into hundreds of instructions, only a small subset of which uses the perf-const. Xkernel therefore begins by identifying seed instructions through binary differencing: we modify the perf-const at the source level and rebuild the kernel, then use the diff to drive symbolic execution. We run symbolic execution on both binaries and derive the transformed value (IV).

Finding seeds. Seed instructions are those that differ when the perf-const value changes in source code. Xkernel finds seeds by assigning the perf-const a magic value that differs from the original value and rebuilding the kernel binary. For example, when $V' = 10$, the seed instruction is `add eax eax`. In principle, instructions in the binary diff are the seeds.

From seeds to symbolic state expressions. Symbolic execution expands from the seeds to derive a converged symbolic state expression that reflects their effect. We exhaustively explore instructions backward and forward until the symbolic state reaches a fixed point while still incorporating the seed effect. The two symbolic executions must converge to the same symbolic form. In theory, extracting IV from a multivariate symbolic expression may require multivariate coefficient matching when multiple symbolic variables (registers or memory locations) appear. However, perf-consts act as simple knobs, and we did not observe such cases in our experience and our extensive evaluation.

A remaining complication is solver canonicalization: symbolic engines rewrite expressions in simplified mathematical forms (e.g., `shl 2` becomes $\times 4$). This matters when the source uses shift operations like ‹‹ or ››. Xkernel explores multiple symbolic execution branches and discards those that cannot preserve a linear relationship with V.

Mapping transformed value IV to the original value V. To recover the relation between IV and V, Xkernel attempts to fit a linear mapping of the form $IV = a \cdot V + b$. We compile additional binaries using another modified value V'', extract the resulting (V, IV) pairs, and solve for a and b via interpolation. When the recovered mapping is non-linear (e.g., $V \times V$), Xkernel reports the case, allowing users to tune the derived $V \times V$ rather than V. However, we never encountered such a case in our evaluation.

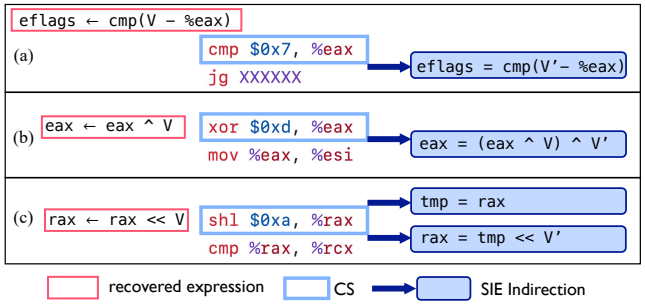

Figure 4: Synthesized SIE indirections for various CSes. An SIE indirection contains pairs of {location, update}. Locations are shown by the blue arrows.

3.4 Synthesizing Indirections

The recovered expression precisely captures how the original value affects runtime state; the next step is to generate instructions using new value. Xkernel turns the instruction replacement problem into a state-update problem. It synthesizes code that overwrites machine state affected by the original execution. The synthesized indirection is in the form of {location, update} pairs; when the specified kernel location is reached, the update code ensures that the effects of the system states is equivalent to that as if the new value V' of the perf-const were used in the kernel source. We introduce a binary representation for each symbolic state expression termed *critical span* and present our synthesis algorithm.

3.4.1 Critical Span

A critical span represents one occurrence of a perf-const at the binary level. Concretely, a CS is a single-entry, single-exit instruction sequence that begins at the first instruction contributing to the perf-const's symbolic state expression and ends either when the resulting state is first consumed or when the basic block ends.

Invariant. Let σ_{in} denote any machine state, CS_v denote the critical span executed with value v, and I denote the synthesized instructions that update v. A value update from v to v' is correct when executing the critical span is observationally equivalent to executing the span with the new value:

$$\forall \sigma_{\text{in}} : \ \text{Exec}\big(\sigma_{\text{in}}, CS_v \circ I\big) \ \equiv \ \text{Exec}\big(\sigma_{\text{in}}, CS_{v'}\big)$$

Here, "$\equiv$" denotes equivalence of externally visible state at the exit of the CS.

Construction. CSes can be automatically constructed for a given perf-const from the recovered symbolic state expression. Xkernel conducts forward and backward slicing to find the start instruction that first consumes the value to the last instruction that can recover the symbolic state expression. A CS is specified as a pair of [start, end] binary addresses.

3.4.2 Synthesis Algorithm

The indirection is synthesized based on the symbolic expression, as exemplified by Figure 4. If R/M affected by the perf-const are not overwritten within the CS, the indirection consists of a single code insertion located after the last instruction in the CS, computing the result using the new value V' and overwriting R/M (Figure 4a).

If R/M are overwritten within the CS, the update depends on whether the overwriting instructions are reversible. For reversible arithmetic or logical operations (Figure 4b), Xkernel synthesizes inverse logic as part of the update.

If the modification cannot be reversed (e.g., due to irreversible arithmetic, bit masking, or information loss), Xkernel generates dual-location: the original value is captured before modification and restored after the CS (Figure 4c).

Note that SIE does not skip the original CS; all instructions in the CS still execute to preserve state equivalence, including instructions that are in the CS but do not depend on the perf-const, e.g., `xor` instructions in Figure 3(a). By construction of the symbolic state expression, SIE updates only the states related to the perf-consts.

SIE relies on the Kprobe mechanism [48] to redirect execution to JITed update code. Because each trigger incurs overhead and different probe locations have different costs, Xkernel adjusts the placement within a CS, using the symbolic state expression to ensure correctness (details in §4).

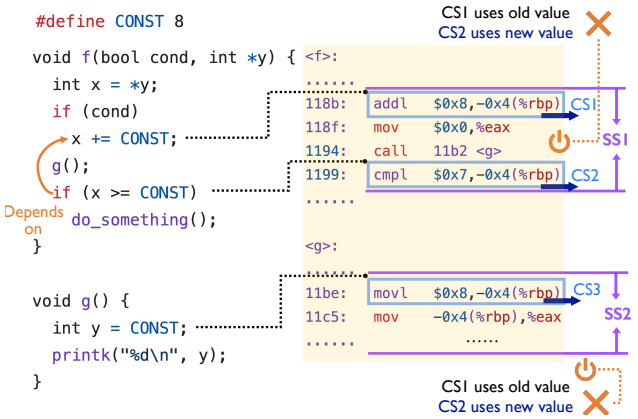

Figure 5: An example of a perf-const's CSes and SSes. Binary representation: SS1[118b, 1199], SS2[11be, 11c8].

3.5 Safe Transition

A symbolic state expression and critical span (CS) of a perf-const enables runtime updates of its value. However, it does not guarantee a *safe* transition of system states from the original value to the new. Figure 5 gives examples where unsafe transition of `CONST` could introduce inconsistent system states. If SIE is enabled when the execution is between CS1 and CS2, the system may execute CS1 with the old value and CS2 with the new. The program point right before `g()`'s return is also unsafe. Although CS3 has no dependency on CS1 or CS2, its call stack lies between them.

The core of safe transition is a well-defined transition scope that reflects the required safety guarantees; transitions are allowed only when execution is outside that scope. We formalize this scope as a safety span (SS), which captures the required safety guarantees and their binary representa-

tion (e.g., SS1 and SS2 in Figure 5). Safety span provides a concrete foundation for safe transition in Xkernel.

Xkernel enforces an update on a perf-const to happen *after* all the instructions that consume its value finish their execution, i.e., the lifetimes of all data objects derived from the perf-consts have expired upon exiting its safe spans. We call this property *side-effect safety*.

3.5.1 Safe Span

A safe span (SS) represents the execution unit in which *transitive dependencies* of a perf-const's critical span (CS) are encapsulated (see Figure 5). An SS includes not only instructions in the CS, but also all subsequent instructions that consume values derived from the perf-const. Concretely, an SS is a single-entry, multi-exit program slice constructed to satisfy a *confinement* property—any instruction that consumes objects that have dependencies with the perf-const's specific version must execute within the SS. So, once execution leaves the SS, no thread retains a dependency on the old value, and switching to a new value is considered safe.

Safety Invariant. Let T denote the set of concerned threads. A transition is safe only when the system is in a state where no thread is active in the SS as per program counters (PCs):

$$\forall t \in T, PC(t) \notin \bigcup SS \Longrightarrow \text{transition}(v \rightarrow v') \text{ is safe.}$$

Xkernel primarily focuses on data dependencies and the SSes are in the form of thin slices [66]. Our empirical analysis shows that data dependencies are sufficient in capturing the required safety of updating most perf-consts. The SS analysis is designed to be pluggable for future extensions, e.g., to incorporate control-flow analysis if needed.

Construction. A safe span of a perf-const can be automatically constructed from its critical span (CS) using forward thin slicing [66]. Any instruction that is transitively flow dependent on the perf-const would be included in the SS. Note that the dependency analysis is inter-procedural, because the perf-const's value can be propagated across function boundaries. If two SSes (constructed from different CSes) overlap, they are merged. An SS is specified as a pair of [start, end1/end2/...] binary address intervals in the top-level frame once the analysis terminates.

Safety properties. As SSes of a perf-const encapsulate the side effects of its value, Xkernel enables *side-effect safety* when updating perf-consts.

Existing Kernel live patching (KLP) mechanisms [1, 60, 67] offer per-thread *version atomicity*—a thread must execute either the old or new code, not their mixture [50]. KLP does so in the unit of functions, assuming every function having a well-defined semantic and being self-contained. In Xkernel, version atomicity is guaranteed through CSes. No existing KLP mechanism provides side-effect safety, as side effects of arbitrary function code are difficult to define.

Xkernel also guarantees multi-threading safety beyond per-thread safety by enforcing *global consistency*—all participating threads must be outside the SSes. In effect, the per-thread property must hold for all threads.

3.5.2 Transition Mechanisms

Xkernel ensures per-thread and multi-threading safety by monitoring the execution at the transition points. The monitors are implemented as kprobes [48], inserted at the entry and exit of each SS. These kprobes are used only during the transition. Once the transition is done, they are removed. The same transitioning mechanism is used for rollback and for updating the value of a perf-const.

Per-thread safety. Unlike KLP that implements timer-based polling, Xkernel detects safe transition points proactively by monitoring execution at the SS boundary. When execution reaches an entry kprobe, Xkernel checks if this SS is deep in the call stack of other SSes (e.g., SS2 in Figure 5) by stack inspection. If so, execution continues and the check is retried upon entering another SS.

Global consistency. Xkernel also supports global consistency for multi-threading safety. Unlike Kpatch [60] that uses a dedicated thread to repeatedly invoke `stop_machine` to opportunistically check if all threads happen to be safe for transition. Xkernel introduces a new mechanism termed *self-convergent transition*. The idea is to use efficient global reference counts maintained by entry and exit kprobes of each SS to track safety. Xkernel invokes `stop_machine` only once to initialize the reference count by scanning all running threads and counting the active SS entry boundaries in their stacks. Afterward, participating threads naturally self-converge when crossing SS boundaries and update the reference count. When the global reference count is zero, no thread resides in any SS, and the transition is safe.

Liveness and timeout. Xkernel may fail to find a safe transition point for a perf-const, causing liveness issues. This can happen when the instrumented path is not executed after the update request, or when one or more threads remain inside an SS and prevent convergence. In either case, Xkernel reports the transition as failed after a configurable timeout.

3.6 Programmable Policy Plane

Xkernel provides simple APIs to support expressive tuning policies for each perf-const. To ensure safety, Xkernel disallows users from directly updating kernel states. Any user policy code (Xk-tune) must follow the stubs auto-generated by an Xkernel tool (`xk-gen`) and passed to an in-kernel Xk-runtime. Xk-tune is written in eBPF style and has eBPF observability. Xk-runtime then compiles Xk-tune into an eBPF kprobe which includes SIE-based kernel-state updates.

Usage model and APIs. To tune a perf-const, the user first uses a command-line tool `xk-gen` to generate an Xk-tune stub which includes the unique ID of the perf-const and a header file that declares Xkernel APIs. The user is expected to implement the policy in the stub using the APIs. An Xk-tune follows the eBPF event-driven model; it is invoked when the perf-const is used at runtime. One perf-const may have mul-

```c
/* handler of xkernel context (xk_ctx) */
typedef const struct xk_ctx * xk_handle_t;
/* User probe definition */
#define XK_TUNE(unique_name, perfconst_id, args...)
/* The set and transition API */
long xk_set(xk_handle_t xk_ctx, u64 val);
bool xk_transition_done(xk_handle_t xk_ctx);
```

Figure 6: Xkernel API.

```c
XK_TUNE(tcp_hystart, "net/ipv4/tcp_cubic.c:L349:3:0") {
    // 1. Safety guard (mandatory)
    if (!xk_transition_done(xk_ctx)) return 0;
    // 2. User policy logic
    //    - Obtain the current network flow's RTT
    struct sock *sk = (struct sock *)PT_REGS_PARM1(ctx);
    struct bictcp *ca = inet_csk_ca(sk);
    u32 cur_rtt = BPF_CORE_READ(ca, curr_rtt);
    //    - Set the value to 1 only when RTT > 80ms
    if (cur_rtt >= 80000) xk_set(xk_ctx, 1);
    return 0;
} /* my_policy.bpf.c */
```

Figure 7: An example of Xk-tune. User-written policy code is highlighted; the rest is from the auto-generated stub.

tiple Xk-tunes according to the number of CS.

Figure 6 shows Xkernel APIs. Two core APIs are `xk_set` to update a perf-const value and `xk_transition_done` to check if the transition is completed. An Xk-tune can read kernel state and invoke `xk_set` to update the perf-const. Figure 7 shows an example of Xk-tune which is used for the case study on a perf-const of TCP CUBIC presented in §5.

Supporting kernel-state updates. eBPF programs are restricted to read-only access to kernel memory to prevent arbitrary writes. To support controlled updates, Xkernel exposes one single kernel-state update API as a BPF kfunc [45]. Kfuncs enable extended functionality through kernel modules. The Xkernel kfunc, `sie_write_kernel`, can be invoked only by Xk-tune (see §4). The kfunc calls the SIE indirections generated for the target perf-const to modify registers in `pt_regs` or kernel memory. The `pt_regs` holds the CPU register state at the moment the probe is triggered and provides a direct reference to the kernel context. Linux already exposes this state to tracing infrastructures (e.g., Kprobe and ftrace), and it is part of a stable tracing ABI [49]. Our kfunc extends this from read access to write access.

Transpiling Xk-tune into eBPF. Each Xk-tune is transpiled into an eBPF kprobe (`BPF_KPROBE`), corresponding to a CS for the perf-const. Figure 8 shows the source-code form of the eBPF code of the Xk-tune in Figure 7. Xk-runtime uses the scope table to locate the SIE indirections for the perf-const and wraps the update logic into generated functions, e.g., `impl_sie_logic_cs1` in Figure 8. A pointer to this function is stored in the `xk_ctx`, effectively implementing `xk_set` for that perf-const. In each generated Kprobe handler, the user-written policy function (e.g., `__user_policy_tcp_hystart`) is invoked. Hence, the policy code has the kernel context (via `ctx`) and the implementation of SIE indirections is provided as embedded function pointers. The safety of Xk-tune is checked by the eBPF verifier.

```c
// 1. Helper: SIE Indirection
static __always_inline void impl_sie_logic_cs1(
    struct pt_regs *regs, u64 val) {
    // Recovered symbolic state expression:
    //   ebx = (regs->bx) >> 3   (original value: 3)
    u64 new_bx = ((regs->bx) << 3) >> val;
    // Writing back to pt_regs using the kfunc
    sie_write_kernel(&regs->bx, sizeof(regs->bx), &new_bx);
}
// 2. Kprobe attachment: CS address (function+offset)
SEC("kprobe/tcp_cubic_hystart_check+0x4F")
int BPF_KPROBE(impl_cs_1) {
    // Wrap raw context into safe xk_ctx
    struct xk_ctx xk_ctx = {
        .regs = ctx,
        .set_fn = &impl_sie_logic_cs1,
    };
    // Call user policy (inlined)
    return __user_policy_tcp_hystart(&xk_ctx, ctx);
} /* my_policy.internal.bpf.c */
```

Figure 8: eBPF kprobe (in a source form) transpiled from the Xk-tune shown in Figure 7.

Transaction semantics. Xkernel supports tuning multiple perf-consts by bundling Xk-tunes in a single file. All Xk-tunes in the file form an atomic transaction—their tuning logic is loaded or unloaded together. Each perf-const may belong to at most one active transaction. The scope table tracks each perf-const status. If any perf-const is in an active transaction, it cannot be tuned in a new transaction.

4 Implementation

We implement Xkernel with ∼1.7K lines of kernel C code for Xk-runtime. Xkernel's toolchain is implemented in about 11K lines of Python, with ∼5K lines for CS and SS analysis via symbolic execution.

CS and SS analysis. We implement a symbolic execution engine specific to CS analysis. Upon capturing the CS, it synthesizes all potential SIE indirections ({location, update}). We implement the SS analysis on kernel bitcode using an LLVM pass. By correlating CS and SS with the `.section` metadata in the binary diff, we resolve the precise target function and offset for Kprobe attachment.

Minimizing Kprobe overhead. Linux Kprobe may have high overhead if breakpoint or single-stepping traps are used [32]. Linux saves the overhead through boosting (skipping single-step traps when post-handlers are absent) and jump-optimization (replacing breakpoints with direct jumps). Xkernel exploits these optimizations to minimize runtime overhead. To enable boosting, Xkernel replaces post-handlers with pre-handlers on the next instruction (`pc+1`). This assumes the next instruction is not a jump destination; this is almost always the case because Xkernel targets the precise point where V enters runtime states. Xkernel maximizes jump-optimizations by strategically attaching kprobes. We implement a new optimization that handles the case when immediate values of perf-consts are directly used in conditional jumps, which Linux Kprobe does not handle. We describe the optimization in Appendix B.

Table 2: Summary of case studies that demonstrate Xkernel's features and capabilities.

Case #	Perf-const	Subsystem	Default	Performance Tuning Regime
Case-1	BLK_MAX_REQUEST_COUNT	Storage (Block layer)	32	Adapting to hardware devices and workload patterns (see §2.1)
Case-2	MAX_SOFTIRQ_RESTART	CPU (Interrupt)	10	Choosing tradeoffs between tail latency and CPU utilization
Case-3	SHRINK_BATCH	Memory (Reclamation)	128	Controlling kernel internal behavior (e.g., maintenance)
Case-4	NR_MAX_BATCHED_MIGRATION	Memory (Page migration)	512	Tuning and reasoning with kernel and hardware observability
Case-5	HYSTART_DELAY_[MAX, MIN, factor]	Network (TCP CUBIC)	[16, 4, 3]	Collective tuning of interdependent perf-consts

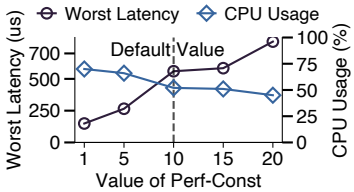

Figure 9: Cost-benefit tradeoff that can be tuned by changing values of MAX_SOFTIRQ_RESTART.

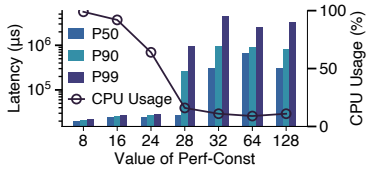

Figure 10: Tuning SHRINK_BATCH can significantly reduce write latency of the workload.

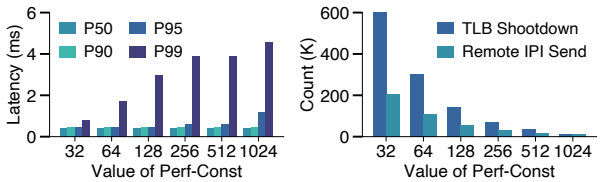

Figure 11: Tuning NR_MAX_BATCHED_MIGRATION to reduce tail latency, which requires understanding TLB shootdown behavior.

Xk-runtime. The runtime is implemented as a kernel module (xk-sie.ko). In addition to transpiling Xk-tunes to eBPF kprobes and loading them, it registers BPF Kfuncs and manages transitions. sie_write_kernel is registered for SIE internal use, and xk_transition_done is exposed to users to check transition status. It tracks completion via global refcounts maintained in Xk-runtime (multi-threading) or BPF_MAP_TYPE_TASK_STORAGE (per-thread). The kernel module attaches monitoring kprobes at SSes and detaches them with the help of a background monitor kthread. For multi-threading safety, it employs stop_machine to initialize refcounts via stack traversal before activating kprobes.

Xkernel tools. We implement a series of userspace tools. xk-build generates the scope table from the source patch. xk-gen specifies the ConstID in the scope table and outputs the Xk-stub. xk-load invokes Xk-runtime to transpile the xk-tune code with standard BPF tool-chains, install resulting BPF kprobes and ensure safe transition. Finally, xk-unload performs a symmetric, ordered teardown.

5 Case Studies

We present case studies that tune perf-consts across kernel subsystems, provide a glimpse at the broader policy space enabled by Xkernel, and discuss the resulting implications for tunability and complexity.

5.1 Performance Benefits and Tuning Rationales

Table 2 summarizes the case studies; we then discuss their performance benefits and tuning rationales.

Case-1: Adapting to hardware and workload patterns. Xkernel enables users to tailor perf-const values according to specific hardware properties and workload patterns. We revisit the perf-const BLK_MAX_REQUEST_COUNT presented in §2.1. Users can use a single Xk-tune program to simultaneously set the value to 128 for the sequential FIO workload on the HDD and to 1 for the RocksDB random workload on the NVMe SSD, obtaining the performance benefits shown in Figure 1. Meanwhile, other workloads can continue using the default value.

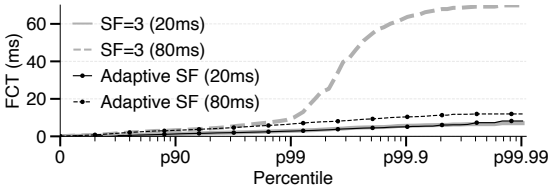

Figure 12: Flow completion time (FCT) of different scaling factors (perf-consts) under different RTTs running NGINX.

Case-2: Choosing performance tradeoffs. Xkernel enables users to choose points along performance tradeoff curves to better satisfy SLOs; such tradeoffs are widespread in OS kernels, with examples such as latency vs. throughput and resource utilization vs. latency.

We show how Xkernel enables balancing the tradeoff between CPU efficiency and tail latency in the CPU (interrupt) subsystem. The perf-const, MAX_SOFTIRQ_RESTART limits how many times the software interrupt (softirq) handler can be rerun in one iteration before yielding, preventing indefinite softirq processing. Increasing its value improves CPU efficiency but may increase tail latency of running tasks. Therefore, it has major impacts on latency-critical workloads, especially when they are colocated with throughput-oriented workloads [57].

We run a latency-critical workload W_l using cyclictest [63] and a throughput-oriented workload W_t on a 4-node cluster with 25 Gbps networking, varying the perf-const values.

Figure 9 shows a clear tradeoff between tail latency of W_l and CPU utilization. The original value (10) provides a reasonable balance with 52% CPU utilization and a worst-case latency of 560 us; achieving the optimal tail latency of 149 us requires paying a penalty of 22% CPU utilization.

Case-3: Controlling kernel internal behavior. Oftentimes, application performance is affected by the kernel's internal behavior such as memory reclamation, which is hard

to control externally. With Xkernel, kernel *internal* behavior can be aligned with the application's access patterns.

We demonstrate this capability using `SHRINK_BATCH`, a perf-const for Linux shrinkers, i.e., kernel callbacks that reclaim slab objects under memory pressure. It controls how many entries a shrinker checks when it scans a slab's LRU list for memory reclamation. `SHRINK_BATCH` was introduced before 2005 [73] and its value (128) has remained unchanged since then [46]. Linux implements 43 shrinkers for different slab objects (zswap entries, inode, dentry, etc). We focus on the zswap-shrinker for the zswap subsystem [52] that is widely used in datacenters [30, 37].

We run a workload that writes data blocks sequentially into a large anonymous mmaped region and periodically overwrites written blocks, which resembles data analytics with a memory budget (constantly triggering zswap). The periodic reuse exposes a classic working-set effect. When the batch size is small, fewer pages are reclaimed and swapped, increasing the chance to reuse data in memory. In contrast, an aggressive batch size may trigger thrashing.

As shown in Figure 10, the original value of 128, despite the relatively low CPU utilization (11%), incurs a large latency penalty. In fact, any values above 24 cause thrashing with unnecessary disk I/O, slowing the user workload. In contrast, smaller values ($\leqslant$24) provide much lower latency.

Case-4: Tuning and reasoning with observability. Written in eBPF, policy code in Xkernel has observability on kernel and hardware metrics and behavior. These internal metrics are valuable for reasoning about performance, confirming tuning effectiveness, and being incorporated directly into tuning policies to decide values.

We use `NR_MAX_BATCHED_MIGRATION`, a perf-const that specifies the batch size of pages migrated across NUMA nodes [58], to demonstrate this feature. The default value (512) was introduced in 2023 [79] and has never been updated. This perf-const controls the amortized costs of TLB shootdowns and page migration. Larger batches amortize per-page migration cost but defer TLB shootdowns, which could increase stall time for concurrent threads accessing pages under migration. Online experiments with Xkernel help us understand the relationship between local memory access and TLB shootdowns.

We run a workload with one group of threads repeatedly touching hot data on a NUMA node, while another group continuously migrates hot pages to that node to shift the hot region over time. This workload mimics memory-intensive applications with moving working sets.

We vary `NR_MAX_BATCHED_MIGRATION` values and measure the tradeoff between latency of memory access to hot pages during migration and TLB shootdowns, as shown in Figure 11. A small value can effectively reduce tail latency by prioritizing memory access over migration, with a penalty of increased TLB shootdowns. Tuning this perf-const values requires observability of TLB behavior.

Case-5: Collective tuning of interdependent perf-consts. With Xkernel, users can jointly tune multiple perf-consts that collectively decide fine-grained behavior with transaction semantics (§3.6).

We demonstrate this capability by tuning the behavior of TCP CUBIC's HyStart delay-based congestion window. When a connection is in slow start, TCP CUBIC checks whether the current RTT exceeds a delay threshold computed from three perf-consts (two defined as macros and one used as an operand in a shift operation). If the measured delay exceeds this threshold, CUBIC assumes congestion and exits slow start. The optimal threshold is highly dependent on RTT. With high RTTs, the current perf-consts are overly sensitive and trigger premature slow-start exit; with low RTTs, they are too conservative and delay exiting slow start. These perf-consts were introduced in 2008 [26] and changed three times [17, 18, 25]. Prior work reported the importance of tuning them [27], but they remain constants.

We first ran a microbenchmark to understand scaling factors (SFs) under different RTTs. To provide sufficient room for the scaling factor to take effect under high RTT, we change `HYSTART_DELAY_MAX` from 16*ms* to 32*ms*. We find that SF=1 significantly reduces tail latency for slow flows, but increases tail latency for fast flows compared to SF=3 (default). Based on this observation, we implement a selective tuning policy that dynamically adjusts the SF of TCP Cubic for flows with long RTT (Figure 7).

We show performance gains of tuning these perf-consts collectively on NGINX, deployed as a web server for photo and video content [55]. We run a mixed workload of concurrent 20*ms* and 80*ms* flows, representing fast and slow connections. As shown in Figure 12, Xkernel achieves a significant FCT reduction (81% at P99.99) for long-RTT flows while maintaining performance parity for short-RTT flows.

5.2 A Glimpse into Xkernel-Enabled Policies

Xkernel enables powerful tuning policies and creates opportunities for policy innovation. We briefly discuss three directions that hint at a broader unexplored policy space.

Flexible granularity. One major benefit of Xkernel is its flexible granularity in applying tuning policies. Unlike hard-coded granularities, such as processes, cgroups, or devices, Xkernel allows users to define tuning granularity using conditions unforeseen before binary deployment.

As demonstrated by the cases in Table 2, Xkernel allows values to be set at the granularity of a given application (potentially spanning multiple processes or threads), a specific device type, or a set of network flows. Users can update these granularities by changing the condition under which `xk_set` is applied in a new Xk-tune. The zswap shrinker (Case-3) is an interesting example: 43 shrinkers across subsystems share the same perf-const as their batch size, yet Xkernel allows customizing batch sizes for different shrinkers at runtime by checking the caller's name (see Appendix D).

```
XK_TUNE(...) {
    // Get the pid upon invocating this kernel code path
    u64 pid = bpf_get_current_pid_tgid() & 0xFFFFFFFF;
    // Leverage hints from the application process
    int *hint = bpf_map_lookup_elem(&hint_map, &pid);
    if (hint) {  xk_set(xk_ctx, 1);  }
}
```

Figure 13: An example of an application-informed policy. The application communicates the hint through an eBPF map (`hint_map`), and the Xk-tune uses this hint to apply the tuning value to selected threads.

```
/* Track consecutive failed attempts to merge adjacent
   blocks and store the count in fail_cnt for use as a
   tuning heuristic */
SEC("kretprobe/blk_attempt_plug_merge")
int BPF_KRETPROBE(blk_attempt_plug_merge_ret, long ret) {
    int *fail_cnt = bpf_task_storage_get(&fail_cnt_map,
        bpf_get_current_task_btf(), ...);
    if (ret == 0 && fail_cnt) (*fail_cnt)++;
    else *fail_cnt = 0;
}
/* Retrieve the heuristic and tune accordingly */
XK_TUNE(blk_add_rq_to_plug, "block/blk.h:L312:32:0") {
    int *fail_cnt = bpf_task_storage_get(&fail_cnt_map,
        bpf_get_current_task_btf(), ...);
    // Heuristic: treat the workload as random when many
    // (16, an ad-hoc threshold) consecutive merges fail
    if (fail_cnt && *fail_cnt >= 16) xk_set(xk_ctx, 1);
}
```

Figure 14: An Xk-tune program using ad-hoc workload heuristics. It instruments `blk_attempt_plug_merge` with a kretprobe to track historical merge failures.

Application-informed policies. Xkernel enables a class of application-informed tuning policies that better coordinate with application-level semantics and knowledge of workload patterns. This feature relies on eBPF's mature user-kernel communication. Figure 13 illustrates one such collaboration, where a workload-pattern hint is passed via an eBPF map. For example, a RocksDB application can use such hints to distinguish foreground threads from compaction threads.

Ad-hoc tuning heuristics. Xkernel enables ad-hoc tuning heuristics that are easier to identify once workloads and deployment scenarios are known, without requiring such heuristics to be baked into the source code. Figure 14 illustrates one such heuristic for Case-1, where kernel-internal observability metrics are used to infer whether the workload is sequential or random. Moreover, because an Xk-tune runs on each execution, Xkernel supports adaptive policies, such as linear or exponential changes to the tuning value.

5.3 Tunability and Complexity

Choosing values for perf-consts faces inherent complexity: the best value depends on the workload, hardware, and policy objective in a given deployment. Existing practice hides this complexity behind fixed compile-time choices, but this can leave significant performance opportunities fundamentally unattainable. In contrast, Xkernel makes perf-consts tunable and programmable in a unified framework, exposing the broad and powerful policy space discussed above.

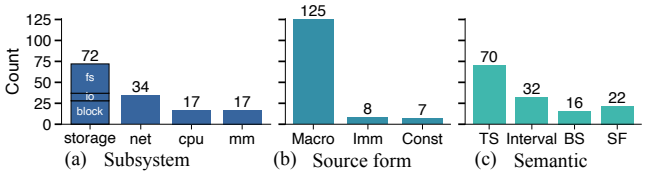

Figure 15: Characteristics of the evaluated perf-consts. The categories are specified in Table 1.

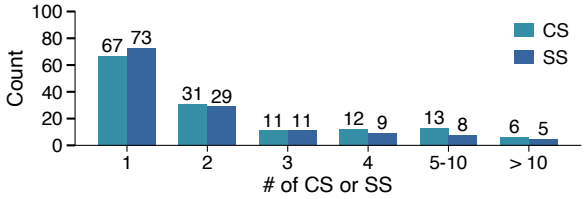

Figure 16: Number of CS and SS per perf-const.

Such exposure does not create new complexity; rather, it allows users, for the first time, to tackle this complexity in a principled manner. Exposing only a subset of perf-consts is insufficient when multiple constants jointly affect system behavior; one untunable perf-const can limit the effectiveness of others. We believe managing the full perf-consts set with Xkernel opens a promising research direction.

6 Evaluation

To evaluate the generality, safety, and efficiency of Xkernel, we collected 140 perf-consts from four Linux subsystems. These perf-consts cover common semantics and source-code forms, as shown in Figure 15. Note that the evaluated perf-consts are a small subset of all perf-consts in Linux, though the number is comparable to that of `sysctl` performance-related knobs. Evaluations run on a machine with 128 GB RAM, a 28-core Intel Xeon Gold 5512U CPU (2.1 GHz), and two 800 GB NVMe-Gen4 SSDs on CloudLab [19].

Xkernel supports all but one (99.3%) perf-consts. The one Xkernel fails to support is due to limitations of Kprobe (see Appendix C for more details).

We show that: (1) SIE incurs negligible runtime overhead; (2) Xkernel supports millisecond-scale policy updates and safe transitions; and (3) the cost of offline, one-time static analysis is about 18 minutes per perf-const.

6.1 Characteristics of Critical and Safe Spans

We first present the characteristics of critical spans (CSes) and safe spans (SSes) of the evaluated perf-consts. The information helps interpret our experiment results. As shown in Figure 16, the 140 perf-consts have 367 CSes in total. Most constants are highly localized: 48% map to a single CS, and 86% map to fewer than five. A long tail also exists: in 4% of cases, a constant maps to more than ten CSes; `DEF_PRIORITY` and `NFS4_POLL_RETRY_MAX` have the highest counts (16 and 17) due to aggressive inlining of their enclosing callers.

Out of the 367 CSes, 82 have symbolic values IV that differ from the perf-const value V in the source representation (§3.3.2). Xkernel correctly recovers the symbolic relations

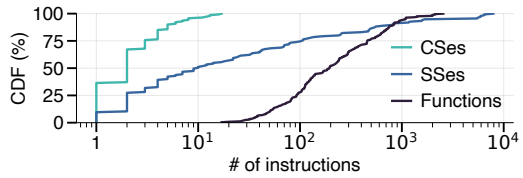

Figure 17: Size of CSes, SSes, and Functions. CS size is measured precisely. SS size is approximated by summing the instructions in the span, including the callees. For functions, we count only the instructions in the function body (excluding callees), so the value is an underestimate.

for all cases. Only three CSes require dual-location indirections to handle irreversible updates (§3.4.2).

We obtained 300 SSes in total from the 367 CSes. As shown in Figure 16, 26 of the perf-consts exhibit CSes that have data dependencies, resulting in a smaller number of SSes compared to their number of CSes.

Figure 17 compares the sizes of CSes, SSes, and kernel functions. CSes are small, mostly containing a single instruction; only 12 contain two, and one each at lengths 3, 4, 5, and 7. This confirms that the point where a perf-const first affects runtime state is simple and compact. The median SS contains only 10 instructions, showing that safe transitions are usually confined to a small scope. SS size, however, has a long tail significantly larger than CS size, reflecting the inherent complexity of kernel data dependencies. The largest SS in our dataset is about 8K instructions. SSes make these dependencies explicit. Functions expand the scope unnecessarily and are much larger than SS except in extreme cases, but with weaker safety guarantee than SSes.

6.2 SIE Overhead

We evaluate SIE overhead along three dimensions: the per-trigger CPU cost, the frequency at which SIE kprobes fire, and the number of SIE kprobes enabled at the same time.

Per-trigger cost (CPU cycles). An SIE invocation includes the underlying kprobe cost plus SIE-specific work: checking transition state (O1), executing indirection (O2), and, when needed, reading kernel state (O3) or accessing BPF maps (O4) for user-space policy interaction. We attach SIE kprobes at different offsets inside a kernel function (`vfs_write`) to compare jump-optimized and INT3-based probes. We use a single-byte write workload with an intentionally short kernel path bottlenecked at `vfs_write`. Table 3 shows that the kprobe mechanism dominates: an empty jump-optimized kprobe adds 168 cycles (for 84.2% of evaluated CSes), whereas an empty INT3-based kprobe adds 1765 cycles. O1–O4 add little additional cost.

Trigger frequency. We evaluate the impact of trigger frequency using a controlled benchmark. We implement a multithreaded workload that uses `io_uring` and performs asynchronous one-byte writes to `/dev/null` with an SIE kprobe attached to `io_issue_sqe`. We vary both the offered IOPS (to control the trigger rate of SIE) and the amount of per-operation computation. Figure 18 shows the slowdown at

Operation	Cycles/Op	Overhead(%)	Cases #
Baseline	946		
Empty BPF Kprobe (JMP)	1114	+18%	
Xkernel (JMP+O1)	1146	**+21%**	
Xkernel (JMP+O1+O2)	1167	**+22%**	309
Xkernel (JMP+O1+O2+O3)	1186	**+25%**	(84.2)%
Xkernel (JMP+O1+O2+O3+O4)	1187	**+25%**	
Empty BPF Kprobe (INT3)	2711	+187%	
Xkernel (INT3+O1)	2752	**+191%**	
Xkernel (INT3+O1+O2)	2801	**+196%**	58
Xkernel (INT3+O1+O2+O3)	2795	**+195%**	(15.8)%

Table 3: CPU cycles breakdown of one SIE invocation. O1: Transition state check; O2: Indirection's execution; O3: Kernel Memory Read; O4: BPF MAP Access

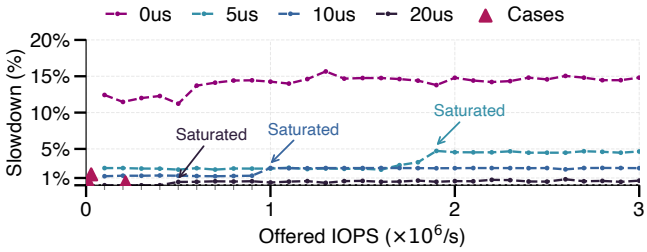

Figure 18: Slowdown of median latency. The trigger rate of SIE kprobes is equal to the offered IOPS before saturation and remains unchanged afterwards.

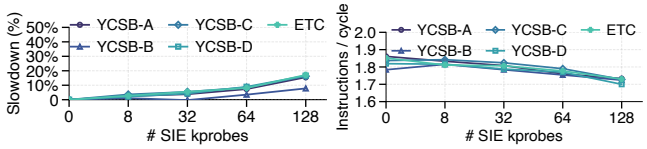

(a) Throughput slowdown (b) Instructions per cycle (IPC)

Figure 19: Redis slowdown with multiple SIE kprobes.

different trigger rates; we also annotate the data points from case studies (§5) by triangles.

When the workload performs essentially no work (0μs) in each operation, the slowdown caused by SIE is 15%; the slowdown drops to 5% and 2% when each operation includes 5μs and 10μs of computation, respectively. Once per-operation processing reaches 20μs, the overhead falls below 1%. The slowdown curve remains relatively flat as trigger rate increases, indicating that the overhead scales predictably even under high execution frequency of SIE. These results show that Xkernel introduces negligible overhead, even when triggered millions of times per second. In practice, applications tend to execute their own logic for more than 20μs, making the overhead even more negligible.

Multiple SIE kprobes. We evaluate how the per-trigger cost accumulates when many tunable constants are active under a real application. We run Redis [61] with YCSB [9] and Facebook ETC workloads [3], and vary the number of enabled SIE kprobes; each SIE kprobe is placed on the critical path. Figure 19 reports throughput and instructions per cycle (IPC). With 32 SIE kprobes, throughput drops by at most 4%. Even with 128 SIE kprobes, throughput slowdown

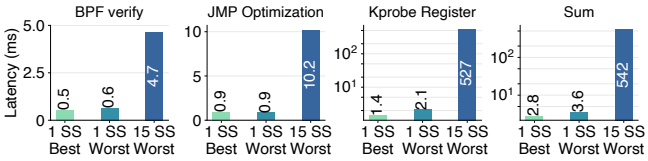

Figure 20: Policy-update time. Best case: only one kprobe is required per CS. Worst case: two additional kprobes are needed to ensure global consistency.

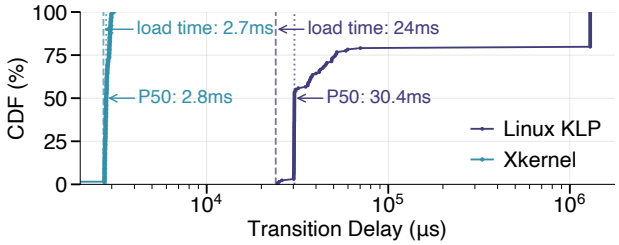

Figure 21: Transition time of Xkernel using CS versus Linux KLP. The target function has 898 instructions.

is 7–14% across workloads, while IPC drops by about 6%. These results show that Xkernel is practical to tune many perf-consts with modest overhead.

Finally, a tuning should be enabled when its benefit outweighs the pure cost of SIE invocations; in our case studies, the benefits usually far outweigh this overhead.

6.3 Policy-update and Transition Time

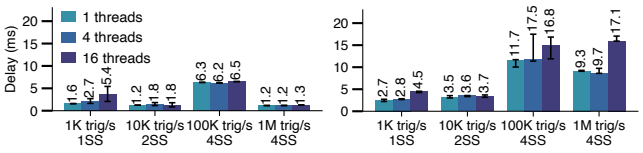
We measure the time to load a policy program (Xk-tune) and the time to transit from the original value to a new one.

Policy-update time. Figure 20 shows the breakdown of loading an Xk-tune program, including BPF verification, jump-optimization, and Kprobe registration. The main cost is Kprobe registration, and thus the number of kprobes has a major impact on policy load time. Even in the case where the perf-const has 15 SSes, Xkernel bounds the policy-update time to 542 milliseconds, meeting our design goal.

Transition time. Xkernel provides the near-optimal transition time for per-thread version atomicity and side-effect safety, and is scalable with many concurrent threads.

Per-thread version atomicity. We compare Xkernel with Linux KLP [50] on version atomicity; both support version atomicity. We tune a perf-const which controls TCP backlog size [51] and measure transition time with an `iperf3` [71] workload of 128 flows (threads). Figure 21 shows the CDF of the *end-to-end* latency, including the policy-update time (2.7 *ms* for Xkernel and 24 *ms* for KLP modulo 7-minute patch-generation time). The median latency for KLP and Xkernel is 2.8ms and 30.4ms, respectively. This shows that CS is a much more efficient transition unit than function.

Per-thread side-effect safety. Figure 22a shows transition time of four representative cases with different triggering rates of Xk-tunes and the number of threads that load Xk-tunes. We do not compare with KLP which does not support side-effect safety. In all cases, the transition time is less than 10 milliseconds. A per-thread transition completes as soon



(a) Per-thread (b) Global consistency

Figure 22: Transition time of side-effect safety.

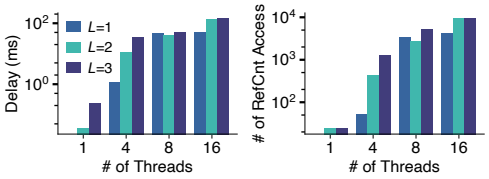


Figure 23: The impact of SS size with global consistency. L is the length of function calls to reach the CS of a perf-const; it is used to control the SS size.

as the first kprobe fires upon entering the first SS. We see no clear correlation of the triggering rate and the number of the SSes with the transition time—all configurations trigger at least once per millisecond and complete the transition immediately once the entry kprobe fires.

Global consistency. Figure 22b shows transition time with global consistency on side-effect safety with multiple threads. The time increases compared to per-thread safety. We do not compare with Kpatch [60] because its global-consistency mode was later deprecated [59] and it does not support side-effect safety.

To understand the time in more depth, we run a controlled experiment using the microbenchmark in §6.2, varying the SS size (controlled by L levels of call stacks) and the number of threads. Figure 23 shows that transition time increases with higher concurrency (fewer safe points) and larger SS sizes. The number of reference-count updates shows the same pattern: a larger number of updates indicates a lower likelihood of leaving the SS. Overall, the transition time is low (144*ms*) even under high concurrency (16 threads).

6.4 Offline Static Analysis Time

Xkernel incurs a one-time cost per perf-const for static analysis; after that, the perf-const can be tuned online anytime. This offline process consists of two kernel compilations, symbolic execution to recover symbolic state expressions and CSes, and analysis to construct SSes. On average, the process takes 18 minutes per perf-const. The analysis of different perf-consts can be done in parallel using spot instances. Compilation takes about seven minutes (two compilation runs executed in parallel across 56 threads). The remaining time is dominated by SS construction, which varies significantly based on the dependency structure. On average 11 $\pm$ 20 minutes and up to 124 for the most complex case.

Overall, Xkernel's offline cost is linear in the number of perf-consts in the kernel source code. For N constants, constructing the scope table requires $2N$ recompilations. In contrast, KLP or source-level recompilation requires one binary per target value; with M possible values per constant, all

combinations can require up to M^N builds. The scope table is reusable across machines running the same kernel binary, allowing cost amortization across a deployment.

7 Discussion

Applicable constants of Xkernel. Xkernel prefers safety over completeness, while still supporting a broad range of perf-consts. Xkernel does not target constants which can directly change kernel memory layout (e.g., array sizes or struct padding), as such changes can introduce dangerous pointer arithmetic and are challenging to make safe. Xkernel rejects the constants it cannot handle upon detection. The layout changes can be reliably detected by reading debug information such as DWARF (e.g., `pahole`). Xkernel can also detect and reject dead-code elimination cases where the offline analysis finds the constant absent from one binary.

Concurrency safety. A CS is a very short instruction sequence (Figure 17) that materializes a constant into runtime state; it typically contains no lock operations, blocking primitives, or memory barriers. An XK-tune only changes this materialization, so it preserves the original concurrency semantics and does not introduce the risk of races from breaking locks. The kprobe mechanism also provides a solid foundation, as probe insertion is atomic.

Choosing a good value. To maximize flexibility, Xkernel does *not* impose any built-in bounds on new values (except for architectural constraints such as register width limits). Such bounds belong to the performance semantics of each perf-const, not the SIE mechanism. Users can encode range checks, device-specific constraints, specifications defined by RFCs, and any other value checks in XK-tune. Xkernel treats them as policy, keeping mechanism and policy separate.

The focus of this work is the mechanism and interface to realize principled OS tunability (§2.3), not the policies on deciding the optimal values of each perf-const. We expect the new opportunities and flexibility enabled by Xkernel to inspire many new tuning techniques (e.g., with AI [41]).

Maintenance of offline results. The scope table is tied to the exact kernel source, compiler version, and build configurations to match the running binary. Xkernel assumes that the compiler version and build configurations of the running kernel are available. This holds because (1) they are inherently known for customized kernels, and (2) for out-of-the-box kernels, they can be retrieved from official sources.

Out-of-tree modules and drivers. Xkernel is not limited to in-tree kernel code. SIE also supports loadable kernel modules and vendor drivers with available source code. Each scope table entry is tied to a specific module or driver version and must be regenerated after it is rebuilt or updated.

8 Related Work

OS and system performance tuning. Tuning has long been essential for OS performance [2, 24, 64]. Existing practice, however, relies on the limited set of knobs exposed through `sysctl` and `sysfs`, leaving substantial performance potential unexplored. Kernel configuration systems (e.g., Kconfig [47]) customize the OS but are designed for feature selection [36, 65, 68, 69], not performance tuning, since they operate purely at compile time. Recent techniques using AI agents show promise in improving search strategies [41, 42], but they are limited to a fundamentally constrained tuning space. We view Xkernel as a new foundation to expand this space and advance tuning techniques. Our techniques and principled tunability can potentially benefit many other systems that actively explore tuning policies [34, 35, 43, 70].

Programmable kernel extensions. Kernel extensibility has long been a central topic in OS research [15]. This area has seen renewed momentum with the rise of eBPF, which has been used to customize kernel behavior across many subsystems [11, 29, 31, 33, 78, 81, 83]. These efforts share our motivation of adapting kernel behavior to diverse workloads and hardware. Our work focuses on perf-consts and principled tunability. While Xkernel uses eBPF as its policy interface, its core contribution is SIE, which enables principled in-situ tuning. TCP-BPF [8] provides a similar capability by allowing TCP parameters to be tuned through an eBPF program. However, it is limited to the TCP subsystem and requires substantial engineering effort to restructure kernel code paths. In contrast, Xkernel is general to any perf-consts.

OS and program live update. SIE shares attributes with live-update systems, but is designed specifically for perf-consts—users (or agents) specify a value and Xkernel synthesizes the update instructions. OS live update has been widely studied [7, 10, 22, 23] and has led to products such as Ksplice [1], Kpatch [60], and KLP [50]. As discussed, these systems treat functions as the unit of version atomicity, making them a poor match for perf-consts. User-space live-update systems also operate at function-level unit [28, 62]. A recent effort, PlugSched [53] provides live updates for CPU scheduling but depends on policy-specific understanding of kernel scheduler data structures to reconstruct state. In contrast, Xkernel provides a general and principled mechanism without relying on specific kernel data structures.

9 Conclusion

We presented Xkernel which uses Scoped Indirect Execution (SIE), the first mechanism to achieve principled OS tunability and enable safe, fast in-situ tuning of *any* perf-consts in OS kernels. Xkernel offers a new path for OS performance and opens untapped performance opportunities.

A Sysctl Performance Knobs

We did a pilot study of `sysctl` knobs on Ubuntu 24.04 LTS which uses Linux v6.14. The number of `sysctl` knobs may vary slightly across distributions. We found 702 `sysctl` knobs in total (deduplicated due to NIC name prefix) and inspected all of them. Among them, 145 `sysctl` knobs are related to performance tuning. The others are for debugging, observability, and feature toggles.

We study the evolution of these 145 `sysctl` knobs, and summarize the results in Figure 24. We observe that the `sysctl` knobs evolve slowly. Among the 145 `sysctl` knobs, 96 have not changed since 2005 (earlier commit history is unavailable). Only 49 knobs were indeed evolved from constants—perf-consts studied in this paper. Among them, 19 (columns 1–19 in Figure 24) were historically converted from a perf-const. The other 30 were extended from system-wide values to per-namespace (cgroup) values. Reading the commit messages and the related discussions, it is clear that converting a perf-const into a `sysctl` knob is very slow due to the conservative upstream practice in Linux. For example, the TCP ping-pong threshold was set to 1 originally, raised to 3 in 2019, reverted to 1 in 2022, and only recently exposed as a `sysctl` in response to application demands (e.g., SQL workloads) in 2023 [80]. Therefore, waiting for a perf-const to be converted to a `sysctl` knob may be unwise.

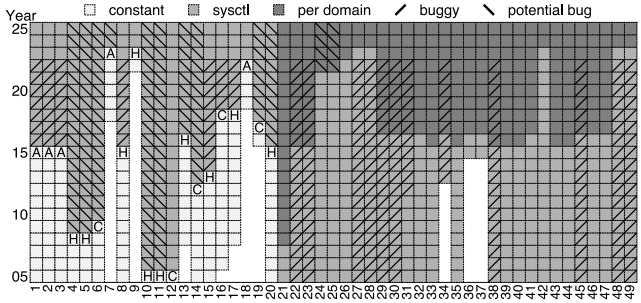

Figure 24: Evolution of `sysctl` knobs. Each box shows the status of a knob. constant: a fixed perf-const in the source code; `sysctl`: exposed as a `sysctl` knob. per-domain: the `sysctl` knob is made per namespace. buggy: time between the introduction of a bug and the commit that fixes it. potential bug: a likely bug identified by our inspection. A/H/C: reason for the change (A: application-driven, H: hardware-driven, C: exposing control of an inherent trade-off).

Note that converting a perf-const into a `sysctl` knob is non-trivial and error-prone. As shown in Figure 24, 20 knobs required bug fixes after their conversion, taking an average of 12 years to resolve. Most issues stem from race conditions introduced by the new global variable. We check the bug pattern of all the 149 `sysctl` knobs, and identify 43 additional knobs with likely unresolved bugs. Basically, converting a perf-const into a writable interface adds complexity: external writers (i.e., callers of the interface) can update the value while kernel threads may still read the old one. Fine-grained control adds further complexity. For example, changing the dirty-ratio knob to operate per device introduced a deadlock because the `sysctl` configuration path was not aware of the new semantics [82]. Xkernel addresses these problems by safely updating perf-const values through SIE (see §7).

B Optimization for Conditional Branches

When the immediate value of a perf-const is used in a conditional branch (e.g., Figure 4(a)), the location target of SIE is the corresponding `jmp` instruction. However, a conditional jump cannot be jump-optimized by Kprobe [32].

For such cases, we implement a new optimization that allows jump-optimized kprobes. The key idea is to modify R/M in the `cmp` in advance (at a position that jump-optimization is possible), and restore it along the control flow via extra jump-optimized kprobes, synchronized by a task-local flag, as shown in Figure 25. In this way, the same effect as synthesizing an SIE indirection to modify `eflags` can be achieved by proactively adjusting R/M used in the conditional jump. For example, in Figure 4(a), changing the immediate value from 7 to 4 is functionally equivalent to adding 3 to `eax` before the comparison. More generally, if we want to replace V with V', we can adjust the R/M operand by $\Delta V = V - V'$ in advance, and later restore its original value along all relevant control-flow paths. This optimization increases the fraction of jump-optimized kprobes from 66.6% to 88.3% in our evaluation.

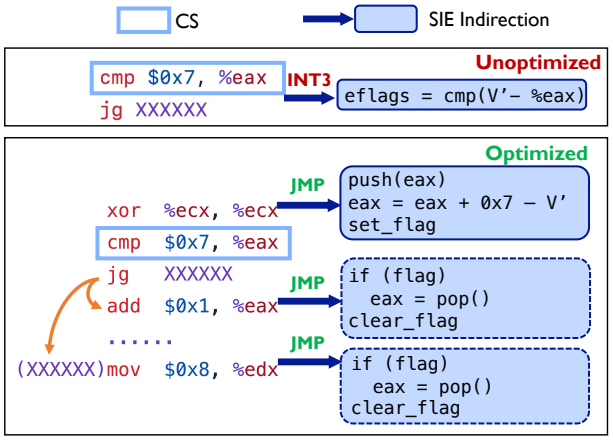

Figure 25: Optimization for conditional branches. The `cmp` instruction is undesired because its length is less than 5 bytes, which prevents Kprobe jump-optimization. Xkernel attempts to attach the probe to a preceding instruction to enable Kprobe jump-optimization.

To implement this optimization, Xkernel inserts two extra kprobes at the jump target and the subsequent instruction. These kprobes query the task-local storage and restore the operand. To ensure restoration occurs only when control flow originates from the CS, and not from unrelated execution paths, we employ a task-local flag. This flag is set upon entry to the first kprobe and cleared when the two extra kprobes trigger. If the first kprobe and either of these two kprobes fail to enable jump-optimization, we fall back to the

```
XK_TUNE(do_shrink_slab, "mm/shrinker.c:L381:128:0") {
    // 1. Safety Guard (Mandatory)
    if (!xk_transition_done(xk_ctx)) return 0;
    struct shrinker *s = (struct shrinker *)
        PT_REGS_PARM2(ctx);
    char name[32];
    if (bpf_probe_read_kernel(name, sizeof(name),
        &s->name) < 0) return 0;
    // 2. Tune SHRINK_BATCH only for zswap
    if (bpf_strncmp(name, 12, "zswap-shrink") == 0)
        xk_set(xk_ctx, 64);
    return 0;
} /* SHRINK_BATCH.bpf.c */
```

Figure 26: An Xk-tune for zswap shrinker; it identifies zswap shrinkers by checking the name.

```
#define MAX_ROCKSDB_THREADS 16
struct { // Filled by RocksDB threads
    __uint(type, BPF_MAP_TYPE_HASH);
    __uint(max_entries, MAX_ROCKSDB_THREADS);
    __type(key, u32);
    __type(value, int);
} hint_map SEC(".maps");
XK_TUNE(blk_add_rq_to_plug, "block/blk.h:L312:32:0") {
    // 1. Safety Guard (Mandatory)
    if (!xk_transition_done(xk_ctx)) return 0;
    // Get the pid upon invocating this kernel code path
    u64 pid = bpf_get_current_pid_tgid() & 0xFFFFFFFF;
    // 2. Leverage hints from the application
    int *hint = bpf_map_lookup_elem(&hint_map, &pid);
    if (hint) xk_set(xk_ctx, 1);
    return 0;
} /* BLK_MAX_REQUEST_COUNT.bpf.c */
```

Figure 27: An application-informed policy for RocksDB. RocksDB characterizes threads with random-read patterns and exposes their IDs through a BPF map. Xk-tune leverages this hint to enable per-thread tuning.

original SIE location. When successful, this optimization replaces one INT3-based kprobe with two jump-optimized kprobes. Despite introducing extra kprobes, this approach is beneficial: a jump-optimized kprobe is an order of magnitude cheaper than an INT3-based kprobe.

C Kprobe Limitation

In our evaluation (§6), Xkernel failed to handle one perf-const, where the target kernel functions could not be attached. The perf-const, `SEND_MAX_EXTENT_REFS`, is located in `fs/btrfs/send.c` within the `check_extent_items()` function. In Linux v6.14, the symbol `check_extent_item()` has multiple definitions (e.g., appearing simultaneously in the kernel core and a loadable module). When registering a kprobe using the syntax `[MOD:]SYM[+offs]`, the kernel's `trace_kprobe` mechanism resolves the symbol name. However, to prevent ambiguity, the kernel rejects the registration if multiple matches are found, causing the kprobe creation to fail with `EINVAL` or `-EADDRNOTAVAIL`.

D Policy Code with Xkernel

We present three Xk-tune programs that illustrate the policies enabled by Xkernel (§5.2): object-level tuning granularity, application-informed policy, and ad-hoc heuristics. These examples show how users express such policies in Xkernel.

Figure 26 shows an Xk-tune program that customizes perf-consts for different objects. Written in eBPF, Xk-tunes can incorporate many features to customize tuning granularity. The perf-const is `SHRINK_BATCH` (Case-3 in §5.1). Figure 27 shows an Xk-tune program for an application-informed policy for a RocksDB application. The perf-const is `BLK_MAX_REQUEST_COUNT` (Case-1 in §5.1). Figure 28 shows an Xk-tune program that coordinates with other kprobes and uses ad-hoc workload heuristics. The perf-const is `BLK_MAX_REQUEST_COUNT` (Case-1 in §5.1).

```
#define MERGE_FAIL_THRESHOLD 16
struct { // Filled by blk_attempt_plug_merge()
    __uint(type, BPF_MAP_TYPE_TASK_STORAGE);
    __uint(map_flags, BPF_F_NO_PREALLOC);
    __type(key, int);
    __type(value, int);
} hint_map SEC(".maps");
/* Track consecutive failed attempts to merge adjacent
   blocks and store the count in fail_cnt for use as a
   tuning heuristic */
SEC("kretprobe/blk_attempt_plug_merge")
int BPF_KRETPROBE(blk_attempt_plug_merge_ret, long ret) {
    struct task_struct *task = bpf_get_current_task_btf();
    int *fail_cnt = bpf_task_storage_get(&hint_map,
        task, NULL, BPF_LOCAL_STORAGE_GET_F_CREATE);
    if (!fail_cnt) return 0;

    if (ret == 0) (*fail_cnt)++;
    else *fail_cnt = 0;

    return 0;
}
XK_TUNE(blk_add_rq_to_plug, "block/blk.h:L312:32:0") {
    // 1. Safety guard (mandatory)
    if (!xk_transition_done(xk_ctx)) return 0;
    struct task_struct *task = bpf_get_current_task_btf();
    // 2. Leverage hints from blk_attempt_plug_merge()
    // Heuristic: treat the workload as random when many
    // (16, an ad-hoc threshold) consecutive merges fail
    int *fail_cnt = bpf_task_storage_get(&hint_map,
        task, NULL, 0);
    if (fail_cnt && *fail_cnt >= MERGE_FAIL_THRESHOLD)
        xk_set(xk_ctx, 1);
    return 0;
} /* BLK_MAX_REQUEST_COUNT.bpf.c */
```

Figure 28: An Xk-tune program using ad-hoc workload heuristics for RocksDB. The Xk-tune instruments `blk_attempt_plug_merge` with a kretprobe to track historical merge failures. Upon detecting a high failure rate, the Xk-tune adjusts the threshold to a smaller value (1).

E Xkernel Tool Commands

We show a few commands that use Xkernel tools (§4).

```
xk-build /usr/src/linux tune.patch # > ConstID
xk-gen ConstID xk-stub.h
xk-load [global/task/imm] xk-tune.c
xk-unload ConstID/all
```

Murakkab: Resource-Efficient Agentic Workflow Orchestration in Cloud Platforms

Gohar Irfan Chaudhry Esha Choukse[†] Haoran Qiu[†] Íñigo Goiri[†]
Rodrigo Fonseca[†] Adam Belay Ricardo Bianchini[‡]
MIT CSAIL [†]*Microsoft Azure Research* [‡]*Microsoft Azure*

Abstract

Agentic workflows commonly coordinate multiple models and tools with complex control logic. They are quickly becoming the dominant paradigm for AI applications. However, serving them remains inefficient with today's frameworks. The key problem is that they expose workflows as opaque sequences of model and tool calls that tightly couple agent logic with model and hardware choices. This prevents systems from holistically reasoning about trade-offs across accuracy, latency, energy, and cost. This leads to resource waste and degraded service-level objectives (SLOs).

We present Murakkab, a resource-efficient serving system for agentic workflows. Murakkab introduces a declarative abstraction that decouples workflow specification from execution configuration. A profile-guided optimizer and adaptive runtime jointly manage the full stack: orchestrating workflow components, mapping them to models and hardware, and dynamically reconfiguring execution to satisfy user-defined SLOs. By exposing the internal structure of agentic workflows, Murakkab enables cross-layer optimization that existing frameworks and cloud schedulers cannot achieve.

Our evaluation on diverse workflows shows that, compared to state-of-the-art systems, Murakkab reduces GPU usage by up to 2.8×, energy consumption by 3.7×, and cost by 4.3× while maintaining SLOs.

1 Introduction

The rise of complex, multi-step tasks in domains like scientific discovery, education, and health analytics has driven the emergence of *agentic workflows* [16, 22, 35, 41]. These workflows integrate large language models (LLMs) and multimodal variants with external, specialized tools such as search engines, code interpreters, and databases, allowing them to reason and act dynamically [71, 82, 88]. Modern cloud platforms [7, 8, 19] (*e.g.,* Azure AI Foundry) are rapidly evolving to support these agentic workflows, providing a unified platform to develop, orchestrate, and run them on managed model deployments and compute infrastructure.

Motivation. Despite this foundational infrastructure, deploying and operating complex agentic workflows at scale is fundamentally challenging. Today's systems follow an *imperative*, *siloed* paradigm where developers manually configure and compose a sequence of agents and tools (*e.g.,* using frameworks like LangGraph [46] or LlamaIndex [53]), while the cloud providers handle model deployments (with autoscaling) that treat LLM inference requests from the agents no different from standard LLM API calls (*e.g.,* ChatGPT). This approach suffers from a critical architectural limitation where optimization is performed in strict silos:

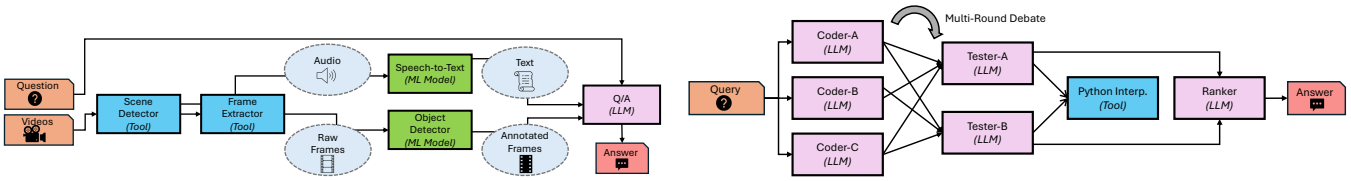
- *Workflow-level*: What specific agents to include and how to structure the workflow topology.
- *Agent-level*: Tuning specific parameters (*e.g.,* what model to use per-agent, or what frame sampling frequency to set for video analysis etc.).
- *Hardware-level*: Resource provisioning (*e.g.,* accelerator type and quantity, parallelism configuration etc.).

Since these layers are optimized independently, the system cannot reason about global, *end-to-end objectives* such as minimizing cost while meeting a per-query accuracy SLO or maximizing throughput under a latency constraint. Consequently, deployed workflows are rigid, often suffer from poor resource utilization, and require laborious manual reconfiguration across all layers to handle any necessary adaptation (*e.g.,* a sudden increase in traffic or a model update).

This inefficiency gap points to a missing architectural principle in current cloud platforms: unified, end-to-end orchestration that spans the agentic logic, the model serving layer, and the underlying infrastructure. We propose a paradigm shift, moving from the current siloed deployment to a *declarative*, *holistic* optimization approach, closing the gap for running agentic workflows in cloud platforms like Azure AI Foundry [8] or Google Vertex AI [19]. The core idea is to introduce a control plane that treats the entire agentic workflow: the sequence of LLM calls, tool executions, and data dependencies, as a single, optimizable computational graph running on a cloud platform's model deployments.

Our Work. We present Murakkab[1] [12], a resource-efficient system for serving multi-tenant agentic workflows, built on two principles: (1) declarative workflow specification and, (2) adaptive, SLO-aware runtime system design.

[1] An Urdu/Persian word (مُرَکَّب) meaning "compound" (referring in this context to agentic workflows composed of many pieces).



(a) Video Q/A workflow [87]: multi-modal with tools handling different modalities before feeding into an LLM for answering the query.

(b) Code generation workflow [25, 55]: text-only with an LLM Debate structure to write, test and execute code.

Figure 1: Two agentic workflows with different characteristics and components.

Murakkab lets developers focus on application logic–similar to serverless–while the runtime manages workflow orchestration, model selection, and resource provisioning to meet SLOs efficiently. This is critical in emerging environments where a single entity manages both models/agents and infrastructure. By unifying workflow configuration, model selection, and resource management, Murakkab achieves higher efficiency than today's fragmented systems, where layers operate in isolation.

Developers describe workflows with a declarative specification as *logical* tasks and dependencies, decoupled from model, tool, or hardware choices. This separation enables Murakkab to integrate workflow orchestration with resource management, dynamically reconfiguring workflow parameters (*e.g.,* models or tools) and hardware configurations as needed, based on offline profiles and online monitoring to optimize quality, latency, energy, and cost objectives.

This design enables Murakkab to efficiently explore the configuration space of workflow-, agent- and hardware-level knobs while meeting user-defined SLOs. Unlike existing deployments that treat agentic workflows as opaque, Murakkab leverages end-to-end visibility to coordinate scheduling, colocation, and multiplexing across multi-tenant workflows.

We evaluate Murakkab on representative workflows (video question answering, code generation and math problem solving) using production-scale traces. Murakkab achieves up to 2.8× lower GPU usage, 3.7× less energy, and 4.3× lower cost than LangGraph, a state-of-the-art agentic workflow orchestration, while preserving quality and latency SLOs.

Summary. This paper makes the following contributions:

- A declarative programming model and adaptive runtime unifying orchestration with resource management.
- Profile-guided optimization and workflow-aware scheduling for multi-tenant workloads.
- Evaluation showing significant efficiency gains without workflow quality or execution latency SLO violations.

2 Background and Motivation

2.1 Agentic Workflows

We define an ***agent*** as a composable unit that autonomously makes decisions, invokes tools, and participates in workflows, either independently or in collaboration with other agents [11, 20]. Each agent is typically powered by: (1) a *model* (*e.g.,* an LLM) for reasoning and language understanding, (2) a set of *instructions* specifying its goals, behavior, and constraints, and (3) *tools* for retrieving knowledge or taking actions. When multiple agents (each with specialized roles) interact and collaborate to achieve complex goals, we call the resulting process an ***agentic workflow***.

Serving agentic workflows differs fundamentally from single-model inference. Such workflows require coordinated interaction and data exchange among multiple agents to produce a final response. These agents often span diverse use cases, modalities (*e.g.,* text, audio, images etc.), execution times, and software/hardware requirements. Composing effective workflows, thus, demands a nuanced understanding of the trade-offs between task accuracy, request-serving latency, energy consumption, and hardware cost [43].

2.2 Example Workflows

We consider three widely used, representative workflows [66]: *Video Q/A*, *Code Generation*, and *Math Q/A* which exhibit distinct characteristics. For the rest of the paper, we focus on the first two, as shown in Figure 1, and include evaluation of the third one in Section A.1. A wide range of other workflows can be orchestrated using a similar approach.

Video Q/A. Video Q/A workflows are deployed for interactive query processing [74], security footage analysis [69], and many other use-cases [75, 80]. We construct a comprehensive agentic workflow to capture these diverse use-cases [2, 87]. This multi-modal workflow answers textual queries about input videos (Figure 1a). Several agents in this workflow collaborate to produce the final result:

1. *Scene Detector* to separate the input videos into distinct scenes that ensure better capture of key-frames and extract the audio clip corresponding to each scene.
2. *Frame Extractor* to sample frames from each scene.
3. *Speech-to-Text* for audio transcription.
4. *Object Detector* to annotate frames with objects of interest that are related to the query.
5. *Multi-modal LLM* (or LMM) to answer the user query given the processed frames and audio transcript.

The resulting agentic workflow can be modeled as a di-

rected acyclic graph (DAG), where nodes represent individual agents (*e.g.,* Speech-to-Text transcription) and edges capture data flow and execution dependencies among agents (*e.g.,* passing frames from Frame Extractor to Object Detector).

Code Generation. An important use case for agentic workflows is coding and software engineering [4, 28, 33, 58] or generating code on-the-fly for accomplishing tasks in a workflow [83]. We present a representative text-only workflow that translates natural language descriptions into executable Python code (Figure 1b). It adopts the *LLM Debate* framework [25, 55], where coder agents propose candidate solutions and tester agents generate tests and execute them using a Python interpreter. Each agent plays a unique role (*e.g.,* algorithm developer, unit tester) and may employ the same or different LLMs. The agents engage in iterative rounds of debate, aiming to reach consensus or terminating after a predefined number of rounds. The final output is selected as the highest-voted solution, determined by an LLM based on both the proposed candidates and the original query.

Dynamic Coding Pipeline. A complementary class of coding workflows [4, 28] constructs the execution workflow *dynamically* for each request, rather than relying on a fixed multi-agent structure. We build a representative pipeline inspired by production code assistants (*e.g.,* Claude Code [4]) that translates natural-language tasks into executable Python programs while adapting its execution structure to each request (problem prompt). The pipeline comprises three LLM roles: (1) a *writer* that generates candidate solutions, (2) an optional *reviewer* that critiques candidates using test outcomes, and (3) an optional *orchestrator* that selects the writer specialization and compute budget per problem. Writers can adopt specialized roles such as *algorithmic* or *I/O-oriented*, with reasoning efforts of *detailed* or *concise*, each emphasizing a different solution strategy tailed to the given problem prompt.

Each outer iteration launches a configurable number of parallel writer calls whose outputs are ranked against the problem's public tests, after which the top-performing candidate is selected. If all public tests pass and the reviewer is disabled, execution terminates early. Otherwise, failing test traces (and optionally reviewer feedback) are fed back as structured guidance for the next iteration. The reviewer may run on every iteration or only as a fallback when tests fail, while still preserving early termination.

Unlike the static code-generation workflow, the execution structure of this pipeline is determined on a per-request basis. In addition, each sub-workflow exposes configurable knobs such as number of review rounds, writer candidates, iteration budget, reviewer usage, and model assignment. Together, these decisions jointly define a large space of possible execution strategies, making the workflow a challenging testbed to navigate across heterogeneous operating points with diverse performance-cost tradeoffs.

```python
# == Workflow nodes (coupled app logic + configs) ==
scene_detection = Tool(
    fn=SceneDetector(),    # Implemented earlier by the
      developer.
    key=AWS_KEY, resources={"CPUs": 32}
)
frame_extractor = Tool(
    fn=FrameExtractor(),   # Implemented earlier by the
      developer.
    key=AWS_KEY, params={"num_frames": 15}, resources={"CPUs": 32}
)
speech_to_text = MLModel(
    name="Whisper", key=OPENAI_API_KEY, resources={"PTUs": 50}
)
object_detection = MLModel(
    name="CLIP", key=AZURE_KEY, resources={"CPUs": 128}
)
question_answer = LLM(
    name="Llama-3.2", key=DATABRICKS_API_KEY,
    params={"batch": 256}, resources={"GPUs": 8, "Type": "H100"},
    system_prompt="You are an agent that can understand videos.",
    user_prompt="Answer the given question about the video."
)
# == Query and data ==
ques    = "What is the name of the person wearing the red dress?"
videos  = ["road_trip.mp4"]
# == Workflow (ordering of nodes and data flow) ==
scenes, audio  = scene_detection(videos)
frames         = frame_extractor(scenes)
transcript     = speech_to_text(audio)
obj_frames     = object_detection(frames)
answer         = question_answer(ques, transcript, obj_frames)
```

Listing 1: Simplified video Q/A workflow definition. It shows tightly coupled application logic and execution details typical of existing frameworks.

2.3 Rigid and Imperative Definitions

Current state-of-the-practice for agentic workflow development are frameworks such as LangGraph [46], LangChain [45], LlamaIndex [53], AutoGen [6] and CrewAI [21]. They follow an ***imperative*** paradigm: developers define workflow components (*i.e.,* agents), their execution logic, interactions, and numerous ***configuration parameters***.

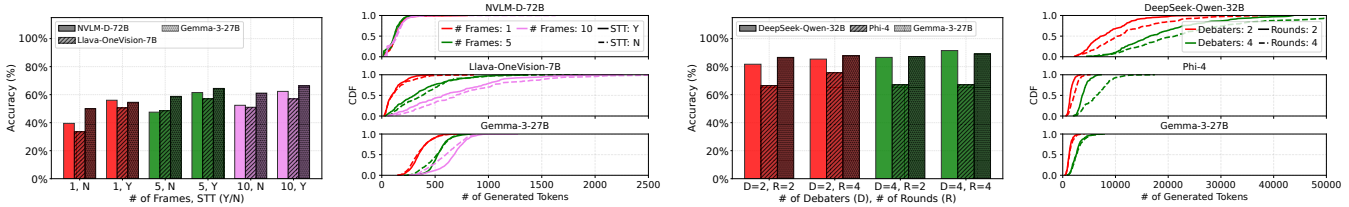
For example, in a video Q/A workflow (Listing 1), the developer specifies parameters for `FrameExtractor` (number of frames per scene), enables options like speech-to-text or object detection, and defines the ***execution mechanism***, or model, for each component (*e.g.,* `SceneDetector` in OpenCV, Whisper [65] for transcription, Llama-3.2 [36] for reasoning).

Developers must also make ***resource allocation*** decisions, such as assigning CPUs/GPUs for self-hosted or rented VMs, or choosing service tiers (*e.g.,* provisioned throughput units or PTU [10]) for managed services.

This tightly couples configuration choices with the workflow DAG, making deployed workflows *rigid*. Any change requires manual updates and redeployment across the stack.

2.4 Fragmented Stack and Goals

Agent developers create and deploy workflows that expose endpoints callable by end users. Entities involved in developing, using, and executing agentic workflow (*i.e.,* developers, end users, and providers) prioritize different goals. *Developers*



(a) Video Q/A accuracy. Varying frames, enable STT, and LMM.

(b) Video Q/A tokens generated by varying the knobs.

(c) Code Gen. accuracy. Varying debaters, rounds, and LLM.

(d) Code Gen. tokens generated by varying the knobs.

Figure 2: Workflow accuracy under different configurations and the token generation load on the respective models.

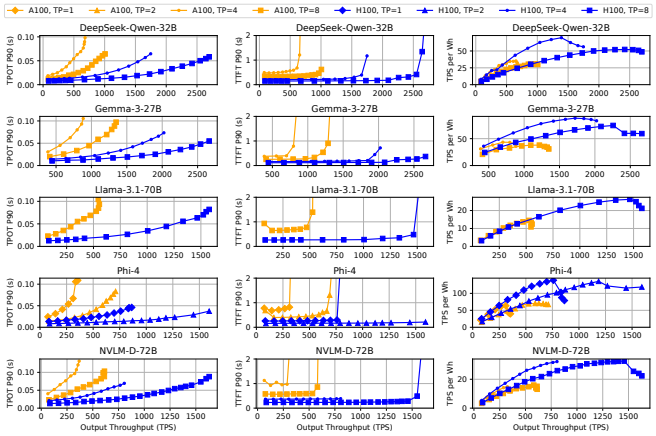


Figure 3: Model performance under different hardware and parallelism configurations.

value response quality, latency, or both. *End-users* additionally care about execution cost. *Providers* prioritize resource efficiency and cost. However, the decision-making burden for workflow configuration today largely falls on developers, who must navigate an overwhelming design space and deployment knobs without holistic system visibility. Ultimately, these decisions impact all involved entities in the agentic workflow life-cycle. These configurations include:

- ***Workflow-level configurations***: *e.g.,* whether to include a Speech-to-Text Transcript agent.
- ***Agent-level configurations***: *e.g.,* how many frames to extract in Frame Extractor, which LLM to use for Q/A.
- ***Hardware-level configurations***: *e.g.,* CPU *vs.* GPU and parallelism degree for each model.

2.5 Characterization and Motivation

Poor Resource Efficiency. Frameworks for agentic workflows (*e.g.,* LangGraph [46] and LlamaIndex [53]) place the burden of workflow configuration on developers. Most developers are neither systems nor ML experts, and cannot reason about accelerator choice, model parallelism, or model selection. Configurations are therefore often arbitrary and inefficient, leading to poor performance and high cost. Even experienced developers, lacking insight into user priorities, default to maximizing accuracy at the expense of efficiency.

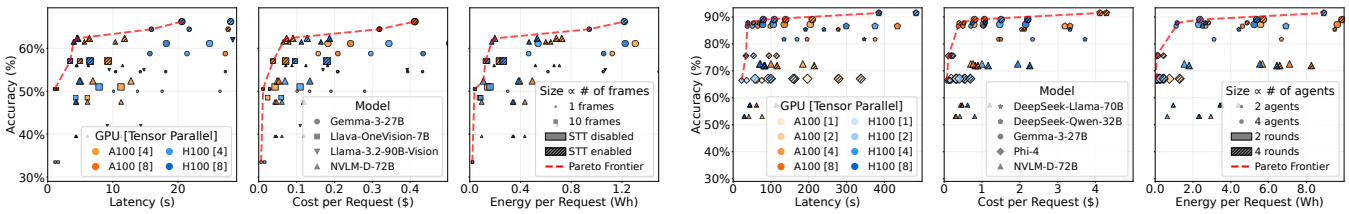
From the cloud provider's perspective, these workflows are opaque. The cloud platform has little visibility into workflow components (*e.g.,* models) or interactions (*e.g.,* task sequences and data flow). Tightly coupled application logic and execution details prevent the platform from reconfiguring workflows to improve resource efficiency while meeting SLOs on accuracy or latency. The result is resource underutilization, increased costs, and a larger energy footprint (often passed on to users through higher prices).

> **Insight 1:** *Cloud platforms lack visibility into workflow internals* (e.g., *tasks, requirements), preventing end-to-end optimization. Meanwhile, developers lack control or insight into system-level resource behavior.*

Multi-level Trade-offs. Configurations spanning across workflow level, agent level, and hardware layer introduce complex trade-offs over accuracy, latency, energy, and cost.

Workflow- and Agent-level knobs. Figure 2 shows a subset of configurations for the video Q/A and code generation workflows and their response accuracy. For video Q/A, Figure 2a shows that both workflow-level knobs (*e.g.,* whether to enable speech-to-text) and agent-level knobs (*e.g.,* number of frames extracted) significantly affect accuracy. Figure 2b shows the tokens generated for each configuration. Higher token generation is associated with higher latency, cost, and GPU load. For example, using Gemma-3-27B [81] with 10 frames and STT enabled achieves the highest video Q/A accuracy (66.2%) but also generates the most tokens compared to other configurations of the same model. Token counts vary widely across requests, from 250 to nearly 1000, often with a heavy tail.

For the code generation workflow, accuracy is sensitive to the number of debaters and rounds in LLM Debate (Figure 2c). Some configurations, such as DeepSeek-Qwen-32B [24] (a reasoning model), achieve the highest accuracy but at a much higher token generation cost (Figure 2d). At the median, it generates ≈20,000 tokens versus ≈2,500 for Gemma-3-27B under the same workflow configuration. Yet token counts alone do not capture the full end-to-end workflow characteristics, such as latency, cost, or energy.



(a) Video Q/A workflow.

(b) Code generation workflow.

Figure 4: Large space of workflow configurations along a subset of knobs and metrics.

Hardware-level knobs. Different models in a workflow have varying compute/memory requirements. Their interaction with the hardware determines whether a workflow can meet user SLOs while satisfying cloud platform constraints, like the number of GPUs allocated. Figure 3 shows models running on different hardware configurations (*e.g.,* GPU types and parallelism). We evaluate time to first token (TTFT) and time per output token (TPOT) under varying load, and measure energy efficiency as throughput (in tokens per second or TPS) per Wh. The results reveal a rich trade-off space, where configurations offer different balances of throughput, latency, and energy efficiency.

Insight 2: *Configuration knobs introduce fundamental trade-offs: workflow- and agent-level knobs affect accuracy* vs. *latency/cost, while additionally, hardware-level knobs drive cost* vs. *performance trade-offs, making it challenging to optimize workflows across multiple objectives.*

High-Dimensional Configuration Space. The configuration space for the end-to-end agentic workflow can grow exponentially with the configuration choices of the individual agents that make up the workflow. Figures 4a and 4b show that even modest agentic workflows like video Q/A or code generation, with only a small set of knobs, produce explosive configuration spaces to choose from. Each point in these Pareto frontiers represents a valid end-to-end configuration derived from varying model selection, hardware accelerator assignments, and resource scaling (with model parallelism) strategies. Navigating this configuration space manually is infeasible given that: (1) objectives vary across users (*e.g.,* low-latency *vs.* low-cost *vs.* high accuracy), (2) the optimal configuration depends on dynamic runtime context (*e.g.,* user traffic, model availability, cloud resource availability), and (3) model and hardware choices are rapidly evolving.

Insight 3: *Configuration complexity of each workflow grows combinatorially with the number of agents and their parameters at each level: ($O(\#WorkflowKnobs \times \#AgentKnobs \times \#HardwareKnobs)$).*

3 Murakkab Design

In light of this characterization, we propose Murakkab [12], a system that: (1) has visibility into workflow requirements, (2) holistically controls the entire workflow development and execution stack, and (3) enables automated configuration.

Instead of rigid, imperative workflows hand-tuned by developers, Murakkab supports *declarative* specifications that *decouple* high-level intent from low-level configuration. Developers focus on application logic, while the system *dynamically configures* workflows to adapt to evolving runtime conditions. *Developers* define workflow structure and task dependencies, *end-users* specify SLOs (*e.g.,* quality, latency, cost), and the *platform* dynamically optimizes execution for resource efficiency (*e.g.,* energy, cost) in a multi-tenant environment. Thus, workflows can automatically adapt to new models, varying load, or changing resources (without code rewrites or redeployments).

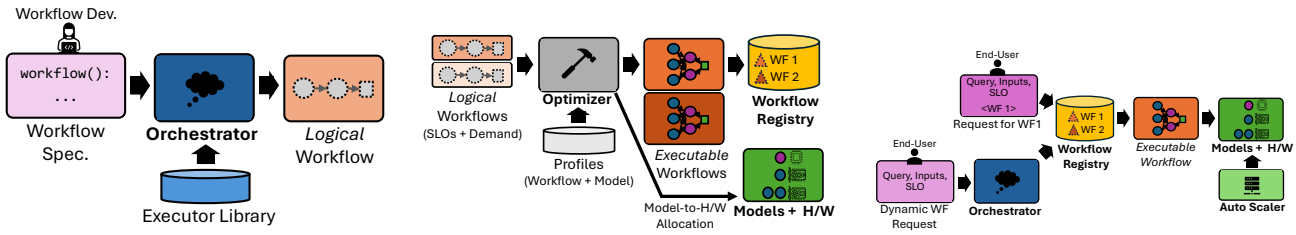
3.1 Workflow Life-Cycle

Murakkab cohesively manages the end-to-end life-cycle, unlike existing systems that fragment these among different entities. There are three main phases in an agentic workflow's life-cycle, as shown in Figure 5: (1) Workflow Development (Figure 5a), (2) Workflow Optimization (Figure 5b), and (3) Workflow Execution (Figure 5c). We summarize these in Table 1 and cover each of them in more detail below.

3.2 Development

Murakkab adopts a declarative paradigm for workflow specification that decouples *application logic* from low-level *execution details*. Workflow developers may specify high-level tasks, and optionally, the data flow between them, without the need to provide any workflow configurations (*e.g.,* resource allocation or model selection details).

Executor Library. Murakkab is designed to interoperate with existing model and tool ecosystems. It supports LLMs and traditional machine learning (ML) models from repositories such as Hugging Face [26], as well as tools from open-source libraries and platforms, including OpenAI Agents SDK [67], Google Vertex AI Agent Garden [34], NVIDIA NeMo Agent Toolkits [61], and Microsoft Azure AI Foundry Tools [9]. In Murakkab, an *executor* is a functional unit within a workflow



(a) Development phase. (b) Optimization and deployment phase. (c) Execution phase.

Figure 5: Murakkab manages end-to-end workflow life-cycle: from development to optimized deployment and execution.

Decision	Frequency	Scope	Notes
Phase 1: Workflow Development (Orchestrator)			
Workflow DAG structure	Once at onboarding	Workflow	Per-query for dynamic requests
Executor assignment per DAG node	Once at onboarding	Workflow	Refined per SLO tier by optimizer
Phase 2: Workflow Optimization (Optimizer)			
Final model/tool per executor	Per epoch	(Workflow, SLO)	
GPU type and parallelism	Per epoch	(Workflow, SLO)	Implicit via model-profile choice
Workflow-level knobs	Per epoch	(Workflow, SLO)	
Per-model instance count (n_m)	Per epoch	Model	Sized for projected peak load
Phase 3: Workflow Execution			
Reactive scale-out / scale-in	Continuous	Model	Auto-Scaler
Batch composition	Continuous	Instance	
Per-request routing and dispatch	Per request	Request	

Table 1: Decisions made by Murakkab across the workflow life-cycle.

```
# == Sub-tasks in the workflow ==
scene_detect   = "Given a list of videos, identify scenes in each."
frame_extract  = "Given a list of scenes, extract frames."
stt            = "Given a list of scenes, convert audio to text."
q_a            = "Answer the query given some context."
# == Workflow description (sub-tasks and data flow) ==
def workflow(query, videos):
    scenes      = scene_detect(videos)
    frames      = frame_extract(scenes)
    transcript  = stt(scenes)
    answer      = q_a(query, [frames, transcript])
    return answer
# == Execution with example request ==
query   = "What is the name of the person wearing the red dress?"
videos  = ["road_trip.mp4"]
result  = run(workflow(query, videos), slo=LOW_LATENCY)
```

Listing 2: Murakkab's declarative workflow specification of the video Q/A abstracts away configuration details, letting developers focus on application logic.

that can take one of three forms:

1. ***LLM***: specialized LLM configurations (fine-tuning, few-shot learning, or even just domain-specific prompting);
2. ***Structured compositions***: aggregations of models, *e.g.,* a self-reflection [73] or an LLM-Debate pattern [55] built from multiple LLMs;
3. ***Tool***: utility modules for AI workflows to take actions with (*e.g.,* OpenCV frame extractor for video processing, web-search, file-search, computer-use, or any third-party tools that follow the MCP specification [70]). Traditional ML models are also included as tools (*e.g.,* CNN-based image classifiers or Word2Vec sentiment analyzers).

Attributes. Each model or tool in the library exposes three attributes: (1) a textual description, (2) an interface specification, and (3) a key-value list of configurable parameters. For example, the frame extraction tool exposes the knobs: `F` (number of frames to extract) and `cores` (number of CPU cores to run on). The LLM Debate composition exposes the knobs: `D` (number of debaters), `R` (number of rounds), and `model` (which LLM to use). The *orchestrator* uses these descriptions and interfaces to rank and assign executors (models or tools) for workflow tasks, deferring parameter configuration to a later optimization phase (Section 3.3).

A key design choice in Murakkab is mapping a broad range of unknown tasks to executors that are built from a finite, known set of models and tools in the library. If none is found, Murakkab prompts the developer to onboard a suitable one.

Workflow Specification. We allow tasks to be expressed in *natural language* with varying levels of control over how the task may be executed, in contrast to imperative paradigms dis-

cussed earlier. Recent agentic-workflow development frameworks (*e.g.,* DSPy [77]) are moving in this direction. Murakkab takes this a step further and completely decouples configuration details from the workflow specification.

Declarative Specification. Developers can manually decompose tasks into sub-tasks and define data flow between them, providing precise control over workflow steps. Listing 2 shows the developer specifies sub-tasks (*e.g.,* scene detection, speech-to-text transcription, frame extraction) and their dependencies, ensuring sequential execution to achieve the desired outcome, such as answering a question about a video. Configuration details (*e.g.,* which LLM to use, number of frames to extract, resource allocation) are omitted from the specification. However, Murakkab does not restrict developers from specifying any execution preferences (*e.g.,* particular LLM choice or hardware constraint), which are then incorporated into the optimization process as constraints.

Interface. Once deployed, workflows are exposed to end users via dedicated REST endpoints. Each request may include an SLO, such as accuracy, latency, or cost tier. Murakkab uses these SLOs to configure workflows per request and optimize resource efficiency across tasks.

Workflow Orchestrator. The *workflow orchestrator* transforms a *declarative workflow* specification into a *logical workflow*. It interprets the specification, parses tasks and sub-tasks, and maps each to an appropriate executor from Murakkab's library. At the core is an LLM with tool-calling capabilities [71], which receives a list of available executors and their interfaces, along with task descriptions, and selects the best executor for each sub-task. Recent work [48, 59, 86] has focused on automating the discovery and refinement of effective agentic workflows to maximize task performance and minimize human intervention, which Murakkab can benefit from. A feedback loop allows developers to inspect and refine the generated specification, supporting hybrid workflows with both manual and system-generated tasks.

Logical Workflow. This abstract execution plan captures the functional intent of each task without binding to specific models, resources, or hardware. It is represented as a directed acyclic graph (DAG), where nodes are executors and edges denote data flow. This representation remains request-agnostic, containing no per-request details such as query text, input payloads, or SLOs. Execution specifics (*e.g.,* model selection or hardware allocation) are deferred to later stages.

The orchestrator performs type-checking on the DAG to ensure output types from source nodes match input types of destination nodes. In case of mismatches, the workflow is regenerated with error feedback to the LLM. Persistent errors prompt the developer to revise the specification.

3.3 Optimization and Deployment

Profiles. Accurate, fine-grained performance characterization is essential for optimizing multi-tenant agentic workflows with dynamic execution patterns. Inspired by Profile-Guided Optimization (PGO) [60, 84], Murakkab builds offline profiles across diverse configurations to inform runtime decisions. Each profile captures three key metrics per workflow configuration: response quality, end-to-end latency, and resource usage. To support this, Murakkab maintains two profiling layers: workflow profiles and model profiles.

Workflow Profiles. Murakkab profiles representative agentic workflows (*e.g.,* video Q/A) under different workflow-level knobs (*e.g.,* enabling/disabling STT) and executor-level knobs (*e.g.,* varying the number of frames extracted by the extractor tool). *Quality* is assessed using open-source benchmarks and datasets (*e.g.,* VideoMME [30], HumanEval [15], and Math [39]) with ground-truth results. When public datasets fall short, Murakkab can onboard curated evaluation datasets from developers or collect request-response pairs and user feedback (*e.g.,* rating, approvals), similar to deployed systems like ChatGPT [64]. These inputs are periodically incorporated into profile updates to refine configuration choices for active workflows. Recent studies of production agents show that many deployed workflows are largely static [68], making targeted profiling practical and amortizing the profiling cost across many subsequent invocations for the same workflow.

Configuration choices also affect per-request resource demands. Workflow profiles quantify executor-level load, including prompt and completion tokens for LLM-based executors, serving as a proxy for resource usage. These profiles capture metrics similar to those in our earlier characterization (*e.g.,* Figures 2a and 2b).

Model Profiles. To assess workflow resource demands, executor-level load must be mapped to model and hardware metrics. Murakkab maintains profiles for each model, capturing performance across software configurations (*e.g.,* tensor parallelism, prefill/decode separation) and hardware setups (*e.g.,* GPU type, clock frequency). Each profile reports: (1) latency (TTFT and TPOT for LLMs), (2) energy consumption across hardware, and (3) cost per configuration. Profiles span load levels to expose trade-offs and guide the optimizer in allocating load and instances.

Profiling is lightweight; performed once per configuration and reused across workflows. New models and accelerators are profiled upon integration. Decoupling workflow and model profiles enables workflows to benefit immediately from model updates, with selective re-profiling as needed.

This separation enables independent evolution, profile reuse, rapid model onboarding, and efficient hardware adaptation. The optimizer uses profiles as structured priors to evaluate cost–accuracy–latency trade-offs and drive reconfiguration under dynamic conditions.

Workflow Optimizer. The optimizer transforms the *logical workflow* from the orchestrator into an *executable workflow* by jointly selecting workflow knobs, models and tools per executor, and hardware and parallelism strategies. It com-

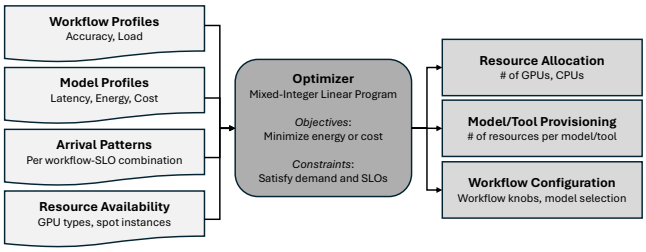


Figure 6: Summary of Murakkab's optimization process.

bines workflow profiles (task accuracy and executor-level load) with model profiles (latency, energy, and cost under varying load) to evaluate candidate configurations, and chooses those that meet per-request SLOs while maximizing efficiency. Beyond individual workflows, the optimizer uses global visibility across all active (workflow, SLO)-pairs to colocate and multiplex executors during each *optimization epoch*, balancing peak and average load. Figure 6 summarizes the inputs, process, and outputs.

3.3.1 MILP Formulation

We formulate the optimizer as a Mixed-Integer Linear Program (MILP). The complete formulation is presented in Section A.5; here we highlight the key components.

Inputs. The MILP takes four classes of inputs:

1. Workflow profiles for each registered logical workflow, capturing per-configuration accuracy and the distribution of executor-level load (e.g., prompt and completion token counts per LLM call) under each setting of the workflow-level knobs.

2. Model profiles for each candidate (model, hardware, parallelism) tuple, reporting throughput, TTFT and TPOT under varying load, energy per token, and dollar cost per GPU-hour.

3. Arrival patterns giving projected request rates for each (workflow, SLO)-pair over the next epoch, derived from recent trends (Section 3.4).

4. Resource constraints specifying the budget of available GPUs by type (including spot capacity), and any per-tenant cost ceilings.

Decisions. For each optimization epoch, the MILP jointly decides the following, which together form the deployment plan written to the workflow registry:

1. Workflow configuration: the workflow-level knob settings (*e.g.,* number of frames, STT on/off, debaters and rounds) for each (workflow, SLO)-pair, considering only those feasible under the accuracy and latency SLO.

2. Model/tool provisioning: the chosen model or tool for each executor in each selected workflow configuration.

3. Resource allocation: the number of instances n_m to launch for each selected model profile m. A profile encodes a specific model, GPU type, and parallelism strategy, so choosing m implicitly fixes the hardware and parallelism degree.

4. Routing map: the fraction of load from each (workflow, SLO)-pair routed to each provisioned instance, encoding cross-workflow multiplexing.

Constraints. The constraints enforce:

1. SLO feasibility: only configurations whose profiled accuracy and latency meet the SLO tier are eligible.

2. Demand satisfaction: the aggregate routed load to each instance must serve the projected peak demand of the workflows assigned to it, leaving headroom for short-term variance that the auto-scaler absorbs (Section 3.4).

3. Capacity: per-instance load stays within the throughput envelope at which the profile satisfies the latency SLO.

4. Resource budget: total GPU usage across all provisioned instances respects the available pool per GPU type.

Objective. The optimizer supports three interchangeable objectives: (a) minimize total energy, (b) minimize total dollar cost, or (c) maximize aggregate accuracy subject to a cost budget. A key design choice is to *decouple peak provisioning from average utilization*: instance counts n_m are sized for projected peak demand (ensuring SLO compliance), while routing fractions are optimized against average demand (driving cost and energy efficiency through colocation).

External and proprietary models. Workflows that call proprietary hosted models (*e.g.,* GPT-4o, Claude) fit the same formulation: such models appear as additional *profiles* with fixed per-token cost and latency, no GPU requirement, and provider-imposed rate limits encoded as capacity constraints. The MILP then naturally trades off self-hosted versus external execution under the same objective.

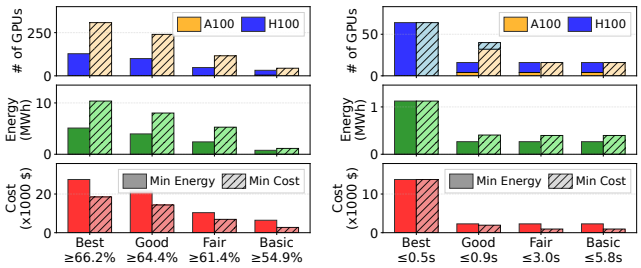
The deployment plan does *not* prescribe per-request dispatch, which remains a runtime responsibility (Section 3.4). Once an executable workflow is generated for all valid SLO tiers of an onboarded workflow, it is added to the Murakkab workflow registry and is ready to serve requests.

3.4 Execution

At runtime, Murakkab receives incoming requests from end-users with a payload that contains the identifier of the agentic workflow being invoked, any input query/data, and the SLOs. Murakkab looks up the registry to obtain the corresponding executable workflow and submits it for execution.

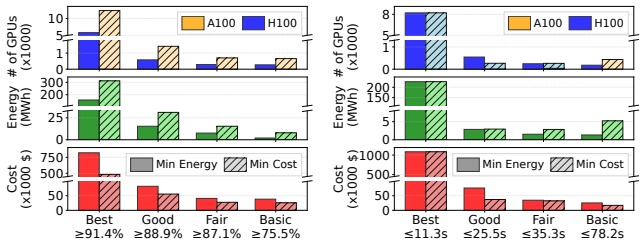
Dynamic Workflow Requests. End-users can either invoke a *particular* agentic workflow or send a request with a natural language query (Figure 5c), any input data to operate on, and SLOs, *without* specifying an agentic workflow to use. The workflow orchestrator parses the query into one or more subtasks, mapping each to an appropriate executor or an existing workflow. Thus, Murakkab dynamically composes workflows from existing building blocks available to it.

SLOs. Each request has the option to specify a quality, latency and cost SLOs. We assign four SLO tiers for quality and



(a) Accuracy SLOs. (b) Latency SLOs.

Figure 7: Video Q/A workflow configured for different SLOs and optimization objectives.



(a) Accuracy SLOs. (b) Latency SLOs.

Figure 8: Code generation workflow configured for different SLOs and optimization objectives.

end-to-end latency: *best*, *good*, *fair*, and *basic*. The SLO tiers correspond to the best, 95^{th}, 80^{th}, and 50^{th} percentile values of accuracy and latency available among the set of all workflow, model, and hardware configurations.

Runtime Optimization. While request dispatch is deterministic given the selected workflow, achieving efficient execution under dynamic, multi-tenant conditions requires continuous adaptation. The optimizer runs in the background after every optimization epoch, in our case every 60 minutes, to adapt to the most up-to-date load and resource availability in the system. The state of the previous epochs is used to project the load for each workflow in the next epoch. Using this information, the optimizer reconfigures the workflows and updates their executable workflows in the registry.

Auto-Scaler. Predicting end-to-end resource usage in agentic workflows is difficult, as input-dependent control flow and intermediate outputs propagating along data flows determine actual demand (*e.g.,* Figures 2b and 2d). For example, a video Q/A workflow with 10 frames and STT on Llava-OneVision-7B [47] produces 600 and 1200 tokens in the 50^{th} and 99^{th} percentile, respectively, highlighting high variance.

To handle such variability, Murakkab includes an *auto-scaler* that monitors per-model instance load over short windows (seconds to minutes) and rapidly scales out when needed. The optimizer can be configured to be conservative (*i.e.,* consider the tail percentile and provision more resources) or optimistic (*i.e.,* consider a more common case and let the auto-scaler handle variations in the short-term).

We set thresholds for auto-scaling based on the performance-throughput characteristic in executor profiles. This mechanism prioritizes avoiding SLO violations over short-term allocation optimality. Murakkab also maintains spare resources to absorb demand spikes and, when it detects significant deviations in workload or resource usage, triggers early re-optimization to adapt quickly.

4 Evaluation

4.1 Experimental Setup

Hardware. We run our experiments on A100 and H100 VMs from Microsoft Azure. Each A100 VM has 8×NVIDIA A100 (80GB) GPUs and an AMD EPYC 7V12 64-Core processor, while each H100 VM has 8×NVIDIA H100 (80GB) GPUs with an Intel Xeon (Sapphire Rapids) processor. We use vLLM (v0.9) [44] as the LLM inference engine, speaches-ai (v0.7) [76] as the speech-to-text model serving engine, and OmDet [89] for object detection model serving.

Production Traces. Since no publicly available traces exist for production agentic workflow serving, we approximate workload arrivals using LLM serving traces collected over a 24-hour period in May 2024 from Azure's LLM inference service for *chat* and *coding* applications [78] (Section A.4).

Agentic Workflows. Our evaluation focuses on the video Q/A and code generation workflows. We map the *chat* requests from the trace to the *video Q/A* workflow and *coding* requests to the *code generation* workflow.

Policies. We consider multiple scheduling policies:

1. *LangGraph* [46] (LG) is a hand-crafted baseline that balances cost and accuracy for both workflows, using Gemma-3-27B and A100 GPUs. However, it lacks visibility into the workflows and has a disconnect between orchestration and resource management, resulting in lack of adaptability to shifting demand.
2. *LangGraph Auto-Scaling* (LG + Auto) is a custom resource auto-scaling policy for LangGraph (since it does not support a default auto-scaling mechanism). This is the same auto-scaling policy used by Murakkab for a fair comparison.
3. *Murakkab Optimized* (Mkb Opt) optimizes each workflow–SLO combination for a specific objective (either minimizing energy or cost).
4. *Murakkab Optimized + Multiplexing* (Mkb Opt+Mult) *jointly* optimizes requests across all workflow–SLO combinations to maximize colocation and sharing of model instances for even better efficiency.

We assume the 90^{th} percentile token generation load from our profiles when making resource allocation decisions for all policies for a fair comparison. When evaluating Murakkab over the production traces, we set the optimization epoch to 60 minutes, and also conduct a sensitivity analysis for this choice in Section 4.7.

4.2 Single-Workflow Optimization

To understand how Murakkab optimizes a single workflow under varying request SLOs and optimization objectives, we run Murakkab with two optimization objectives: *minimize energy consumption* and *minimize execution cost*. We use the workload traces [78] for each workflow and assume that all requests have the same SLO for each experiment. We report the type and number of GPUs allocated, energy consumption in `MWh`, and the cost in `$`.

Accuracy SLOs. Figure 7a shows the requests across SLO accuracies. When minimizing energy, Murakkab lowers energy consumption from 5.1 MWh at 66.2% accuracy (*best*) to 3.9 MWh at 64.4% accuracy (*good*) – an energy reduction of 23.5% with negligible accuracy impact. Tolerating a drop to 61.4% (*fair*) yields substantial savings of 2.6 MWh from the peak consumption. On the other hand, when optimizing for cost, Murakkab reduces from \$18.5k to \$14.3k while marginally dropping accuracy between *best* to *good*. Allowing accuracy to drop further to 61.4% reduces expenses to \$6.9k, a $\approx 4\times$ decrease compared to the most expensive configuration. Murakkab prefers using H100 GPUs when minimizing energy, trading off cost for energy savings.

Figure 8a shows results for the code generation workflow. Energy use ranges from 312 MWh to 2 MWh, and cost from \$820k to \$25k, across varying accuracy levels. Relaxing the accuracy SLO from *best* to *good* yields a sharp drop in energy ($\approx 10.5\times$) and cost ($\approx 8.7\times$), mainly due to Murakkab switching from DeepSeek-Qwen-32B to Gemma-3-27B, which has lower token and operation costs.

Latency SLOs. Murakkab serves latency-sensitive requests with varying SLO tiers, while minimizing energy or cost. A similar pattern in resource and cost savings emerges for both workflows as shown in Figures 7b and 8b. We guarantee a basic accuracy tier even for latency SLO requests (*e.g.,* 50% for video Q/A). For example, Murakkab can reduce energy consumption from 1.1 MWh to 266 kWh at a slight increase in end-to-end latency, from 0.5 s to 0.9 s for the video Q/A workflow. On the other hand, it can reduce energy consumption from 227 MWh to 2.8 MWh (as a result of changing to a different model with different tensor parallelism).

We detail the most common workflow configurations chosen by Murakkab's optimizer for each of the experiments over the entire arrival trace in Sections A.2 and A.3 (Tables 5 and 6). We observe similar trends for the Math Q/A workflow and report the results in Section A.1 (Figures 17a and 17b).

Policy	# of GPUs	Energy (MWh)	Cost ($\times$1000 \$)
LangGraph	2568	82.1	211.7
LangGraph+Auto	2472	80.6	112.3
Murakkab Opt	1164	27.7	57.2
Murakkab Opt+Mult	912	22.1	47.2

Table 2: Comparison of resource usage, energy, and cost. Murakkab substantially reduces GPUs, energy, and cost compared to LangGraph, with further gains from multiplexing across all video Q/A and code generation workflow requests.

4.3 Multi-Workflow Optimization

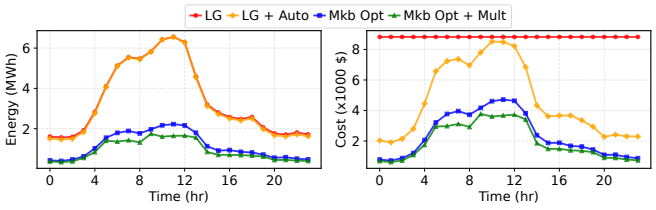
We measure the improvements in efficiency as a result of joint optimization and multiplexing across different workflow–SLO combinations. For this experiment, we run video Q/A and code generation requests together and assign 70% requests to be high-accuracy and 30% requests to low-latency, both with *good tier* (Section 3.4).

Figure 9a shows LangGraph has a fixed allocation with a fixed cost. Its energy consumption varies depending on resource usage, but is significantly higher than the other configurations due to higher idle-power consumption of its GPUs. Table 2 summarizes the results for the 24 hour trace. This configuration uses ≈2,568 A100 GPUs, leading to a flat hourly cost. With auto-scaling, LangGraph reduces idle power consumption and achieves approximately $1.8\times$ cost savings compared to vanilla LangGraph. A non-hand-crafted baseline could be *significantly* more inefficient than our current baseline from requiring bigger models and more resources or result in more SLO violations if under-provisioned.

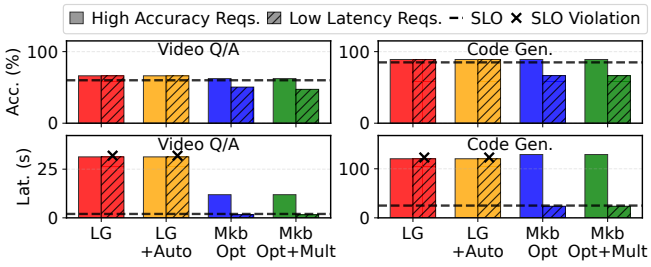
Mkb Opt. This policy optimizes each workflow–SLO combination to minimize cost, although *without* considering the demand across other combinations running in the system. It can adapt to changing load (leveraging the difference between peak and average utilization) to change model and resource allocation over time. It requires 1,164 A100 GPUs, 27.7 MWh energy, and \$57,224 cost.

Mkb Opt+Mult. This policy additionally leverages its *holistic* view of all workflows and their demand to maximize multiplexing opportunities. It requires 912 A100 GPUs (21.6% reduction), 22.1 MWh energy (20.2% reduction), and \$47,238 cost (17.4% reduction) respectively.

Accuracy and Latency. LangGraph cannot distinguish between per-request SLO variations to configure workflows appropriately. Therefore, high-accuracy and low-latency SLO requests have the same accuracy and latency, resulting in latency SLO violations, as shown in Figure 9b. Murakkab leverages per-request SLO information to provision enough resources for each request, as can be seen in the difference in accuracy and latency of the two categories of requests, allowing for higher resource-efficiency.



(a) Energy and cost over time. LangGraph is agnostic to load shifts, LangGraph with auto-scaling simply scales the same models and resources, while Murakkab completely reconfigures workflows to maximize resource-efficiency.



(b) Accuracy and latency for all requests. LangGraph does not distinguish between request SLO categories.

Figure 9: Comparing: (1) a hand-crafted LangGraph configuration (*LG*), (2) LangGraph with auto-scaling (*LG+Auto*), (3) Murakkab optimizing individual workflows (*Mkb Opt*), and (4) Murakkab jointly-optimizing across workflows + multiplexing resources (*Mkb Opt+Mult*).

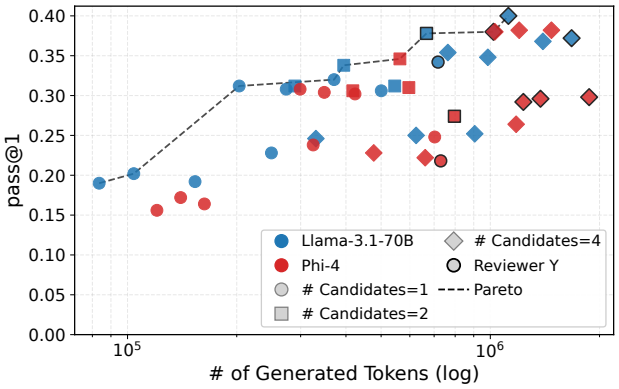


Figure 10: Cost–accuracy frontier of the dynamic coding pipeline on LiveCodeBench. Each point is a workflow configuration; color denotes the code-writer model, marker shape the number of parallel candidates, and a bold edge indicates that a review phase is included. The dashed line is the Pareto frontier across all configurations.

4.4 Dynamic Coding Pipeline

Dynamic coding agents (*e.g.,* Claude Code [4]) provide a challenging setting because execution paths are highly adaptive and cannot be captured by a static workflow graph. To understand how dynamic coding pipelines benefit from Murakkab, we focus on the *workflow-optimization* phase as the evaluation of the other dimensions like hardware allocation and auto-scaling have already been studied extensively in Sections 4.2 and 4.3. We evaluate the workflow on LiveCodeBench-v5 [40] and report pass@1 on hidden test cases that Murakkab has never observed.

The workflow exposes a rich configuration space spanning multiple dimensions: the model used for code writing and reviewing, the number of candidate solutions to generate in parallel, whether to include a code-review phase, and how the review interacts with the iteration loop. For each request, an orchestrator LLM selects an appropriate writer specialization based on the task being solved (*e.g.,* algorithmic or I/O processing etc.) and determines the level of effort to allocate (*e.g.,* detailed reasoning vs. concise). Execution is dynamic at runtime: requests may terminate after a single attempt if public tests pass, or continue through additional refinement iterations driven by reviewer feedback and test failures. Moreover, several workflow components are themselves hierarchical workflows with independent configuration choices, such as reviewer model selection and review iteration budgets.

Results. Figure 10 shows the resulting Pareto frontier across a representative subset of configurations. The frontier spans an order of magnitude in completion tokens and roughly 2× in pass@1, with neither writer model uniformly best: the smaller model anchors the cost-efficient regime while the larger model contributes the highest-accuracy points when paired with a specialized prompt or reviewer. The review phase itself is not universally helpful – it improves accuracy for some (model, task) combinations and degrades it for others – reinforcing that the right configuration is workload- and request-specific. Across all runs, a substantial fraction of requests terminate early on a public-test pass, while a smaller fraction exhaust the iteration cap, confirming that iteration budget is consumed adaptively rather than uniformly.

Implication. These results illustrate the challenge of deploying coding agents with a static configuration. A static deployment of the coding pipeline must commit to one configuration per workload class – and thereby either over-spend on easy problems or under-perform on hard ones. In contrast, Murakkab leverages the heterogeneous operating points exposed by the workflow frontier to select the most appropriate configuration for each request based on predicted difficulty and current system conditions. The hardware-allocation and auto-scaling benefits demonstrated in Sections 4.2 and 4.3 compose naturally with these workflow-level optimizations, enabling end-to-end efficiency improvements across both algorithmic and infrastructure dimensions.

Available A100s	Available H100s	Allocated A100s	Allocated H100s	Energy (MWh)	Cost (×1000 $)
2000	0	1292	0	24.7	55.7
2000	100	780	100	17.8	52.4
2000	200	536	200	14.5	60.3
2000	300	288	300	12.4	64.8
2000	400	50	400	11.1	70.6
2000	500	0	495	11.0	75.4

Table 3: Murakkab serving multiple workflows varying resource constraints minimizing energy. As more H100 GPUs are available, Murakkab trades off cost for energy (same SLO).

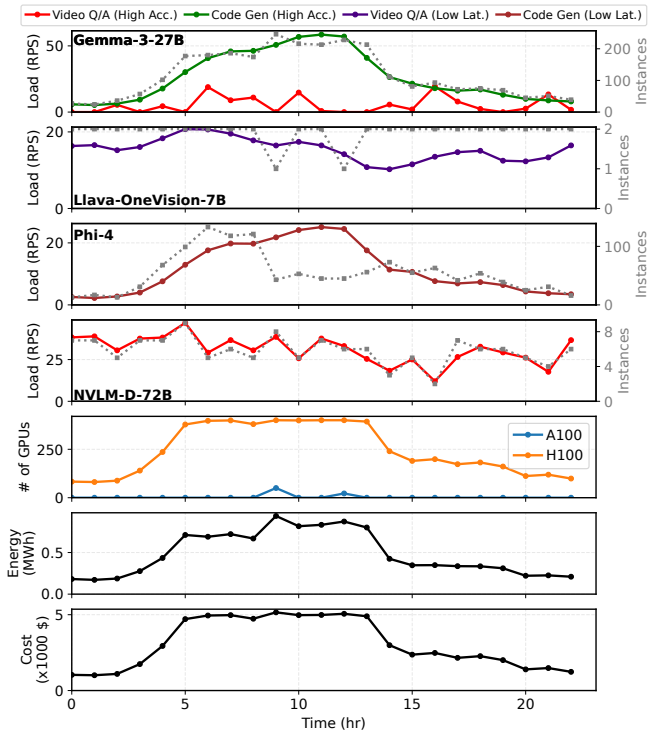

Figure 11: Murakkab adjusts resource allocation and model instances across all workflow-SLO combinations with changing load (under a constraint of 400×H100 GPUs.)

4.5 Adapting to Dynamic Resource Availability

To evaluate how Murakkab adapts to changes in resources (*e.g.,* spot-instances, cloud provider prioritizing resources for other services), we run the same arrival pattern and workflow-SLO distribution from Section 4.3. However, we constrain the type and amount of resources available to Murakkab. We then constrain the resources available to Murakkab: the cluster always provides 2,000 A100 GPUs, while the number of H100 GPUs varies from 0 to 500 in increments of 100. We configure Murakkab to minimize energy consumption while serving incoming workflow requests.

Table 3 shows that Murakkab leverages the H100 GPUs as they become available, while reducing the number of A100 GPUs. Starting with an allocation of 1292 A100 GPUs and no H100 GPUs, which consumes 24.7 MWh energy, Murakkab adapts to the changing H100 availability and leverage most of them (up to 495 H100s) to bring down the energy consumption to 11 MWh. This shows that Murakkab adjusts its resource allocation under resource-constrained settings to satisfy the SLOs while striving for higher resource efficiency.

Execution Analysis. Figure 11 shows Murakkab adapting to changes in load. We consider the *400×H100 GPUs* configuration (without loss of generality) and observe that:

1. Murakkab *scales model instances up/down* after every optimization epoch to adapt to the shift in load dynamics.
2. Murakkab *changes GPU allocation* with system load. It prefers H100 GPUs due to their energy efficiency and uses A100 GPUs for the rest, depending on load fluctuations (*e.g.,* at T=9 hours).
3. Murakkab *reconfigures workflows to maximize colocation*. For example, Gemma serves code generation requests with high-accuracy SLOs and multiplexes load from video Q/A requests with high-accuracy SLOs when there is surplus capacity (*e.g.,* from T=5–9 hours and T=15–19).

4.6 Workflow/DAG-Aware Scheduling

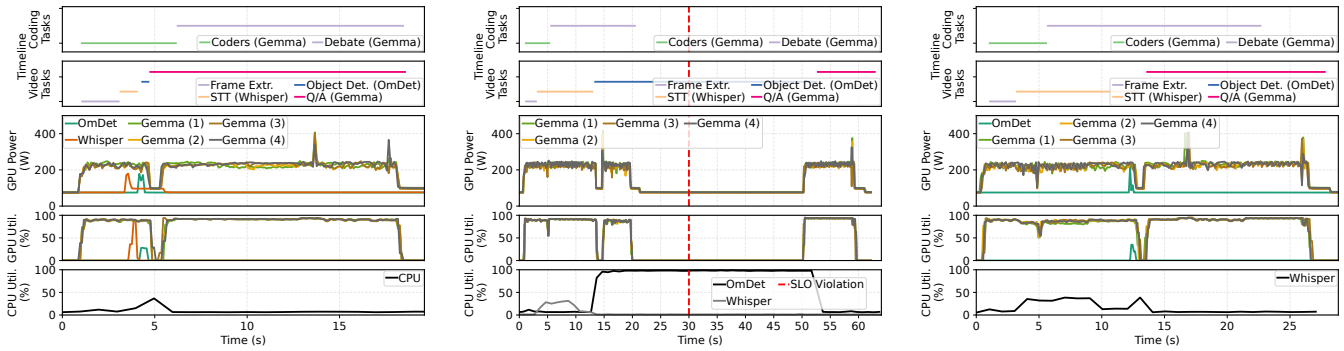
Consider the request: *verify the student's coding solution from a video*, with a *30-second latency SLO*. The orchestrator constructs a DAG with a fan-out for the two sub-tasks that can execute in parallel: (1) video Q/A (Figure 1a) to extract the student's solution, and (2) code generation (Figure 1b) to produce a reference solution for comparison.

Scheduling. Leveraging workflow and model profiles, Murakkab identifies viable scheduling options based on cluster resource availability (Figure 12). All configurations use Gemma-3-27B on 4×A100 GPUs. We highlight setups that leverage both GPUs and CPUs for improved efficiency.

OmDet and Whisper on GPUs. Figure 12a shows OmDet and Whisper running on dedicated A100 GPUs, with a total of 6×A100 GPUs. The two sub-tasks run in near-perfect parallel, with full overlap in execution. However, despite meeting the latency goal, dedicated GPUs are underutilized, and CPUs are mostly idle.

OmDet and Whisper on CPUs. Figure 12b shows Whisper and OmDet running on CPUs, reducing GPU usage to 4×A100 and utilizing idle CPU resources. Whisper runs efficiently without saturating CPUs, making it a good candidate for offloading. In contrast, OmDet fully loads all cores and significantly increases latency, resulting in an SLO violation.

OmDet on GPU, Whisper on CPU. Figure 12c shows OmDet running on 1×A100 GPU and Whisper on CPUs, with a total of 5×A100 GPUs provisioned. Both sub-tasks complete nearly simultaneously, and Whisper's added CPU latency has minimal impact on end-to-end time. This configuration meets the latency SLO while reducing GPU usage compared to the all-GPU setup.

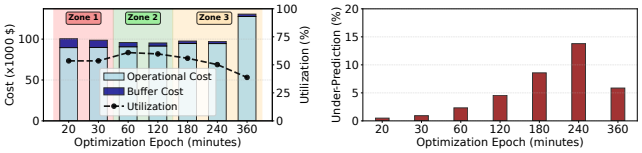


(a) OmDet on 1×A100, Whisper on 1×A100, Gemma on 4×A100s. End-to-end execution completes *within* latency SLO *(6 GPUs)*.

(b) OmDet on CPUs, Whisper on CPUs, Gemma on 4×A100s. End-to-end execution ***violates*** latency SLO *(4 GPUs)*.

(c) OmDet on 1×A100, Whisper on CPUs, Gemma on 4×A100s. End-to-end execution completes *within* latency SLO *(5 GPUs)*.

Figure 12: Executing a user request involving parallel video Q/A and code generation. Murakkab selects the configuration in Figure 12c to minimize energy use while meeting the 30-second latency SLO and maintaining response quality.



(a) Cost *vs.* resource utilization. (b) Demand under-prediction.

Figure 13: Murakkab sensitivity to optimization epoch.

Murakkab in Action. Leveraging workflow stage visibility and pre-generated execution profiles, Murakkab selects the configuration with OmDet on GPU and Whisper on CPU (Figure 12c) as the most resource-efficient option (balancing overall utilization and latency). In contrast, traditional systems treat agentic workflows as opaque, lacking coordination between orchestration and scheduling. This leads to inefficient execution, higher costs, and SLO violations.

4.7 Optimization Frequency Sensitivity Analysis

The choice of optimization epoch presents a fundamental trade-off between resource efficiency, cost, and system responsiveness. We evaluate intervals from 20 minutes to 6 hours, measuring cost, utilization, and worst-case dropped requests. Provisioning new instances (*i.e.,* VM allocation, software setup, and model transfer to GPUs) is assumed to take 20 minutes [31, 38, 62]. We use an exponentially weighted moving average (EWMA) [18], with $\alpha = 0.5$, to predict workload demand at every epoch.

Three-Zone Cost Structure. Figure 13a shows three distinct zones that guide optimal selection.

Zone 1 (10–60 minutes): Buffer-dominated. Frequent reoptimization induces high transition overhead. Excessive GPU provisioning during transitions leads to lower utilization, despite responsive demand adaptation. Frequent model and tool changes can also reduce KV cache efficiency for LLMs.

Zone 2 (60–180 minutes): Balanced. Transition costs and prediction uncertainty offset, yielding peak cost efficiency. Utilization peaks at an epoch of around 60 minutes, reflecting the best balance between adaptation frequency and stability.

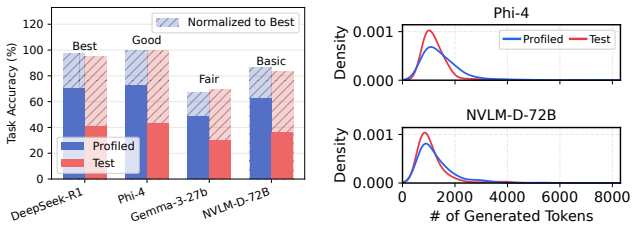
Zone 3 (180+ minutes): Uncertainty-dominated. At long intervals, buffer cost from transition overhead is minimal, but coarse-grained provisioning increasingly diverges from fine-grained, dynamic demand. This reduces prediction accuracy and drives over-provisioning, lowering efficiency.

Worst-case System Responsiveness. We measure responsiveness by demand under-prediction (requests that would be dropped without auto-scaling). This reflects the *worst-case*, as auto-scalers can mitigate mismatches post-provisioning. Figure 13b shows under-prediction is minimal at short intervals but rises steadily, peaking at ∼15% around 240 minutes. Beyond that, longer intervals lead to over-provisioning, lowering under-prediction but hurting utilization.

Operational Implications. This analysis reveals a key trade-off: short intervals improve responsiveness but increase transition costs, while long intervals reduce overhead but hurt prediction accuracy and utilization. Providers can tune this balance based on priorities (*e.g.,* cost, utilization, responsiveness). In our setup, a 60-minute interval offers a middle ground (high utilization, low cost, and manageable shortage risk). While we use EWMA for forecasting, the trade-off holds with more advanced predictors as well.

4.8 Workflow-Profiling Generality Analysis

A core component of Murakkab is its profile-guided optimization, which uses profiles of accuracy, token load, and other performance metrics to guide workflow configuration. To operate reliably across diverse agentic workflows, these profiles must generalize to inputs that were unseen during profiling.



(a) Accuracy and assigned SLOs. (b) PDF of generated tokens.

Figure 14: Murakkab's workflow-profiling generality on an unseen test benchmark.

To evaluate generality, we consider a multi-round mathematical problem solving workflow. Murakkab generates profiles from the Math-500 benchmark [27] (*Profiled*) and tests them on a different MathEval benchmark [32] (*Test*) which was not used during profiling. Figure 14a shows that the same trend in accuracy holds between the profiled and test benchmarks across different models. Therefore, Murakkab can reliably select model configurations based on a request's accuracy SLO requirements without having prior knowledge of the inputs. Figure 14b shows the probability density functions (PDF) of tokens generated by the workflow between the two benchmarks. The distributions closely match with a similar shape, spread and peak indicating that the profiled distribution generalizes well to the test set. Murakkab's optimizer can reliably predict the load demand for incoming requests and provision enough resources to meet the SLOs.

These results demonstrate that Murakkab's profiling captures transferable performance characteristics, enabling the optimizer to make informed decisions on previously unseen workloads (from a similar domain)—a key property for robust, cross-workflow optimization.

5 Related Work

Agentic Workflow Development. Frameworks like LangGraph [46], LangChain [45], and AutoGen [6] build agentic workflows *imperatively*, composing model and tool calls. DSPy [77] and Palimpzest [51, 52] take a *declarative* approach, focusing on prompt and query optimization. However, these frameworks still blur configuration and logic, burden developers with resource management, and struggle to scale efficiently across large configuration spaces.

Automated Workflow Generation and Planning. There has been extensive work from the ML community on automating workflow generation to improve response quality [48, 52, 54, 59, 85, 86]. This line of work is complementary to Murakkab, which can integrate these workflow generation techniques into the Murakkab workflow orchestrator (Section 3.2). Circinus [50] and Aragog [23] perform input-based workflow planning but do not consider resource heterogeneity, dynamism in resource availability and energy/power efficiency. Furthermore, they do not handle dynamism in per-query input/output sizes that may result in load-fluctuations, a common characteristic in LLM-based agentic workflows.

Systems Optimization. Prior systems have focused on accelerating workflow execution with improved data flow management [72, 79], device-aware workflow compilation [5] and scheduling of LLM inference calls in the context of agentic applications [49, 56]. Others target response quality by exploring model selection [14, 29] and scaling properties [13, 63] of test-time compute. Systems like SpotServe [57] and Loki [3] address resource and load dynamism, but remain confined to single-model serving. Some recent works [17, 42, 43] have examined the energy costs of test-time compute and their impact on response quality for individual models. In contrast, Murakkab introduces a fully automated system to navigate these complex tradeoffs for agentic workflows, considering load and resource dynamism in multi-tenant cloud settings.

6 Conclusion

Murakkab brings a declarative programming model and adaptive runtime to the serving of multi-tenant agentic workflows. By decoupling workflow logic from execution configurations and tightly integrating orchestration with cluster management, Murakkab enables dynamic reconfiguration and resource-aware scheduling while honoring diverse SLOs. Our evaluation shows that Murakkab substantially improves efficiency (reducing GPU usage, energy consumption, and cost) without compromising workflow quality or latency. We see opportunities in extending adaptive co-optimization across larger clusters, supporting more heterogeneous accelerators, and exploring workload specialization for emerging classes of agentic applications.

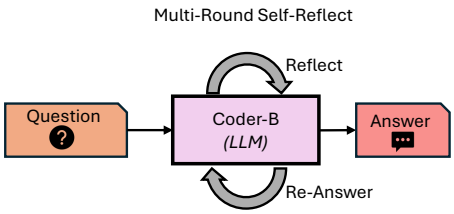

Figure 15: Math Q/A workflow with self-reflect [73] structure.

Policy	# of GPUs	Energy (MWh)	Cost (×1000 $)
Static	4448	169.87	367.2
Mkb Opt	1875	62.88	123.0
Mkb Opt+Mult	1660	52.66	104.6

Table 4: Comparison of resource usage, energy, and cost. Murakkab substantially reduces GPUs, energy, and cost compared to static allocation, with further gains from multiplexing across all math Q/A and code generation workflow requests.

A Appendix

A.1 Math Q/A

Math Q/A, as shown in Figure 15, is a workflow to answer mathematical problems. It uses a self-reflect [73] structure where a *mathematician* agent generates a response to the question, self-reflects on the response, and iteratively continues this until it is confident in the answer or a limit on the maximum number of rounds is reached.

A.1.1 Characterization

We present the results (Figure 16) for different models and different number of self-refine rounds (R) (Figure 16a) and the token generation load in terms of prompt (Figure 16c) and completion tokens (Figure 16b) for different configurations.

A.1.2 Single-Workflow Optimization

Similar to Section 4.2, we optimize the math Q/A workflow using Murakkab for different accuracy and latency SLO tiers and optimization objectives. The results are presented in Figure 17.

A.1.3 Multi-Workflow Optimization

Similar to Section 4.3, we evaluate end-to-end execution of running 24 hours of Azure traces [78]. This time, the two categories of requests from the traces map to two agentic workflows: *chat* requests maps to *math Q/A* workflow requests and *coding* requests map to the *code generation* workflow (Figure 1b). The results are shown in Figure 18. The handcrafted *static* baseline policy (similar to LangGraph [46]) has a fixed allocation of DeepSeek-Qwen-32B for the math Q/A workflow and Gemma-3-27B for code generation workflow – balancing quality and resource usage. As explained in Section 4, the static baseline has no visibility into the workflow, load or resource availability and suffers from underutilization. Murakkab on the other hand is adaptive to load for each workflow–SLO combination and appropriately configures workflows at each optimization epoch, resulting in massive resource savings. When allowed to multiplex across resources, it yields further savings by colocating the requests from all workflows onto shared model instances whenever appropriate. Table 4 summarizes the results for the 24 hour duration. We observe a reduction of $\approx 2.7\times$ in GPUs, $\approx 3.2\times$ in energy, and $\approx 3.5\times$ in cost from the static baseline to Murakkab's best optimization policy.

SLO	Objective	Tier	Model	STT	Frames	GPU	TP	TPOT (s)	TPS

Table 5: Video Configurations with GPU Details

A.2 Video

We present the most commonly chosen configuration by Murakkab for each workflow–SLO combination of the video Q/A workflow under different optimization objectives in Table 5 (corresponding to the experiment presented in Section 4.2). It shows various knobs (*e.g.,* model, number of frames, GPU type etc.) and the offered load per model instance in tokens-per-second (TPS) with the observed latency in time-per-output-token (TPOT) For example, we can observe the changing model and number of frames processed as the accuracy SLO is relaxed. For the latency SLO requests, Murakkab keeps the same workflow- and model-level knobs but changes GPU type and increases the allowed load per model instance to increase batching as the SLO is relaxed.

A.3 Code Generation

We present the most commonly chosen configuration by Murakkab for each workflow–SLO combination of the code generation workflow under different optimization objectives in Table 6 (corresponding to the experiment presented in Section 4.2). It shows various knobs (*e.g.,* model, number of debaters, number of debate rounds etc.) and the offered load per model instance in tokens-per-second (TPS) with the observed latency in time-per-output-token (TPOT) For example, we can observe the changing model and number of debaters as the accuracy SLO is relaxed. For the latency SLO requests, Murakkab mostly keeps the same workflow- and model-level knobs but changes GPU type and increases the allowed load

per model instance to increase batching as the SLO is relaxed. Notably, it also changes the tensor parallelism for the same model (Phi-4 [1]) between optimizing for cost and energy.

A.4 Azure Traces

We use a subset of LLM serving traces released by Azure [78] from 08:00 05/15/2024 to 08:00 05/16/2024 shown in Figure 19.

A.5 Optimization Formulation

We formulate our optimization problem (Section 3.3) as a temporal resource allocation task for serving multiple workflows with heterogeneous SLOs across diverse hardware and model profiles.

Sets and Indices.

- $\mathcal{W}$: workflows
- $\mathcal{S}$: SLO types
- $\mathcal{M}$: model profiles
- $\mathcal{C}_w$: workflow configurations for w
- $\mathcal{G}$: resource types

Parameters.

- $\lambda^{\text{peak}}_{w,s}$: Peak request rate for workflow w with SLO s
- $\lambda^{\text{avg}}_{w,s}$: Average request rate for workflow w with SLO s
- α: Unified buffer factor (default 1.15)
- $\tau_{w,s}$: SLO threshold for workflow w and SLO type s
- a_c: Accuracy of workflow configuration $c \in \mathcal{C}_w$
- t_c: Tokens per request for workflow configuration c
- θ_m: Token throughput (tokens/sec) for model profile m
- ℓ^{TTFT}_m: Time to first token for model profile m
- ℓ^{TPOT}_m: Time per output token for model profile m
- g_m: Parallelism for model m
- e_m: Energy consumption (kWh) for model profile m
- c_g: Cost per instance per second for resource type $g \in \mathcal{G}$
- B_g: Maximum available resource instances of type g

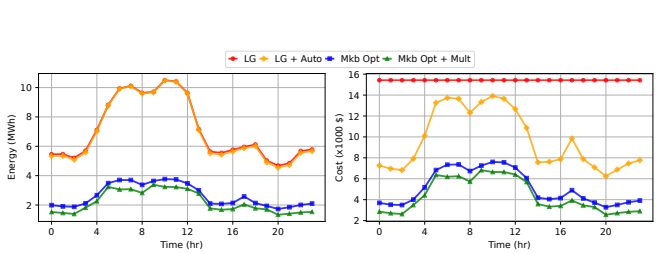
Decision Variables.

- $n_m \in \mathbb{Z}^+$: Number of instances of model profile m
- $x^{\text{peak}}_{w,s,c,m} \in \mathbb{R}^+$: Peak load allocation from (w,s,c) to model m
- $x^{\text{avg}}_{w,s,c,m} \in \mathbb{R}^+$: Average load allocation from (w,s,c) to model m

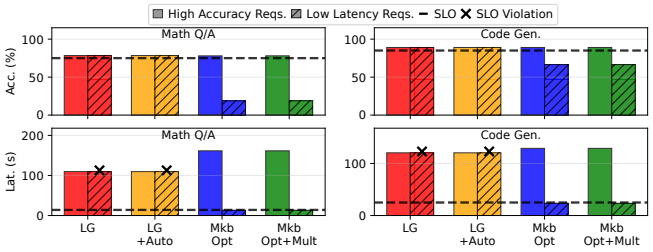
Constraints. Demand Satisfaction (Peak):

Ensure peak demand is met with buffer:

$$\lambda^{\text{peak}}_{w,s} \leq \sum_{c \in \mathcal{C}_w, m \in \mathcal{M}} x^{\text{peak}}_{w,s,c,m} \leq \alpha \cdot \lambda^{\text{peak}}_{w,s}, \quad \forall w \in \mathcal{W}, s \in \mathcal{S} \quad (1)$$



(a) Energy and cost over time. Static policy is agnostic to load shifts while Murakkab reconfigures workflows for higher resource-efficiency.



(b) Accuracy and latency for all requests. Static policy does not distinguish between request SLO categories.

Figure 18: Comparing a hand-crafted static configuration (only A100s) to: (1) Murakkab optimizing individual workflows, and (2) Murakkab jointly-optimizing across workflows + multiplexing resources (Math Q/A + Code Gen).

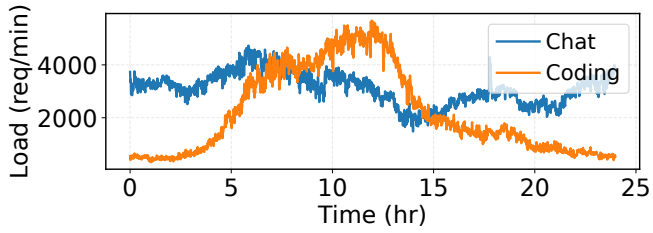


Figure 19: Azure LLM serving traces.

Demand Satisfaction (Average):
Similar bounds for average demand:

$$\lambda^{\text{avg}}_{w,s} \leq \sum_{c \in \mathcal{C}_w, m \in \mathcal{M}} x^{\text{avg}}_{w,s,c,m} \leq \alpha \cdot \lambda^{\text{avg}}_{w,s}, \quad \forall w \in \mathcal{W}, s \in \mathcal{S} \tag{2}$$

Capacity Constraint with Multiplexing:
Account for statistical multiplexing:

$$\mu_m \cdot \sum_{w,s,c} x^{\text{peak}}_{w,s,c,m} \cdot t_c \leq n_m \cdot \theta_m, \quad \forall m \in \mathcal{M} \tag{3}$$

where μ_m is the model-specific multiplexing factor.

SLO Filtering:
For accuracy SLO ($s = \text{max_accuracy}$):

$$x^{\text{peak}}_{w,s,c,m} = 0 \quad \text{if } a_c < \tau_{w,s} \tag{4}$$

For latency SLO ($s = \text{min_latency}$):

$$x^{\text{peak}}_{w,s,c,m} = 0 \quad \text{if } \ell^{\text{TTFT}}_m + t_c \cdot \ell^{\text{TPOT}}_m > \tau_{w,s} \tag{5}$$

Cost Budget Constraint:
If cost SLO is specified:

$$\sum_{w,s,c,m} x^{\text{avg}}_{w,s,c,m} \cdot \frac{t_c}{\theta_m} \cdot g_m \cdot c_{g(m)} \leq \text{Cost}_{\text{budget}} \tag{6}$$

where $\text{Cost}_{\text{budget}} = \sum_{w \in \mathcal{W}} \tau_{w,\text{cost}} \cdot \sum_s \lambda^{\text{avg}}_{w,s}$.

Resource Budget Constraint:

$$\sum_{m:\text{GPU}(m)=g} n_m \cdot g_m \leq B_g, \quad \forall g \in \mathcal{G} \tag{7}$$

SLO Filtering Constraints:

$$x^{\text{peak}}_{w,s,c,m} = 0 \quad \text{if } a_c < \tau_{w,s} \quad \text{(accuracy)} \tag{8}$$

$$x^{\text{peak}}_{w,s,c,m} = 0 \quad \text{if } \ell^{\text{TTFT}}_m + t_c \ell^{\text{TPOT}}_m > \tau_{w,s} \quad \text{(latency)} \tag{9}$$

Cost Budget Constraint:

$$\sum_{w,s,c,m} x^{\text{avg}}_{w,s,c,m} \frac{t_c}{\theta_m} g_m c_{g(m)} \leq \sum_w \tau_{w,\text{cost}} \sum_s \lambda^{\text{avg}}_{w,s} \tag{10}$$

Objective Functions. Minimize Energy:

$$\min \sum_m n_m e_m g_m \tag{11}$$

Minimize Cost:

$$\min \sum_m n_m g_m c_{g(m)} \tag{12}$$

Maximize Accuracy Under a Cost Budget:

$$\max \frac{\sum_{w,s,c,m} x^{\text{avg}}_{w,s,c,m} a_c}{\sum_{w,s} \lambda^{\text{avg}}_{w,s}} - \varepsilon \cdot \text{Cost}_{\text{total}} \tag{13}$$

where $\varepsilon = 0.001$.

Solution Method. The formulated Mixed Integer Linear Program (MILP) is solved using Gurobi [37] with a time limit of 300 seconds. The solution yields an allocation of model instance counts n^*_m and load distributions across model instances for all workflows.

ECO: An AI-Driven Code Efficiency Optimizer for Warehouse Scale Computers (Operational Systems)

Abstract

Large Language Models (LLMs) have shown significant promise in automating code efficiency optimization. While prior work demonstrates these techniques on artificial datasets such as programming competitions or small benchmarks, deploying these techniques at scale in production has remained an open problem. Arguably, two challenges have prevented the adoption in large-scale real-world systems: opportunity localization and reliability. First, applying an LLM to every line across a large code base is expensive and prone to generating an overwhelming number of low-quality suggestions, placing unsustainable cognitive load on human code reviewers. Second, the inherent unreliability of LLM-generated code risks introducing errors that can lead to production incidents. These challenges are largely orthogonal to the ML techniques prior work has focused on; they are real-world systems problems.

This paper introduces ECO, a system that automatically modifies source code to improve performance at scale. ECO overcomes the localization problem by combining fleet-wide continuous profiling to identify performance-critical code with an embedding-based search to pinpoint specific optimization candidates, guided by a mined dictionary of performance anti-patterns. It overcomes the reliability problem through a multi-stage verification approach that uses automated testing, LLM-based self-review, and post-deployment monitoring to ensure changes are both correct and effective. Fully productionized and deployed within Google's hyperscale production fleet, ECO has successfully landed over 6,400 commits, changing more than 25,000 lines of production code. Incorrect changes are caught before they are submitted to production, and 99.5% of the submitted commits did not cause any rollbacks. These optimizations have resulted in savings equivalent to several hundred thousand normalized CPU cores, showing that ECO makes LLM-based optimization both practical at scale and highly impactful in real-world settings.

1 Introduction

Over the past few years, an increasing amount of work has shown the potential of Large Language Models (LLMs) to analyze and optimize code for performance [1–10]. By automating a task that traditionally requires extensive and costly manual engineering, LLMs promise to unlock significant efficiency gains, particularly in the long tail of workloads. A study of Google's data centers has shown that a large fraction of CPU cycles in warehouse-scale computers are spent on workloads that are individually too small to justify manual optimization effort [11]. Automating this process could therefore yield substantial resource and energy savings.

However, while these LLM-based approaches show promise on benchmarks such as programming competitions [2, 5, 7, 9, 12, 13], directly applying them in a large-scale, production environment presents significant challenges that hinder their practical adoption. The challenges are not with the LLMs alone (where existing work has focused), but with making them practical in the context of real-world systems:

- **Opportunity Localization**: LLM-based methods need to be provided the code to optimize. In production environments with millions or billions of lines of code, naively running an LLM across the entire repository is computationally prohibitive and generates an overwhelming number of false positives. A practical system must first find and localize high-impact optimization opportunities before attempting to apply a fix.

- **Reliability**: State-of-the-art LLM methods often report success as the best result out of many attempts (e.g., top-$\mathcal{K}$ accuracy) [13]. In a real-world production setting, however, precision is paramount. Any incorrect change can cause outages, and the high rate of subtly buggy or non-performant suggestions from an unguided LLM creates a large verification burden.

In addition, benchmarks fail to capture **system integration** and **attribution**. In complex, large-scale systems, attributing a performance inefficiency to a specific piece of code is difficult [14]. Furthermore, AI-based optimization must integrate with existing engineering workflows, including testing, code review, and deployment, aspects absent in benchmarks.

We present ECO (**E**ngine for **C**ode **O**ptimization), a system that makes LLM-based optimization practical at scale by introducing novel techniques for targeted localization and robust verification. ECO begins by mining historical commits

*Hannah Lin and Martin Maas contributed equally to this work.
†Now at Point72, work done entirely at Google.
‡Now at Meta, work done entirely at Google.

to create a database of performance anti-patterns. These anti-patterns are then used to guide a large-scale vector similarity search [15] across the codebase. To focus this search, we combine it with data from a fleet-wide continuous profiling system, allowing ECO to identify code that is both costly and a likely candidate for a known optimization.

Once a candidate is localized, ECO uses a fine-tuned LLM to generate a code transformation. To ensure the reliability of this edit, it is passed through a multi-stage verification pipeline that includes automated build and unit testing, LLM-based self-review to detect common errors, and finally, human review. Once deployed, the change is continuously monitored to measure its performance impact and avoid regressions.

This paper makes the following contributions:

1. An approach for identifying and localizing performance optimization opportunities by combining continuous profiling with an embedding-based similarity search guided by a mined database of anti-patterns.
2. A methodology for making unreliable LLM-generated edits reliable for production use through automated testing, self-review, and post-deployment monitoring.
3. The design, implementation, and evaluation of ECO, a fully deployed system that embodies these techniques and successfully integrates AI-driven changes into a large-scale, human-in-the-loop engineering workflow.
4. A study focusing on human adoption of code edits, including a human evaluation of 960 code edits to assess the quality of changes, and an at-scale production study of how human engineers adopt ECO-generated changes in Google's production setting.
5. An analysis of ECO's deployment at Google, showing it has successfully landed over 6,400 commits, changing over 25k lines of code and saving the equivalent of several hundred thousand normalized CPU cores. By filtering out and discarding incorrect changes before they are submitted to production, >99.5% of the 6,400 commits did not have to be reverted.

While there has been a substantial amount of prior work on LLM-based code optimization, ECO is largely orthogonal to this work. Instead, it solves the systems problems required to turn these capabilities into scalable impact in a large-scale system infrastructure deployment. We believe it is the first operational system to achieve this.

2 Background & Overview

The use of LLMs in code optimization has seen a large amount of research in the past several years [1]. We begin with an overview of how our approach improves upon the state of the art to solve problems that have prevented adoption of automated optimization in real-world systems.

2.1 Why LLMs for Code Optimization?

Automated code optimization is well-studied, but existing approaches have limitations. Compiler optimizations must be provably correct, preventing them from making semantic changes that a programmer knows are safe in a given context. Static analysis tools like Clang-Tidy [16], Facebook Infer [17], or Semantic Patch [18] can apply rule-based edits to perform such changes, but struggle with the high syntactic variability of real-world code. These tools require narrowly defined patterns and often fail on complex control flow. For example, Clang-Tidy can suggest adding `vector<T>::reserve` to a simple, single-statement loop [19], but cannot handle common real-world cases where a vector is populated across multiple loops, conditional branches, or helper functions (Figure 3b). Writing heuristics for every variant is often more work than fixing the instances manually. Further, many optimizations require domain knowledge that static tools lack, such as when a sorted map can be replaced with a faster, unsorted one.

LLMs overcome these limitations in two ways. First, they can generalize from a few examples to recognize and fix anti-patterns across a wide range of syntactic variations, reducing the need for hand-crafted heuristics. Second, they can often infer developer intent and domain-specific context from the surrounding code and comments, enabling semantic optimizations that are out of reach for traditional tools. Figure 3 shows several examples. While LLMs are more computationally expensive than static checkers, we show in Section 7.4 that the cost of inference is negligible compared to the fleet-wide savings they unlock.

2.2 High-Level Approach

Figure 1 shows an overview of ECO's approach. We start by mining decades of code changes across Google's billions of lines of code spanning over 100,000 packages and thousands of projects [20], to identify a set of canonical code optimizations. Each consists of an *anti-pattern* and a corresponding *optimization* that fixes it. Two examples[1] of these anti-patterns, pre-sizing a vector at allocation time and removing redundant accesses to data structures, are shown in Figure 3. We group similar anti-patterns together into categories. Table 1 shows several of the anti-pattern categories in our database.

Using this anti-pattern database, we identify candidate locations in the codebase for similar optimizations. This problem is challenging, as exact matching fails to surface these locations due to differences in variable names and code structure. We find this problem is well-suited to machine learning and develop a code similarity search technique based on vector similarity [15] to identify a set of *candidates* similar to a given anti-pattern. To focus this search, we leverage fleet-wide con-

[1] Throughout the paper, we rename sensitive variables, names, or values.

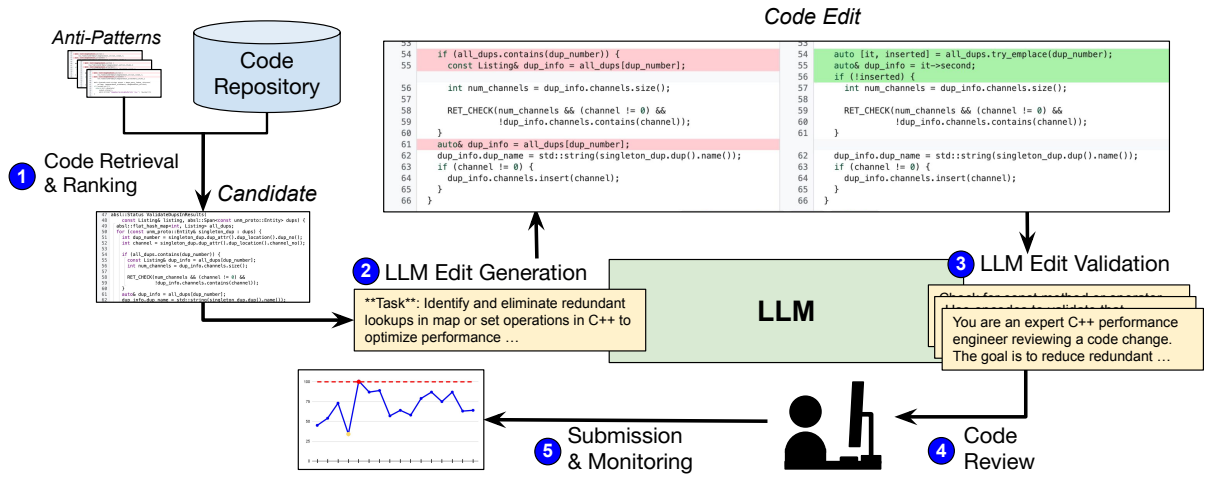

Figure 1: An end-to-end example of ECO, demonstrating the cycle from anti-pattern mining to deployed fix.

Table 1: Anti-Pattern Categories

Category	Description	Count
Alloc	Unnecessary allocations: Allocation of a new object when reuse of an object is possible.	8
Args	Unnecessary copied args: Using an API causing unnecessary copies of arguments from a widely used internal framework.	2501
Copy	Unnecessary copies: Replacing variables with references.	2873
Map	Redundant map operations: See Figure 3a.	985
Move	Missing `std::move`s: The last use of an object is copied instead of moved.	1487
Sort	Unnecessary sorts: Use of a sorted or stable map/set when not required.	91525
Vector	Missing vector reserves: See Figure 3b.	331

tinuous profiling to rank candidates based on resource consumption, identifying the best opportunities.

Subsequently, we use a fine-tuned LLM to generate code that implements the optimization. To mitigate the risk of LLM hallucinations, we improve ECO's reliability by using diverse prompting strategies and a multi-stage verification pipeline. To ensure correctness, we use the LLM to self-review its generated code, similar to [21], run automated tests, and perform checks tailored to each project. We then submit the generated changes for human code review. After submission, we monitor the change in production to detect regressions and measure its performance impact.

ECO's optimization discovery approach results in a database of anti-patterns that can grow over time. Figure 2 outlines the end-to-end process from an operational point-of-view. A small team of engineers operates ECO, beginning by selecting anti-patterns to target. The team ranks known anti-patterns according to observed frequency and savings potential, supported by the data and statistics gathered in the creation of the database. After selecting anti-patterns, they launch ECO to automatically identify optimization candidates from existing examples. The team ranks these candidates (described in Section 4), and uses a library of prompt recipes (evaluated in Section 7) to have ECO automatically apply an optimization across all identified locations, submitting the resulting commits for code review.

Actions by ECO are automated, with engineers directing the system and intervening only when necessary. Most human involvement appears during the review and submission phase. However, this is required for any change generated at Google, regardless of whether or not it is AI-generated. Code changes fail if performance regressions appear in production and they need to be rolled back. ECO's validation process has kept the rate of rollbacks extremely low (Section 7.4). As such, ECO greatly scales up human productivity compared to manually searching for optimization opportunities, writing patches and shepherding them through code review.

3 Performance Optimization Datasets

We now describe how we mine historical commits to create a dataset of efficiency anti-patterns and optimizations.

3.1 A Dataset of Efficiency Anti-Patterns

To enable ECO to drive interpretable and consistent changes, we begin by identifying and categorizing performance anti-patterns from historical data. Google's codebase contains billions of lines of code. It is structured as a monorepo (similar to [22–25]), but the approach would be the same if it was spread across smaller, disparate GitHub repos. While this work targets C++, ECO is not fundamentally limited to it. Despite being organized as a monorepo, this setup covers over 100,000 packages and a wide variety of projects [20], including mirrors of open-source repositories [26]. This diversity

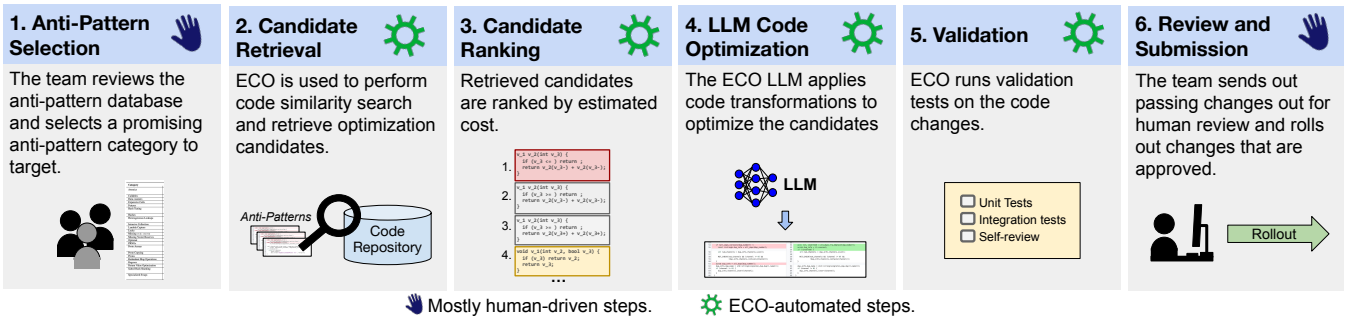

Figure 2: Operational timeline of ECO.

and scale demonstrates ECO's scalability and generalizability across many different kinds of projects.

All code in the repository is searchable, with a complete history of all past commits, including messages, code review comments, and code changes. This is the same setup that a typical organization or open source project building on top of GitHub would encounter. It lets us implement textual search techniques to find historical commits that improved performance. We use two search types: First, we search commit messages for keywords indicating performance improvements (e.g., "speed up", benchmark results), performance-related hashtags, and links to performance-related documentation. Second, we search curated sources like internal newsletters that publicize efficiency improvements. This process is guided by human experts who curate the anti-pattern categories, define relevant search keywords, and set up the data processing pipelines. While our coding culture encourages single-issue commits, ECO is robust to commits with multiple changes.

We run this data extraction on a large-scale distributed computation framework, akin to Apache Beam [27], and maintain a database of these performance-related optimizations and the anti-patterns that they solved. We then use it as the foundation of our optimization approach. Appendix A provides a full list of anti-patterns in our dataset.

3.2 LLM Fine-Tuning Datasets

In addition to using our anti-pattern dataset to identify optimization candidates (Section 4), we also combine it with other data sources to fine-tune an LLM to improve its performance on these specific code refactorings [28]. For the examples and evaluation provided in this paper, we use ECO with Gemini Pro 1.0 [29], which supports fine-tuning via Google's Vertex AI service [30]. Our fine-tuning dataset is highly proprietary and includes source code, selected code commits, metadata of code and commits, and the performance-specific dataset derived from our anti-pattern database ($\approx$ 55k commits). The fine-tuning mechanisms are similar to prior work [31, 32].

While we describe a particular LLM here, ECO's architecture is agnostic to the specific model. We have regularly updated our model and continued to use ECO with more recently released LLMs. However, for consistency, all evaluations in this paper were performed with the original Gemini Pro 1.0 model described above. We note that it is not the goal of this paper to evaluate the capabilities of LLMs at producing code efficiency optimizations, and models continue to rapidly improve in this area, which ECO directly benefits from.

4 Optimization Opportunity Localization

While our anti-patterns dataset contains examples of *past* optimizations, a key challenge is identifying *new* candidates across our codebase. Naively applying an LLM to all of Google's code is computationally expensive with an observed high false-positive rate. In addition, incremental, localized changes are favored to minimize global disruption and facilitate testing and review processes. Therefore, we introduce a search technique based on vector similarity search [15] to identify new potential instances of anti-patterns.

4.1 Performance IR

To search for optimization opportunities, we first design an intermediate representation (IR) of functions across our codebase. We operate at the function level, as functions provide a stable and practical unit of code to track and compare across the millions of daily changes in our repository. This granularity strikes a balance between providing sufficient context for optimization and maintaining tractability. Using the Apache Beam framework [27], we crawl C++ code, parse each file with Clang, and divide it into functions. We annotate each function with its AST-derived types (e.g., of arguments and local variables), which are good indicators for certain optimizations. Figure 4 shows an example. To avoid processing millions of functions that are not performance-critical, we filter this set to focus only on *costly* functions.

4.1.1 Continuous Profiling

To identify costly functions, we leverage *Google Wide Profiling* (GWP), a fleet-wide continuous profiling framework that

```
- bool new_entry = false;
- if (s.current_shard.find(name) == s.current_shard.end()) {
-   s.current_shard[name] = 1;
-   new_entry = true;
- } else {
-   ++s.current_shard[name];
- }
+ int64_t value = ++s.current_shard[name];
+ bool new_entry = (value == 1);
```

(a) **Redundant Map Operations**: Performing duplicated key lookups and reinitializing map values can waste CPU cycles. Here, the LLM had to detect that `[]` may add a missing key, and that for a map with integer values, it gets initialized to 0; the optimization only works in that case and is not sound in general.

```
+ result.reserve(reader->NumRecords());
  for (;;) {
    Info info;
    bool has_msg = reader->ReadToMessage(&info).ValueOrDie();
    if (has_msg) {
      result.push_back(info);
    } else {
      break;
    }
  }
  return result;
```

```
+ error_list.reserve(3);
  int total_error_count = 0;
  for (int i = 0; i < vec1.size(); ++i) {
    const double diff = fabs(vec1[i] - vec2[i]);
    if (diff > abs_error) {
      total_error_count++;
      if (error_list.size() < 3) {
        error_list.push_back(Error(i, diff));
      }
    }
  }
```

(b) **Missing Vector Reserves**: Vectors are a common data structure but can cause unnecessary memory reallocations that pre-allocating space can avoid. In the first case, `reader` is a file API and the LLM had to determine that it can query the full number of entries with `NumRecords`. It also needed the domain-specific context that `has_msg` is rarely false. In the second example, it had to conclude that the list will only have up to 3 entries.

Figure 3: Examples of ECO performance optimizations.

periodically samples performance metrics from all running applications [33]. For each sample, it collects the program counter, stack trace, and performance counters. These profiles are aggregated into a global database. We use this data to identify costly functions as optimization targets. In addition, correlating it with code versions allows us to evaluate changes in resource usage linked to specific commits. This helps us both identify past optimizations and also measure the impact of ECO's commits after deployment.

4.1.2 Code Annotations with Performance Metrics

To find good optimization candidates, we annotate our IR with performance metrics such as CPU usage, memory allocations, and LLC misses from our profiler. A naive attribution of CPU usage is often unhelpful, as cycles are frequently spent in common, *shared library functions* (e.g., `vector<T>::push_back`) rather than *application-specific code*. These shared libraries are not generally profitable targets for optimization at ECO's level, as they are usually already heavily optimized. Therefore, we re-attribute resource usage to the parent functions in the call stack that are most meaningful for optimization.

```
{"definition":
  "string GetTimeLabel(time_t timestamp) {
     int year, month;
     getYearMonth(timestamp, &year, &month);
     string label;
     bool success = toLabel(year, &label);
     if (!success) return getError(year, month);
     return label;
  }",
...
"variables": [
  { "name": "year", "type": "int" },
  { "name": "month", "type": "int" },
  { "name": "label", "type": "string" },
  { "name": "success", "type": "bool" }
],
"performance": [
  { "instructions": 43052 },
  { "cycles": 109572 },
  { "llc_misses": 501 }
]}
```

Figure 4: A performance-annotated function in the dataset.

Algorithm 1: Retrieving costly functions.

Input: A function F and its parent function P
Output: Costly functions under F's call tree

Function `GetCostlyFns`(F, P)
  if `GetCallees`(F) *is empty* **then**
    if `ShouldPrune`(F, P) **then return** $[F]$;
    return $[F]$;
  costly_fns ← [];
  for callee *in* `GetCallees`(F) **do**
    extend costly_fns with `GetCostlyFns`(callee, F) ;
  end
  if costly_fns *is empty and not* `ShouldPrune`(F, P) **then return** $[F]$;
  return costly_fns;

Function `ShouldPrune`(F, P)
  if `getCyclesOfTree`$(P) > C_{max}$ **then return** *false*;
  if `isSharedFn`(F) **then return** *true* ;
  if `getCyclesOfTree`$(F) < C_{min}$ *or* `getCyclesOfTree`$(F) > C_{max}$ **then return** *true* ;
  return *false*

4.1.3 Identifying Costly Functions

We take per-binary function call trees from profiler samples and apply a pruning and attribution step, outlined in Algorithm 1 and depicted in Figure 5. We traverse the call trees to find the lowest-node *application-specific functions* that are responsible for significant cost. We define application-specific functions as those common to fewer than a threshold of binaries. We recursively prune sub-trees and attribute their cost to their caller. Note that this has no effect on the caller's code representation and only affects its accounted resource consumption for the purpose of identifying costly functions. A sub-tree of shared functions is pruned and its cost attributed

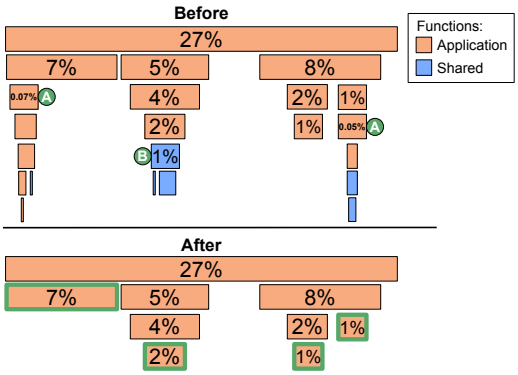

Figure 5: Pruning function call graphs (annotated by percent of the application's total cycles and represented as a flame graph [34], not drawn to scale). Unlabeled functions consume less than 0.01% of the application's cycles. Orange represents application-specific code, blue represents shared code. **A** labels pruned sub-trees roots that form less than C_{min}=0.1% of the app. **B** labels the root of a pruned shared code sub-tree. Boxes outlined green after pruning (bottom) are the leaf nodes of the pruned call graph targeted for optimization.

upwards, unless the caller is already too large (exceeding C_{max} of total binary cycles). Application-specific sub-trees are also pruned upwards until a caller accounts for at least C_{min} and at most C_{max} of the binary's cycles. The upper threshold prevents aggregation at too high a level (e.g., a binary's main function), which is unproductive for localized optimizations. Through empirical tuning, we set C_{min} to 0.1% and C_{max} to 25%. This analysis yields over 10M potential optimization candidates, which form our *search space*.

4.2 Code Retrieval

Given our anti-pattern dictionary and a search space of costly functions, we need to find all candidates that likely match a particular anti-pattern. This is challenging, as instances of an anti-pattern can be textually and structurally diverse (e.g., Figure 3a). Manual heuristics like regular expressions or AST-based techniques such as CodeQL [35] cannot usually capture this diversity. We therefore use a code retrieval technique that discovers new instances of an anti-pattern from past examples.

We first form a database of vector representations (embeddings) of each function in our search space (Figure 6). We then take examples from our anti-patterns database and look for similar functions in our search space using approximate nearest neighbor (ANN) search, a method proven effective in other code recommendation contexts [36]. We use ScaNN [15], an open-source vector similarity search library developed at Google, for this task. Given a vector representation of a *query* (the "before" function state or a code diff embodying an anti-pattern), ScaNN returns an approximate set of similar vectors from the database. To focus on high-impact changes, we only search within the set of costly functions identified previously. For each query, we retrieve the top-$\mathcal{K}$ ($\mathcal{K}=500$) candidates. We then normalize the query and candidates by removing custom names, static strings, and comments, and rank the candidates by a *syntactic similarity* score (Section 4.2.2).

4.2.1 Embedding Design for Semantic Similarity

We explore two strategies for vector embeddings:

(a) Bag of Words (BOW). This approach involves creating embeddings based on a BOW representation. Our intermediate representations provide textual tokens for each function after parsing. The embedding vector of a function is created by forming a token-frequency vector, excluding comments, common keywords (e.g., `return`), and punctuation tokens.

(b) Deep Embedding Models. We use a 1B-parameter dual-encoder *deep text embedding* model [37], originally trained on English query-document pairs, and fine-tune it on 25M samples of: (1) semantically similar function pairs and (2) code diffs and their corresponding "before" function states. Fine-tuning on similar functions allows us to query for similar code snippets. Fine-tuning on diffs allows us to search for specific optimization patterns, focusing the query on the relevant lines of code rather than the entire function. This matches how we later use the deep embedding model (querying it using both code snippets and code diffs) and is similar to how others use diffs or Git commits for training models [38–40].

4.2.2 Ranking Performance Opportunities

After retrieving the approximate top candidates through ANN, we use a *syntactic similarity score* for further, more detailed ranking. The score $\mathcal{S}$ between a query Q and a candidate C is defined as (higher is better):

$$\mathcal{S}(Q,C) = \frac{1}{4}[B(Q,C)+R(Q,C)+T(Q,C)+F(Q,C)]$$

Each component of $\mathcal{S}$ is from 0 to 1 and defined as follows:

- $B(Q,C), R(Q,C)$: BLEU [41] and ROUGE-L [42] score are text similarity metrics. B and R are calculated after normalizing the code (Q and C) to remove custom names, static strings, and comments.
- $T(Q,C) = (|T_Q \cap T_C|)/max(|T_Q \cup T_C|, 1)$, where T_Q, T_C are types present in Q and C from our code representation (Section 4.1.2).
- $F(Q,C)$: Cosine similarity of control flow-related keywords (*e.g.*, `for` , `while`) in the functions' BOW vectors.

The inclusion of B and R captures textual similarity, while T and F incorporate information about types and control flow, improving the representation of semantic similarity and helping further refine the set of candidates, after the approximate match provided by ANN.

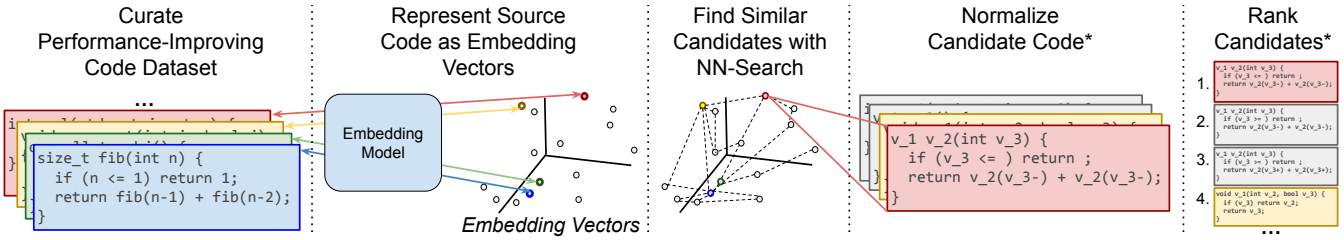

Figure 6: ECO's code retrieval approach. Source code is represented as vectors and ScaNN [15] is used to find nearest neighbors in the vector space. After retrieving nearest neighbors, we optionally rank code by similarity; these steps are marked by (*).

5 Code Edit Generation Strategies

After identifying candidates, we generate code transformations by prompting an LLM (Section 3.2). Since generation quality is highly dependent on the prompt, we explore a variety of prompting strategies, or *prompting recipes*, for engineers using ECO to build upon [43, 44].

LLM prompting is a well-studied area [45]. The simplest approach, *zero-shot prompting*, directly instructs the model to perform a task without giving it any examples. This works for simple edits but struggles with complexity. Since token generation is when the model applies logic, zero-shot prompting leaves few steps for the model to apply complex operations. It also relies on the LLM correctly interpreting the instructions.

Several techniques address this. *Few-shot* prompting includes examples of the desired input-output behavior (e.g., before/after code pairs) in the prompt to help the model with pattern matching, a technique shown to be effective for code [46]. *Chain-of-Thought* (CoT) prompting instructs the model to first output a plan or reasoning steps before generating the final output [43]. This encourages more structured reasoning and works well for code transformation [47]. Finally, *agentic* ReAct-style prompting enables multi-step reasoning by having the model cycle through generating a thought, an action (e.g., a command to execute in an external environment such as, in our case, a shell), and then feeding the output of the command back into the model, allowing it to interactively refine its work [44]. The prompting recipes below apply these paradigms to ECO's code editing task.

5.1 Prompting Recipes

Zero-Shot prompting. Our prompts follow the format in Figure 7a. The LLM response is a code diff compatible with the `patch` command. To improve performance, our fine-tuning data (Section 3.2) includes examples in a similar instruction-following format.

Few-shot prompting. This variant uses a small set of example edits in the prompt to guide the model, as shown in Figure 7b. We select examples of a target optimization type from our database and prompt the model to perform a similar transformation on the target code.

Chain-of-Thought (CoT) prompting. This style elicits intermediate "thoughts" from the model to trace its reasoning [43]. By asking the model to provide ideas for improving code "*step by step*" (Figure 7c), we guide it to identify and then implement a specific optimization strategy.

ReAct prompting. This combines reasoning with action through an iterative loop of thought, action, and observation [44] until a goal is met (Figure 7d). This mimics how humans break down complex tasks. For code editing, this allows the model to examine code, propose a patch, and observe the result, providing a way to navigate ambiguity.

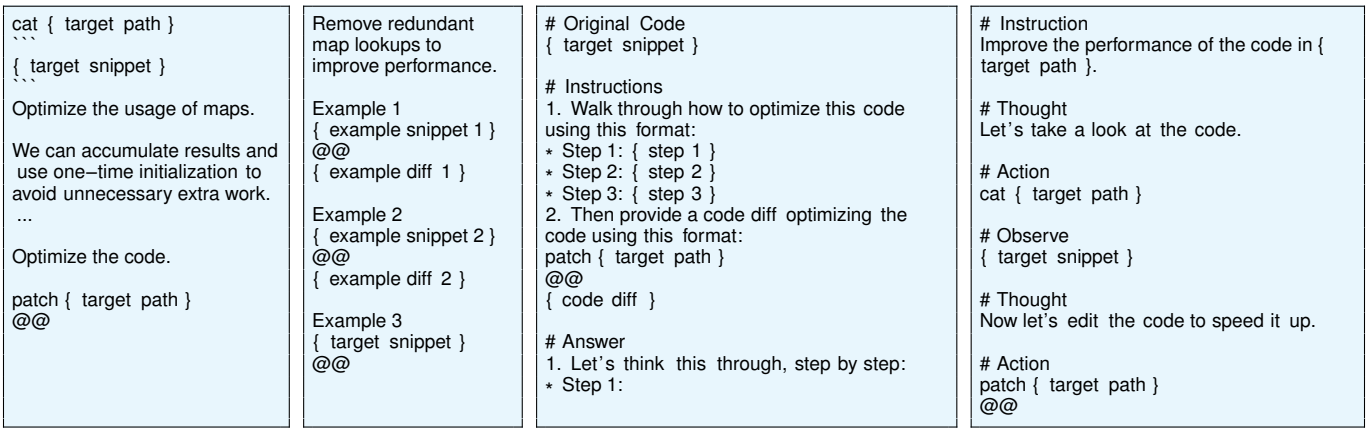
As we show in our evaluation, all four approaches are effective for certain tasks, but no single recipe is universally superior. We therefore maintain a library of these prompting strategies, and engineers select the most appropriate one on a case-by-case basis. Appendix B provides concrete examples of these recipes and their corresponding LLM outputs.

6 Verification, Submission, & Monitoring

Code generated by ECO must meet production standards and achieve a high success rate to minimize the burden on human reviewers. Our edit verification process starts with automated testing. We leverage Google's continuous integration pipelines, which run unit and integration tests, to check the correctness of ECO's edits. We automatically identify and run all tests in our entire monorepo that are affected by a change. If a change causes a build or test failure, we first attempt automated fixes for trivial errors like missing include directives. For more complex errors, we use our fine-tuned LLM to attempt a fix. If the code still fails, the edit is abandoned.

Due to imperfect test coverage, passing automated tests is not a guarantee of correctness. Furthermore, most tests do not evaluate performance and cannot detect neutral or negative efficiency impacts. We therefore incorporate LLM self-review to further improve edit quality. We prompt the model with a checklist of questions about common coding errors, anti-patterns, and optimization goals (see Appendix D). An edit proceeds to human review only after it passes this self-review step. Following Google's policies, all changes are reviewed by code owners, who make the final decision.

Management of these commits is automated using a tool



(a) Zero-shot (b) Few-shot (c) Chain-of-Thought (d) Agentic (ReAct)

Figure 7: Templates for different prompting strategies used by ECO.

called Rosie [48]. Rosie allows ECO to generate a large number of commits (called a *Large-Scale Change* or *LSC* in Google parlance) and then automatically identifies the correct code owners and requests reviews from them. As with any code change at Google, the commits must be reviewed and approved by code owners before they can be submitted. Google engineers are used to these kinds of reviews and perform them carefully [20,49]. This review load is accepted and generally fades into the background. ECO is no different.

A range of Google tools monitor changes in production and automatically roll them back if they cause regressions [50]. After a change is committed, we use our GWP continuous profiler (Section 4.1.1) to monitor its impact. This is non-trivial, since different projects have very different deployment strategies, and services usually roll out gradually over time. We therefore correlate the uptake of a particular commit in binaries measured by GWP with changes in metrics. We track key performance metrics to detect regressions and use monitoring alerts on performance-sensitive functions to notify us of any issues, allowing for prompt investigation. If a change correlates with a performance regression, it can be reverted. This is rare, occurring for <0.5% of ECO's commits (Section 7).

```
std::string CreateSimpleNames(
    absl::flat_hash_map<std::string, Loc> map,
    std::string key) {
  Loc value = map.at(key);
  if (value.locations.empty()) {
    return "simple_name";
  }
  return SimpleStrName(value.locations[0]);
}
```

(a) Original code snippet with an unnecessary copy anti-pattern.

```
     std::string key) {
-  Loc value = map.at(key);
+  const Loc& value = map.at(key);
   if (value.locations.empty()) {
```

(b) Sample of a successful model generated change.

```
 std::string CreateSimpleNames(
-    absl::flat_hash_map<std::string, Loc> map,
-    std::string key) {
+    const absl::flat_hash_map<absl::string_view,
+    Loc>& map,
+    absl::string_view key) {
   Loc value = map.at(key);
```

(c) Sample of a rejected code diff. The proposed type change requires updating the file includes but this was not added by the LLM.

Figure 8: Code optimization samples generated by ECO.

7 Evaluation

We evaluate ECO through measurements from its deployment within our production fleet, and controlled experiments using examples from a small subset of our anti-patterns. We note that while we characterize ECO's code generation abilities, the goal is not to compare LLM generation quality across models (which has been the focus of most prior work [1–10]). Instead, we show how ECO transforms a particular level of carefully characterized LLM capabilities into production impact as measured in end-to-end optimizations landing in production. As LLM capabilities are rapidly improving over time, ECO can directly take advantages of these improvements.

7.1 Microbenchmark Evaluation

We use controlled microbenchmarks to evaluate prompting strategies under conditions not feasible in production, such as testing multiple alternative edits for the same code. These experiments run on dedicated, isolated machines with many repetitions to ensure low-noise measurements. We use three hand-written C++ benchmarks, covering the *Copy*, *Map* and *Vector* anti-patterns in Table 1, and test with zero-shot, few-shot, CoT, and ReAct prompts. Each prompt asks the model to produce *code diffs* to optimize the benchmark (Figure 8). For each benchmark and prompting strategy, we sample the model five times and track the number of lines modified and

Table 2: Microbenchmark edits. We sample the model five times for each prompt type: zero-shot (ZS), few-shot (FS), chain-of-thought (CoT), and ReAct. CodeBLEU scores and speedup compare against unoptimized baselines. We report the number of avg. modified lines (ModLn); avg. generated valid/invalid code diff hunks (ValEd/InvEd); avg. rejected code diffs that broke code (Rej); avg. CodeBLEU score against baselines (CodeBL); Min, Med, and Max speedups; and the speedup of the highest CodeBLEU-scoring sample (CBS). If a generated edit is invalid, we leave the code unchanged when measuring speedup (leading to a speedup of 1).

	Copy	ZS	FS	CoT	ReAct	Human	**Map**	ZS	FS	CoT	ReAct	Human	**Vector**	ZS	FS	CoT	ReAct	Human

	Med	1.01	1.00	1.00	1.01	3.59	Med	1.05	1.06	1.00	1.06	1.22	Med	1.22	1.21	0.99	1.00	1.82
	Max	1.01	1.01	1.26	5.90	3.59	Max	1.07	1.06	1.07	1.06	1.22	Max	1.22	1.24	1.22	1.35	1.82
	CBS	1.01	1.01	1.26	1.01	3.59	CBS	1.05	1.05	1.05	1.06	1.22	CBS	1.22	1.21	0.99	1.00	1.82

whether the edits are valid (i.e., the diff hunks apply cleanly).

To assess the impact of different prompting techniques, we want to obtain a diverse set of model outputs with a given prompt. However, the higher the variance of the output, the less predictable the approach. LLMs configure this trade-off through a parameter called temperature. Its value is usually between 0 and 1, where 0 is most predictable. We pick a temperature of 0.3, which we find strikes a good balance.

In all microbenchmarks, we compare against a human baseline where an expert hand-optimizes the code. Since these benchmarks are specifically written for this evaluation, none of them are in the training set of our model. One challenge in a real-world setting is that we do not know which edit performs best until we deploy it. Since it is not generally feasible to try multiple candidate edits in production, we need a way to pick a good edit prior to deploying or measuring it. This impacts the efficacy of an approach. For example, a prompting approach that occasionally provides a better optimization than other strategies does not help us if we cannot identify this optimization among its outputs. We thus need a reliable approach to pick an output to use.

To pick an output, we compare each edit with the *unoptimized* baseline microbenchmarks using CodeBLEU scores which measure syntactic and semantic similarity using code-based n-gram matching [51]. The lower the score the more an edit changed the baseline's code. While this does not directly indicate the quality of an edit, it can be used to pick the output that represents the most *conservative* (i.e., highest) of the generated edits, which we will see is a good strategy.

If a proposed code edit results in a benchmark that still builds, we accept the edit and mark it as valid. If it breaks the build, the edit is marked as invalid. Figure 8 shows examples of accepted and rejected microbenchmark code edits from ECO. After generating edits, we apply accepted edits to the benchmarks and measure the performance in cycles per operation across 10 runs. We calculate speedup as $\texttt{speedup} = \frac{\texttt{new speed}}{\texttt{baseline speed}}$. Since edits that result in build failures are rejected and result in unchanged code, they lead to a speedup of 1. We report the minimum (Min), median (Med), and maximum (Max) speedup from the five prompt samples, as well as the speedup from the most conservative edit (*i.e.,* highest CodeBLEU score). Table 2 shows the results.

The edit metrics reveal that different prompting techniques yield varying results. CoT, for example, generates the most line changes but also more invalid edits, suggesting it is better for exploration than for generating immediately submittable changes. ReAct prompting most closely mimics how programmers edit code, and achieves higher Max speedups, except in the case of the Map microbenchmark. This confirms that there is no single best prompting recipe; the choice depends on the specific optimization task.

Speedup statistics also indicate that in a third of the cases, the edits achieve maximum speedups from the most conservative edits (when Max equals CBS, the speedup of the highest CodeBLEU-scoring sample). In nearly all cases (except Map/FS), CBS meets or exceeds median speedup, highlighting that small, conservative changes can significantly improve efficiency. We thus see that conservatively picking candidates that perform a minimum amount of semantic changes to the original code selects edits that lead to good efficiency improvements. While humans still outperform the AI, superhuman capability is not required for ECO, since the key benefit of AI is its ability to cover much more code.

7.2 Candidate Retrieval

We now evaluate the effectiveness of ECO's candidate retrieval methods (Section 4.2). We create a test set comprising 63 pairs of code diffs and corresponding "*before*" functions. This set includes 21 pairs each for unnecessary copies, redundant map lookups, and missing vector reserves.

To assess retrieval performance, we build a database of

Table 3: Comparison of Bag of Words (BOW), Deep Text Embedding (DTE), and Deep Code Embedding (DCE), with and without ranking, for identifying optimization opportunities.

Model	Query	Ranked	MAP@5	MAP@10	MAP@20
BOW	Function	No	0.0287	0.0173	0.0128
BOW	Function	Yes	0.0728	0.0398	0.0224
DTE	Function	No	0.0259	0.0190	0.0137

1803 functions, including functions from the 63 test pairs and an additional 1740 functions without known opportunities for the targeted optimizations. For each of the 63 test functions, we use its code embedding to query the database. A successful retrieval model would rank functions of the same anti-pattern higher when queried with a function of that anti-pattern. We compare the retrieval models in terms of mean average precision (MAP), a standard measure for evaluating retrieval models [52]. A query and a function are deemed "*relevant*" if they share the same optimization opportunity.

Table 3 presents the performance of these retrieval models using different query types. MAP@K quantifies retrieval quality by considering the top-$\mathcal{K}$ results for each query. When $K = 5$, bag of words (BOW) only achieves low MAP@K scores even after functions are ranked by syntactic similarity scores (Section 4.2.2). The MAP scores drop even further when K increases to 10 and 20. In contrast, MAP@5 more than doubles from 0.0728 to 0.1633 with function rankings on the deep text embedding model (DTE) and 0.2036 with the deep code embedding model (DCE).

Deep text embeddings show significant improvements over BOW, despite their lack of explicit code training. This suggests that text embedding models inherently capture some code semantics. Deep code embeddings show further improvements over deep text embeddings, which is expected from models trained on semantically similar function pairs.

Finally, applying a second-step syntactic ranking boosts performance for the BOW and text embedding models, underscoring the value of syntactic comparison when a model lacks full code understanding. The deep code model, however, shows little benefit from this re-ranking, suggesting that its end-to-end training already captures the necessary semantic and syntactic information. These findings validate the effectiveness of our embedding-based approach for retrieving optimization candidates.

These findings show the efficacy of ECO's embedding-based approach to code optimization candidate retrieval.

7.3 Edit Generation on Production Code

While microbenchmarks allow easy measurement of performance improvements, they do not capture the complexity of a large-scale production code base. We now assess the quality of generated edits on production code. We focus on the four prompting strategies applied to 48 performance-improving commits from our real code repository (not used to fine-tune our LLM). We aim to determine how accurately each prompt replicates the chosen code edits.

Contrary to the microbenchmark study, we cannot perform isolated performance tests on each generated edit. We thus evaluate these edits along multiple dimensions, each of which captures a different aspect of correctness. First, *validity* captures whether the code compiles (i.e., is syntactically correct). Second, *exact match* to the original edit is a very strong signal for correctness when there is a match, but provides little signal otherwise. Third, *CodeBLEU* scoring with respect to the original edit provides a signal how close the edit is syntactically, but small syntactic changes can make a large difference for correctness (e.g., including an additional `&` or `*`). To capture these subtleties, we also obtain a *quality score* for each edit through human scoring. While work-intensive, the human scoring is critical to provide ground truth, as automated scoring strategies can only provide limited insights in this evaluation setting. This is in line with best practices [53].

Given a target performance-improving commit, we use zero-shot, few-shot, CoT, and ReAct prompts to provide the model with the original source code and instructions to optimize the code. For each prompt, we sample our model five times. Each generated edit is then evaluated using CodeBLEU scores and by humans. Figure 9 breaks down the CodeBLEU and human-reviewed code quality scores for each commit, while Table 4 shows averages across the generated edits.

Zero-shot and ReAct prompting achieve the highest CodeBLEU and human-scored quality scores. In contrast, CoT provides the lowest CodeBLEU and quality scores. Figure 9 indicates that CodeBLEU scores generally align with human scores, trending higher with better code quality scores. However, discrepancies arise when the model proposes minor, non-performance-improving changes (*e.g.*, altering variable names or formatting — commits 47 and 48) in which the edit receives a high CodeBLEU score but a low quality score. On the other hand, if the model generates performance-improving

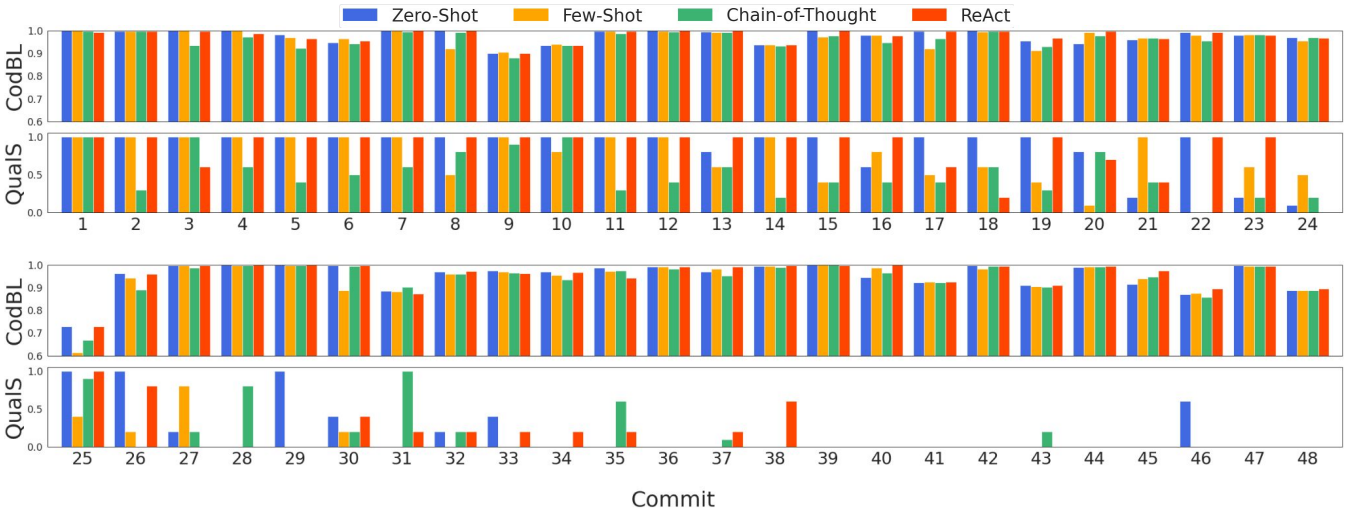

Figure 9: Quality of generated edits by prompting strategy. CodeBLEU scores (CodBL) show comparison to true historical changes. Quality scores (QualS) show code edit quality as scored by human experts reviewing whether the code edit is correct and performance-improving (Rubric: 1 = Yes, 0.5 = Partially, 0 = No). In total, human raters scored 960 examples.

Table 5: Feedback from human and automated code-review.

	Copy	Map	Vector	Description
S_PROD	39.97%	4.86%	40.89%	Submitted to production.
S_USER	6.55%	10.49%	15.99%	Submitted with user discussion (e.g., reviewer questions or suggested changes).
R_REVERT	0.16%	0.14%	0.12%	Submitted to production but later rolled back due to regressions.
R_TEST	16.14%	37.39%	20.07%	Rejected during the validation phase.
R_USER	35.81%	46.55%	22.87%	Rejected by human reviewers.
R_EMPTY	0.00%	0.07%	0.00%	Rejected due to failure to make code modifications beyond formatting.
R_OTHER	1.37%	0.49%	0.05%	Rejected for other reasons, typically non-edit related, such as failure to resolve merge conflicts during submission or failure to identify proper reviewers.
Total Commits	4959	1421	4035	Total number of code commits that were generated.
NC Savings	331k	125k	618k	Efficiency impact of the changes in normalized cores.

changes but also adds extensive documentation (*e.g.*, commit 25), the edit receives a low CodeBLEU score but high quality score. These results suggest that CodeBLEU can provide a weak signal for performance quality when comparing against known performance-improving edits. This study also reveals that insights from microbenchmarks hold true for production edits. CoT prompts produce larger edits but do not always result in the highest quality while targeted approaches like ReAct prompting tend to be more accurate.

7.4 Production Impact Evaluation

We now analyze ECO's production impact and its interactions with Google's infrastructure and processes. ECO has generated thousands of edits to date. We measure compute savings in *normalized cores* (NC), defined as the MIPS provided by a single core on a specific hardware platform [54]. In production, our approach employs a mix of zero-shot, few-shot, CoT, and ReAct prompting strategies on a case-by-case basis. We focus once again on the `Copy`, `Map` and `Vector` anti-patterns.

Edit Quality We quantify the quality of ECO-generated edits at scale by analyzing their code reviews and deployment, which includes human feedback, reverts due to production issues or incorrect changes, and resultant performance improvements using our fleet-wide performance profiler. For every change generated by ECO, a human code owner is asked to review the change before the change is submitted to production. For 40%, 5%, and 41% of `Copy`, `Map` and `Vector` changes, respectively, ECO-generated changes were directly approved and submitted to production without the human reviewers leaving any feedback that had to be resolved.

Table 5 shows a breakdown of additional actions required (see Appendix E for concrete reviewer interactions). Oftentimes, users left comments that were extraneous to the optimization in the code change (`S_USER`). These comments had to be addressed before the code change was submitted. Other times, users rejected changes (`R_USER`) and the changes were not submitted. This could be due to the reviewer judging the change to not be performance enhancing or wanting the code to be untouched for other reasons (e.g., style preferences).

Failure Modes The reasons why optimizations failed were multi-faceted. For example, `Map` has a comparatively low success rate. While `Copy` and `Vector` changes are relatively localized, `Map` changes typically require restructuring and reasoning about large pieces of code while also dealing with subtle semantics of C++ maps. Examples of errors include:

- **Control Flow**: Rewrites often caused subtle changes in behavior along some execution paths (e.g., adding an element too early or too late, confusing the behavior of the [] operator vs. `try_emplace`, `contains`, etc.).
- **Pointer Stability**: The model sometimes assumed that a pointer to a map entry remains valid throughout map modifications even if a `flat_hash_map` is used.
- **Corner Cases**: E.g., `if (!a.contains(k)) { a[k] = v } else { a[k] = min(v, a[k]) }` and `a[k] = min(v, a[k])` are not equivalent.
- **Not a Map**: Sometimes the model thought that something that was not a map was a map (e.g., a proto).
- **No Change**: The change was semantically equivalent or did not improve performance (e.g., replacing a single [] with a `try_emplace`).

Our automated pre-screening filters a significant portion of these before they reach human reviewers, reducing the review burden. Sometimes, we found that it was the reviewer who was mistaken. For example, we saw a case where the model added a `v.reserve(2)`, causing the reviewer to reject the change as erroneous. However, later in the code, there was an assertion `ASSERT_EQ(2, v.size())`, indicating that the change, while unexpected, would have been correct. In one case, a correct ECO code change optimizing a redundant map lookup was sent to a reviewer who suggested using `try_emplace` instead (Appendix E). The reviewer's suggestion was applied instead of the original ECO change. This led to large increases in CPU utilization and had to be reverted (`R_REVERT`). This highlights the subtleties of human-AI collaboration.

Resource Savings Figure 10 shows the savings achieved. Savings per line of code also vary by anti-pattern. Complex `Map` changes require more lines of code and yield lower savings per line than simple `Copy` or `Vector` changes. In contrast, `Vector` edits are often single-line changes but have a high impact, as they can prevent many reallocations of a large data structure.

Over a period of one year, ECO has sent commits covering many anti-patterns (Section 3), worth over several hundred thousand normalized CPU cores. Figure 10 shows the volume of code changes *successfully* submitted, with a rollback rate of less than 0.5%. In total, ECO has submitted over 25k lines of code across 6.4k commits. The majority of these changes modify or add lines, and some edits also remove lines. These results demonstrate the potential of ECO to achieve fleet-wide performance improvements with minimal human effort.

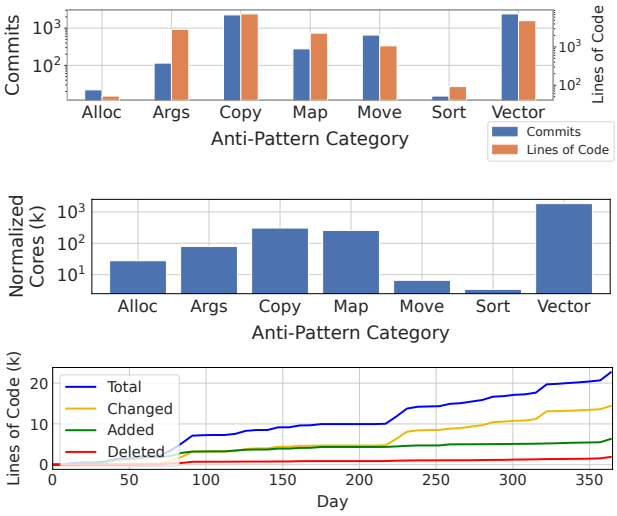

Figure 10: Statistics on landed code edits. Top: submitted code edits. Middle: performance savings. Bottom: landed code edits in production over time.

Cost Analysis An important question is whether the benefits of ECO justify its operational costs. Conservatively using prices for Gemini 3.1 Pro Preview, the most expensive Google model at the time of writing ($2-12 per 1M tokens [55]) and conservatively assuming 10k tokens (90% input) per invocation and 10 invocations per commit (including self-review and refinement), generating 10k commits costs $3,000.

Engineering and infrastructure costs for code review are not unique to ECO and similar to the background review load generated by other automated tools [20], which is generally accepted at Google. Overall, the additional human and infrastructure load for submitting changes from ECO was negligible. While we cannot share the exact number, it represented less than 0.1% of overall resources. This is a one-off cost, while the resource savings are realized on an ongoing basis.

8 Related Work

Code optimization Automatic code optimization has a long history. Stochastic superoptimization [56] explores instruction sequences to find optimal solutions, operating below the source code level. More recently, AlphaTensor [57] and AlphaDev [58] use reinforcement learning for algorithm discovery for specific problems. The Scalene profiler [3] interfaces with ChatGPT to optimize Python code. PIE [2] extends the CodeNet Benchmark [4] and designs evaluation methodologies and prompting techniques for performance improvements. Chen et al. [5] used VAE-based models on Google Code Jam data, while Supersonic [6] applies Seq2Seq models to Codeforces [59] and the CodeNet dataset [4].

Some works attempt to scale these methods beyond competition datasets. Aroma [36] provides general code recommen-

Table 6: Static Analysis vs. ECO vector reserve optimizations. Speedup ranges represent empirical CPU time reductions from micro-benchmarks (* denotes qualitative analysis where no runnable artifact was available).

Pattern	ClangTidy	CppCheck	CARAMEL*	CLARITY*	ECO Speedup	Explanation	Example Code Snippet

A: Standard Loop Insertion	Yes	No	Yes	Yes	0.4% – 7.4%	Trivial loop structure matching directly on standard library vector insertion (`.push_back`).	`dirs.reserve(src.size());`
							`for (auto g : src)`
							`  dirs.push_back(g);`

B: Bulk Move via Algorithms	No	No	No	No	2.1% – 13.8%	Elements are appended via algorithms/wrappers without an explicit local loop in the AST.	`res.reserve(res.size() + src.size());`
							`absl::c_move(src,`
							`  std::back_inserter(res));`

C: Custom Container Assignment	No	No	No	No	5.6% – 9.9%	Target is a protocol buffer; insertion bypasses standard vector analysis via implicit allocations in assignment operators.	`// RepeatedPtrField assignment`
							`cache.mutable_ents()->Reserve(size);`
							`*cache.mutable_ents() =`
							`  {src.begin(), src.end()};`

D: Template Range Copies	No	No	With LTO	Yes	1.4% – 4.1%	Container types are generic template arguments unresolved at static analysis compile-time.	`template <class R> void Copy(const R& s) {`
							`  std::vector<Ent> d;`
							`  d.reserve(s.size());`
							`  d.insert(d.end(), s.begin(), s.end());}`

E: Inter-Procedural Size Maps	No	No	Partial	Partial	3.0% – 13.7%	Sizing context is decoupled. Conditional insertions prevent mapping to `src.size()`; a pre-calculated stat dictates the true needed capacity.	`// st.total_size == count of ok items`
							`d.reserve(st.total_size);`
							`for (const auto& x : src)`
							`  if (x.ok) d.push_back(x);`

F: Custom Pointer Array Buffers	No	No	No	No	3.2% – 12.7%	Target is a custom API class. Static analysis lacks semantic awareness that `.Add()` stores pointers and triggers underlying array expansions.	`CustomPtrBuffer buf;`
							`buf.Reserve(src.size());`
							`for (auto& x : src)`
							`  buf.Add(&x);`

dations across a code base but does not focus on performance. Garg et al. [60] train models on C# performance-improving edits and evaluate on open-source repositories, but focus less on scalability and real-world deployments. Other work like EditLord [61] also fine-tunes LLMs on code edits, but this improves an LLM's capability at code editing as opposed to solving localization and reliability. To the best of our knowledge, ECO is the first to demonstrate and evaluate code optimizations at scale, applying them to billions of lines of code. Unlike prior work, we emphasize automation and the warehouse-scale setting, resulting in thousands of real-world performance improvements.

Code transformations Mining and applying code transformations in existing code is not a new problem. Meng et al. [62] build a sophisticated custom algorithm to generalize from an example and then apply the "same" transformation to other locations. More recently, Miltner et al. [63] present an algorithm to synthesize a script from repetitive changes and enable automated propagation of those changes. In our setting, examples of changes are already provided as anti-patterns, and we find that modern LLMs are capable enough to apply these changes at other locations, with no need for custom algorithms. Overall correctness must be verified, but this is also true of these prior AST-based techniques. Finally, Uber's DR.FIX system [64] also uses LLMs for edits, but applies them to data races in Go, a very different problem.

Repository-level refactoring Our work also relates to recent work in rolling out repository-level code changes, such as CodePlan [65]. While superficially similar, the primary commonality is that the actual transformation is carried out by LLMs. However, the emphasis of CodePlan is to apply a precisely specified edit that requires modifications to multiple files, such as changing a function signature or type, leveraging static analysis to identify additional locations that need to be changed. In contrast, our work focuses on *identifying* opportunities for code optimization across a repository of billions of lines of code, and *generalizing* existing edits to these new contexts. Our work is carried out at a much larger scale—CodePlan's largest repository had ≈ 20k lines of code.

9 Discussion & Future Work

Deployed SOTA Google relies on compilers for optimization, which cannot apply semantics-altering changes like ECO. We also deploy LLVM's Clang-Tidy [16], which uses heuristics to detect errors, including performance issues. However, we found it has notable limitations.

Static Analysis We compare ECO to static analysis tools. Table 6 summarizes vector reserve patterns—a primary anti-pattern category for both static tools and ECO—and whether tools can optimize them. We include Clang-Tidy [16] and CppCheck [66], two widely deployed static analysis tools. We also perform a qualitative comparison to CARAMEL [67] and CLARITY [68], two published static analysis techniques that target performance optimizations (but have no artifacts).

We group common code sequences that can be optimized with vector reserve operations into 6 patterns. For each pattern, we run microbenchmarks spanning 8 to 4,096 container elements and report the resulting speedups, confirming that these changes represent real and significant optimization opportunities. Out of the 6 patterns, Clang-Tidy reliably optimizes only 1, and CppCheck optimizes none, whereas ECO successfully optimizes all 6. The reason is that the first pattern is explicitly encoded in Clang-Tidy as the standard "*performance-inefficient-vector-operation*" [19] check, which identifies simple patterns such as `for (auto e : data) v.push_back(e);`.

In those cases, Clang-Tidy adds a call to `v.reserve`, but this only works if the control flow and structure are trivial.[2]

To determine if this is a shortcoming of specific tools or a fundamental static analysis limitation, we examine CARAMEL [67] and CLARITY [68], two static analysis tools that specifically target loop-related performance optimizations. Directly applying either tool would find none of the 6 patterns, since they are not the target of their analyses. CARAMEL [67] focuses on wasted loop iterations and CLARITY [68] identifies redundant traversal bugs, neither of which are present in the examples in Table 6. We hence only focus on the key ideas of these papers and try to adapt them.

Patterns B, C, and F are out of reach for static analysis since they rely on external functions and domain specific knowledge that are not available to the static analyzer. Pattern D requires templates to have been fully resolved by the time static analysis is applied; they may be within reach with LTO [69]. Pattern E may be within reach for either approach if the `x.ok` field matches one of the patterns it is searching for.

This points to a fundamental limitation of all static analysis tools – they can only identify the specific optimizations that they were designed for. Just like Clang-Tidy and CppCheck, CLARITY and CARAMEL only target specific optimizations. However, within this context, they have a key advantage: It is easier for them to perform inter-procedural analysis that spans disparate locations in the code, a task that used to be challenging for LLMs. Recent work proposed combining static analysis and LLMs to achieve the best of both worlds [70].

Expanding static analysis via custom rules for all corner cases requires prohibitive human engineering effort, quickly surpassing potential resource savings. CodeQL [35] facilitates this but does not solve it. In contrast, ECO is designed to expand beyond a specific optimization. and can perform diverse optimizations via examples, eliminating the need to implement new analysis passes for each optimization.

Deployment Insights One of the early challenges for ECO was to build trust with engineers. We thus prioritized our validation pipelines early on and picked initial edits carefully.

ECO's production success rate exceeded initial expectations, and reviewing changes from ECO helped shift some of our perspectives on the viability of optimizing code at Google with LLMs. Historically, LSCs were generated using deterministic tools, which restricted them to rigid, highly repetitive patterns. ECO helped us expand what we could optimize with automation. However, the increased diversity of commits meant that the team had to carefully monitor and iterate on the review feedback. This feedback loop was critical.

ECO depends heavily on the capabilities of the underlying model. Early on, we developed an evaluation to track the model capabilities on a set of canonical commits and understand what capabilities we could expect. We found it important to expand capabilities incrementally. Some optimization patterns were out of reach initially but later became feasible. E.g., optimizations such as proto arenas (Appendix C) require modifications across many files, which was not possible in early versions of ECO but became feasible over time.

While there are many prompting strategies, we found no clear rule on which works best when. Selecting strategies was highly empirical and sometimes combined techniques.

Some anti-pattern categories are much harder than they appear, e.g., `Sort`. Determining whether a sorted map or set can be replaced with an unsorted version requires judgement and significant context that early LLMs struggled at.

The embedding-based retrieval approach, when scaled to the scale of Google's multi-billion line code base, required careful calibration. There is a trade-off between precision and recall, and getting this balance wrong risks wasting significant reviewer time or missing important opportunities. We found that the most problematic candidates are those that seem plausible but are false positives.

As ECO has been successfully optimizing simple inefficiencies, the remaining opportunities have shifted toward more complex refactorings. These targets yield higher false-positive rates during candidate retrieval (e.g., heap-allocated protobufs that are candidates for arena migration can look semantically similar to code that is not, such as when an external pointer lifetime prohibits safe migration). To catch these false positives, we have begun deploying agent-based LLM validators during opportunity localization.

Future Work Our approach has several potential extensions. Currently, we use a *top-down* approach, leveraging an anti-pattern database to find optimization candidates. A complementary *bottom-up* approach could start from profiling data and then use an LLM to diagnose and fix bottlenecks. Further, our current *reactive* approach improves performance post-deployment. A similar framework could be used *proactively* to suggest edits to developers as they write code.

We believe ECO's core techniques can be replicated elsewhere using openly available tools and LLMs (Appendix F) and apply to smaller and decentralized codebases. We think the primary challenges to wider adoption are often organizational rather than technical, requiring integration with existing developer workflows and review processes.

10 Conclusion

We described ECO, a system for automatic code optimization at data center scale. By assembling a dataset of over 55k performance-improving edits from our code repository, we use code similarity search to identify similar patterns, and LLMs to apply changes automatically. Deployed in production at Google, ECO has changed more than 25k lines of code, saving hundreds of thousands of normalized CPU cores.

[2] Clang-Tidy documentation states that "*the check only detects [...] loops with a single statement body*" [19]. If the loop is more complex (e.g., a while loop or function calls), the pattern matching fails.

Supplementary Material

In this appendix, we provide additional details to the main paper, expanding on key areas such as a comprehensive list of anti-patterns identified, full LLM trajectory examples showcasing various querying approaches, multi-file edit considerations, LLM self-validation examples, human code reviewer interactions, and a discussion on the reproducibility of this work. This appendix is provided to offer a deeper understanding of the methodology, challenges, and outcomes of ECO's approach to automating code efficiency optimization.

A Anti-Patterns

Figure 11 summarizes how ECO takes historical code commits and other code sources and turns them into an anti-patterns dataset (Section 3). This provides additional context and examples for the description in the main paper.

We also provide a full list of anti-pattern categories extracted in the dataset in Table 7. Note that in the main paper, we provide more details on a subset of these categories, but include the full table here for completeness. As new anti-patterns are discovered, the table can grow over time.

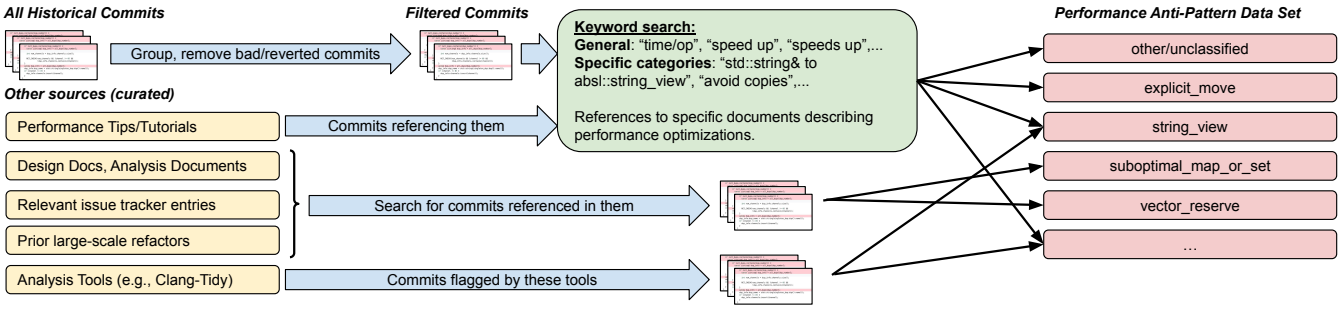

Figure 11: The approach and processing pipeline used to mine performance anti-patterns from our repository's commit history and a number of curated additional data sources.

Table 7: List of all Anti-Pattern Categories

Category	Description
Atomics	Use of std::atomic – std::atomic should be only used for simple properties where the value is returned as is and the property is set at most once with a mutex lock.
Callables	Unnecessary copies of a callable.
Data counters	Inefficient use of data processing counters.
Expensive Calls	Return early, cache results, or change the calling frequency of an expensive function call.
Futures	Using future allows users to treat future-producing APIs as cheaply copyable values with value semantics.
Hash Tuning	Improving hash tables with too many collisions or bits that never change across every hash with well-mixed hash functions provided by Abseil (`https://github.com/abseil/abseil-cpp`).
Hashes	Use of an inefficient hashing library when a more efficient option exists.
Heterogeneous Lookups	Map insertions/lookups causing the conversion of near-equivalent types due to user-specified comparator function to the map.
Intrusive Collection	Use elements of the collection to store state related to the implementation of the collection.
Lambda Capture	Capture by moving rather than copying and capturing individual member variables of an object.
Locks	Use of an inefficient lock type.
Missing `std::moves`	The last use of an object is copied instead of moved.
Missing Vector Reserves	See Figure 3b.
Optional	Use the std::optional when an object can be allocated on the stack but its population is deferred subsequent to construction.
PRNGs	Pseudorandom number generators that can use more efficient random number generation libraries.
Proto Arenas	Reduce the allocation and deallocation costs of protocol buffers by allocating them on a large piece of pre-allocated memory.
Proto Copying	Optimizations to reduce copying expensive protocol buffers.
Protos	Inefficient use of protos.
Redundant Map Operations	See Figure 3a.
Regexes	Inefficient use of regexes.
Return Value Optimization	Eliminate unnecessary copies of objects when returning from a function.
Salted Hash Sharding	To mitigate thread contention associated with a large shared table, shard the table and utilize a salted hash function to determine the appropriate shard for each key.
Specialized Swaps	Define a swap function in the class to swap objects of the class efficiently, and swap the object via std::swap within a scope guard.
String Comparison	String finds that can be replaced with more efficient finding functions.
String Concatenation	String concatenation that can be replaced with more efficient concatenation functions.
String Finds with Char	Use the character overload of `std::string::find()` and friends when the needle is a single character string literal.
String Views	String references that can be stored more efficiently.
Suboptimal Compressions	Changing or updating compression algorithms to improve performance.
Threads	Inefficient use of threads.
Type Erased Views	Use reference-like classes that do not own or copy data to enable code interaction with maps, random access ranges, and function objects without the necessity of templates.
Unmoved Unique Pointers	Avoid using an `std::unique_ptr` if it is never std::move to or from another pointer.
Unnecessary Allocations	Allocation of a new object when reusing an existing object is possible.
Unnecessary Anys	Use of an inefficient any which requires runtime type information and should be avoided in favor of std::variant.
Unnecessary Bound Checking	`std::vector::at` operator adds bounds checking overhead which can be avoided when the index is known to be valid, for example, part of a loop from 0 to size().
Unnecessary Copied Args	Using a particular internal API causing unnecessary copies of arguments from a widely used internal framework.
Unnecessary Copies	Replacing variables with references.
Unnecessary Indirections	Reduce pointer chasing and other forms of indirection
Unnecessary Map Copies	Use of an inefficient mapping function for data processing causing unnecessary copies to occur.
Unnecessary Sorts	Use of a sorted or stable map/set when not required.
Vector Reads	Missed use of a read-only view to the elements of `std::vector<T>`.

B LLM Trajectory Examples

This section provides examples of end-to-end LLM trajectories using the various prompting mechanisms described in Section 5. The prompts in blue show the query that is given to the LLM, and the LLM's responses are shown in grey, with additional syntax highlighting (added by us) to make the generated diff more readable. In the prompts, we added a placeholder for the target code that the prompt is applied to (the responses are based on calling the prompt with a representative example input).

B.1 Zero-Shot

This prompt format only includes the requested optimization, as well as the input code that it should be applied to. The model will respond with a snippet, based on its training.

Prompt 1: Example zero-shot prompt.

```
Reuse object allocations when possible to avoid allocating in a loop
{ target snippet }
```

Code Diff 2: Zero-shot generated code change.

```
@@[redacted]@@

      }
    }

+   [redacted]key;
    for (const auto& [redacted], value] : [redacted]_map) {
-     [redacted]key;
      key.ParseFromString([redacted]);
      emit_fn.Emit(key, value);
    }
```

B.2 Few-Shot

Here, we provide the model with specific positive and negative examples of an optimization. Just like before, the prompt then closes with the input code to optimize, and the model outputs a code diff when prompted.

Code Diff 3: Example few-shot prompt.

```
**Task**: As a C++ expert, you are required to analyze the use of the reserve method for std::vector. Ensure that vectors are pre-allocated ONLY when the
 size can be statically computed in advance.
**Guidelines**:
1. Avoid using reserve for trivial sizes; i.e., don't reserve space for just a few elements.
2. Avoid possible overallocations.
3. Consider special scenarios where reserve might be unnecessary or problematic.
4. The goal is to optimize memory usage without sacrificing runtime performance.
**Negative Examples**:
- **Example**:
  ```cpp
  std::vector<AutomatedRuns> failed_runs;
  std::vector<AutomatedRuns> successful_runs;
  successful_runs.reserve(Runs.size());
  failed_runs.reserve(Runs.size());
  for (auto Run : Runs) {
    if (Run.status == [redacted]::SUCCESS) {
      successful_runs.push_back(Run);
    } else {
      failed_runs.push_back(Run);
    }
  }
  ```
  Issue: Overallocation by reserving space for all Runs.
- **Example**:
  ```cpp
  [redacted].reserve([redacted].size());
  for (const ([redacted]& [redacted]:
  [redacted]) {
    if ([redacted].date >= start_date &&
    [redacted].date <= end_date) {
      [redacted].push_back([redacted]);
    }
  }
  return [redacted]
  ```
```

Issue: Overallocation by reserving space for all
[redacted].
- **Example**:
```cpp
auto arg_landscape = [redacted]->Compute(context);
arg_landscape.Reserve(state_.responses.size());
```
Issue: arg_landscape was already assigned at this point.
- **Example**:
```cpp
[redacted];
[redacted].reserve(options.[redacted]);
[redacted]
[redacted]false,
[redacted],
[redacted]);
if ([redacted].empty()) return;
```
Issue: [redacted]clears the output vector and calls reserve on it.
Positive Examples:
- **Example**:
```cpp
std::vector<std::pair<int, int>> ranges;
ranges.reserve(num_ranges);
//... (rest of the code)
return ranges;
```
- **Example**:
```cpp
std::vector<std::pair<int, int>> ranges;
ranges.reserve(num_ranges);
int last_added = 0;
for (int i = 0; i < num_ranges; i++) {
  const int start = last_added;
  const int end = start + elements_per_range + (i < remainder ? 1 : 0);
  ranges.push_back(std::make_pair(start, end));
  last_added = end;
}
return ranges;
```
Task: Given the above examples and guidelines, determine if we can improve the following code by adding reserve:
{ target snippet }

Code Diff 4: Few-shot generated code change.

```
@@[redacted]@@
  absl::Status s;
  if (expr.union__size() > 0) {
    std::vector<[redacted]*> children;
+   children.reserve(expr.union__size());
    for (const auto& child : expr.union_()) {
      children.push_back([redacted](child, parent_ref, context,
                                    relation_config, policy, source));
```

B.3 Chain-of-Thought

The key part of of this prompt if the last sentence – "Let's think this through step by step". This induces the model to generate a chain-of-thought sequence as opposed to directly outputting the answer.

Prompt 5: Example chain-of-thought prompt.

```
You're a software engineer [redacted] and you have identified the destructor associated with { proto name } in { class name } to be very expensive.
Optimize { class name } by using proto arenas. There are following rules to follow:
1. Declare an instance of proto2::Arena before any instance of { proto name }.
2. Replace any instance of { proto name } with proto2::ArenaSafeUniquePtr<{ proto name }>
3. Every object associated with proto2::ArenaSafeUniquePtr<{ proto_name }> would be constructed using proto2::MakeArenaSafeUnique<{ proto name }>.
4. Ensure that the same arena object is shared across the different instances of proto2::ArenaSafeUniquePtr<{ proto name }>.
5. Use pointer semantics for every object associated with proto2::ArenaSafeUniquePtr<{ proto name }>.

{ target snippet }

Let's think this through step by step.
```

Code Diff 6: Chain-of-thought generated code change.

```
Okay, let's analyze the provided code and apply the requested
changes to optimize [redacted] using proto arenas.

**Understanding the Problem**

The destructor for [redacted] is expensive, indicating
that it is not being allocated in an efficient way. Proto arenas
are a way to manage the allocation and deallocation of protocol
buffer messages in a more efficient way, especially in
high-throughput applications.

**Code Changes**

Here's the diff of the necessary code changes in
[redacted]:

**Explanation of Changes:**

1. **Include arena_safe_unique_ptr.h:** We need to include the
header file that provides proto2::ArenaSafeUniquePtr.
2. **Declare proto2::Arena:** We declare an proto2::Arena
object named arena_ before the declaration of [redacted].
This arena object will be used to allocate the [redacted]
proto.
3. **Replace [redacted] with
proto2::ArenaSafeUniquePtr<[redacted]>:**
The [redacted] member is now of type
proto2::ArenaSafeUniquePtr<[redacted]>.
4. **Allocate [redacted] on the arena:** We use
proto2::MakeArenaSafeUnique<[redacted]>(
&arena_) to allocate the [redacted] proto on the arena when
setting or swapping a new [redacted].
5. **Use pointer semantics:** We use pointer semantics (* or ->)
to access the underlying [redacted] proto. We now check
if the pointer [redacted] is not null and use the pointer
to access the proto.
6. **Clear [redacted]:** Use .reset() instead of =
std::nullopt to clear the [redacted] pointer.

**Impact of Changes**

*   **Improved destructor performance:** The destructor of
[redacted] will be faster because the arena will
deallocate all the allocated [redacted] objects at once,
avoiding the need to recursively call destructors.
*   **Potentially reduced memory fragmentation:** Arena
allocation can reduce memory fragmentation, as all
arena-allocated objects are released together.
*   **Reduced allocation overhead:** Arena-based allocation is
faster than standard new and delete.

**Additional Notes**

*   It is important to note that if [redacted] is used
in a context where the [redacted] is frequently set and
cleared, then the arena might grow significantly, and it might
be advantageous to reset the arena periodically.
*   The provided solution assumes that [redacted] does
```

```
not need to return a raw pointer to the [redacted]. If this
is needed, then it is necessary to return the raw pointer from
the [redacted]member.

This approach leverages the efficiency of proto arenas to
optimize the performance of [redacted]and its handling
of the [redacted]member.

B.4 ReAct

When using ReAct, the LLM is invoked multiple times. In each step, it is given the full trajectory of the execution so far. The given prompt format will induce the model to follow a particular structure that results in it generating a "Thought" followed by an "Action", which is an executable command. The model knows this structure from its pre-training data, which included ReAct examples (an alternative approach would be to provide examples of the desired structure as few-shot examples in the prompt itself). The action is then executed, the output of the action is copied back into the prompt, and the next iteration begins. The final action results in the generation of a diff.

Prompt 7: Example ReAct prompt.

````
# Instruction :
Make a performance enhancing code edit that accomplishes the following:
```txt
Restricts the lambda capture scope
```
# Thought:
We need to first take a look at the source code.
# Action:

C Multi-File Edits

Although the bulk of this paper uses examples with single-function edits, ECO is not restricted to function-level edits. ECO uses an LLM fine-tuned with multi-file code changes and the techniques used in ECO apply to multi-file edits as well: e.g., localizing through code embeddings; targeted prompting for generating code optimizations; and validation through testing, self-review, and code reviews.

We recently expanded ECO to apply more multi-file code changes and we have found that the primary difference between multi-file and function-level edits is a necessity for descriptive prompting. For example, one of our anti-patterns involves optimizing usage of protocol buffers [71]. These protocol buffer edits are particularly complex because they can involve changes across multiple files (often >5 files at a time). Providing more detailed instructions in the prompts for these edits allows us to ensure that all multi-file dependencies/references are captured in the generated edit.

Prompt 5 shows a prompt that allowed us to effectively generate multi-file protocol buffer edits, and Code Diffs 9 and 10 show edits generated with the prompt.

Code Diff 9: File 1 of a change generated with Prompt 5.

D Self-Validation

We provide an example of LLM self-validation for edits generated to fix missing vector reserves (Figure 3b). For evaluation of these edits, we prompt the LLM to answer several questions:

1. Is the reserved amount in the vector appropriate?
2. Is the `push_back` of elements in the vector happening within the scope of a conditional block like `if`? (We want to avoid reserving when we cannot pre-determine the vector size.)
3. Is the vector being modified in the surrounding code and are there `push_back`s happening outside the context of a for-loop? (If yes, we want to avoid reserving to avoid miscalculations.)
4. Does the reserve count in vector depend on nested for-loops? (We want to avoid reserving when we cannot easily compute the nested loop values.)

Prompt 11 provides an example of a self-validation prompt template for the first question. When given Code Snippet 12, the LLM validation returns "No" as shown in Response 13. An example code snippet that receives the opposite response ("Yes") is shown in Code Snippet 14 and Response 15.

Prompt 11: Example of a self-validation prompt.

```
You are an expert C++ performance engineer tasked with reviewing code. Your goal is to assess the quality of a code snippet which seeks to preallocate a
vector to avoid reallocations when elements are continuously added in a for loop. You will be presented with a code and a question.

  Code:
  ```cpp
  { target snippet }
  ```

  Question:
  Is the reserved amount in the vector { target vector } appropriate (only reserve when we know the exact size in advance)? (Yes or No)
```

Code Snippet 12: Example input code for Prompt 11.

```
[redacted]<std::vector<std::string>> [redacted](
    const [redacted]& [redacted], [redacted]<const std::string> input_full_names) {
  [redacted]
  std::vector<std::string> input_paths;
  input_paths.reserve(input_full_names.size());
  std::vector<std::string> missing_full_names;
  [redacted]
  [redacted]<std::string, std::string> [redacted]_map;
  for (const auto& data : [redacted].inputs()) {
    [redacted]_map[data.full_name()] = data.path();
  }
  [redacted]
  for (const std::string& input_full_name : input_full_names) {
    if (auto it = [redacted]_map.find(input_full_name);
        it != [redacted]_map.end()) {
      input_paths.push_back(it->second);
    } else {
      missing_full_names.push_back(input_full_name);
    }
  }
  [redacted]
  if (!missing_full_names.empty())
    return [redacted]Error(
        [redacted]("No paths found in input data for below full names: ",
                   [redacted]StrJoin(missing_full_names, ",")));
  [redacted]
  return input_paths;
}
```

Response 13: LLM response to Prompt 11 with input Code 12.

Okay, let's analyze the `reserve` call in the provided C++ code snippet.

Analysis:

The code aims to find matching paths from a `[redacted]` based on a list of `input_full_names`. It builds a hash map for quick lookup and then iterates through the `input_full_names`. If a name is found in the map, its corresponding path is added to the `input_paths` vector. If not, the name is added to a `missing_full_names` vector, and if this vector is non-empty at the end of the iteration, an error will be returned.

The relevant line is:

```c++
input_paths.reserve(input_full_names.size());
```

Here's a breakdown of whether the `reserve` is appropriate:

* **Worst-Case Scenario:** The code reserves space for `input_full_names.size()` elements. This is the *maximum* number of paths that could be added to `input_paths`. This happens only when all `input_full_names` exist in `[redacted].inputs()`.
* **Likely Scenario:** It's possible (and perhaps even probable) that some of the `input_full_names` will *not* be found in the `[redacted]_map`. In this case, the `reserve` call will have allocated *more* space than necessary.
* **Exact size unknown**: We do not know the exact size of the vector in advance.

Conclusion and Explanation:
The `reserve` call is *not perfectly appropriate* because it reserves the maximum possible size, not the *exact* size. The exact size is not known beforehand, because not all names in `input_full_names` are guaranteed to be found in `[redacted].inputs()`. A more precise `reserve` would be impossible without iterating through `input_full_names` and checking the map first, which would duplicate the work of the main loop.

The current `reserve` is a reasonable optimization, as it avoids reallocations in the best-case/worst-case scenario where all names are found. However, it may lead to over-allocation in other cases. The performance benefit of the current approach likely outweighs the potential cost of over-allocation in most realistic scenarios, especially if the expected number of missing names is small compared to the total number of names. If we knew, for instance, that 99% of names were always present, the current approach would be very efficient.

Answer:

No

Code Snippet 14: Example input code for Prompt 11.

```
std::vector<[redacted]>::[redacted]>
[redacted](const std::vector<int> criterions) {
  std::vector<[redacted]::[redacted]> criterion;
  criterion.reserve(criterions.size());
  for (auto id : criterions) {
    [redacted]::[redacted] tc;
    tc.mutable_criterion()->set_criterion_id(id);
    criterion.push_back(tc);
  }
  return criterion;
}
```

Response 15: LLM response to Prompt 11 with input Code 14.

Okay, let's analyze the code snippet and answer the question.

Code Analysis

The code aims to create a vector of `[redacted]` objects. It takes a vector of integers (`criterions`) as input. For each integer in the input vector, it creates a `[redacted]` object, sets its `criterion_id`, and then adds it to the output vector `criterion`. The core of the question is the use of `criterion.reserve(criterions.size());`.

Explanation and Answer

* **`reserve()` vs. `resize()`:** It's crucial to distinguish between `reserve()` and `resize()`.
  * `reserve(n)`: Allocates enough memory to hold `n` elements *without* changing the size of the vector (i.e., `vector.size()` remains unchanged). Future `push_back()` operations (up to `n` elements) will not trigger reallocations, which are expensive.
  * `resize(n)`: Changes the size of the vector to `n`. If `n` is larger than the current size, the vector is expanded, and new elements are value-initialized (or default-constructed for objects). If `n` is smaller, the vector is truncated.

* **Appropriateness of `reserve()` in this case:** The code correctly uses `reserve(criterions.size())`. The loop iterates exactly `criterions.size()` times, and each iteration adds one element to the `criterion` vector. Therefore, we *know* the final size of the `criterion` vector in advance: it will be equal to `criterions.size()`. Using `reserve()` is the optimal approach here. It prevents any reallocations during the loop, leading to better performance, especially when `criterions.size()` is large.

* **Why not `resize()`?** Using `resize(criterions.size())` would be *incorrect* and potentially less efficient. `resize()` would create `criterions.size()` default-constructed `[redacted]` objects *before* the loop. The loop would then *copy* into these existing objects. The initial default construction is wasteful, and depending on the compiler and standard library implementation, might even be *less* efficient than the reserve-then-copy approach, as resize can also call the copy constructor to grow the container. `resize` also affects the `size()` of the vector, which is not the intent. We want the size to grow naturally with the `push_back` calls.

* **Worst case scenario with no `reserve()`:** Without the `reserve()` call, the `std::vector` would start with a small allocated capacity. As elements are added via `push_back()`, the vector would need to reallocate its internal storage multiple times. Each reallocation involves:
  1. Allocating a new, larger memory block.
  2. Copying all existing elements from the old memory block to the new one.
  3. Deallocating the old memory block.

  This reallocation process is O(N) in time complexity, and if it happens repeatedly, the overall performance degrades to O(N^2) in the worst case (though `std::vector` implementations typically use an exponential growth strategy to mitigate this).

Conclusion

The use of `reserve()` is appropriate and beneficial in this code. We know the exact size of the vector in advance, and `reserve()` is used to allocate the memory upfront, preventing costly reallocations.

Answer to the Question:

Yes

E Interactions of ECO and Code Review

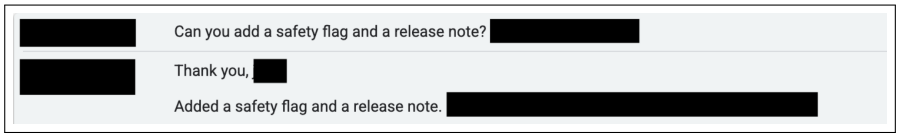
For every change generated by ECO, a human code owner is asked to review the change before the change is submitted to production. For 40%, 5%, and 41% of copy, map, and vector changes, respectively, ECO-generated changes were directly approved and submitted to production without the human reviewers leaving any feedback that had to be resolved. Table 5 in the main portion of the paper shows a breakdown of when additional action was required. We now provide a few examples of these specific reviewer interactions below.

Oftentimes, users left comments that were extraneous to the efficiency optimization on the code change (`S_USER` in Table 5). These comments had to be addressed before the code change was submitted to production. Figure 12a shows an example of feedback provided for a change that was submitted to production after reviewer comments were resolved.

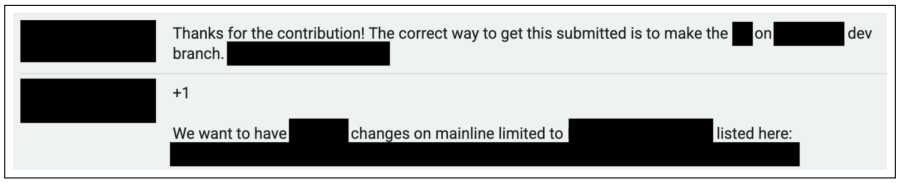
Other times, users rejected changes (`R_USER` in Table 5) and the changes were not submitted to production. This could be due to the human reviewer judging the code change to actually not be performance enhancing or the human reviewer wanting the code to be untouched for other reasons (e.g., style preferences). Figure 12b provides an example of such feedback.

ECO has also encountered code changes where feedback from human reviewers has caused regressions not initially present. For example, ECO generated the change in Code Diff 16. This change attempts to remove the redundant map lookups on `opt_out_handler_`. The reviewer for this change suggested using `try_emplace` instead, and in response to the reviewer's comments, the code was modified as reflected in Code Diff 17.

However `try_emplace` evaluates its argument expression every time, regardless of whether an insertion has occurred. This led to many calls to `make_unique` and caused a large increase in CPU consumption. Due to the regression, the change had to be reverted (`R_REVERT` in Table 5).



(a) Feedback that had to be resolved before ECO's change was submitted to production.



(b) Feedback rejecting change due to reasons unrelated to code performance.

Figure 12: Examples of reviewer feedback.

Code Diff 16: Initial ECO-generated code diff.

F Reproducibility

Since ECO is built for Google, the majority of ECO-generated changes shown in this paper have been targeted at Google's code base. However, ECO's techniques can be applied in the context of other organizations' systems infrastructure and code bases. Today, there are many open-source LLMs [72–74] that can be fine-tuned with open-source libraries or with LLM offerings [75–78]. Our methods for identifying performance opportunities and localizing candidate code can also be replicated using various open-source performance profiling tools [79] and similarity-search libraries like ScaNN [15], with required resources scaling with the size of the organization's code base.

Additionally, ECO has generated code changes not only on Google's code base but also on open-source code. Code Diff 18 shows an example of a change generated by ECO on TensorFlow (https://github.com/tensorflow/tensorflow) [80]. This change removes a redundant map lookup and was committed into TensorFlow's upstream repository [81].

Code Diff 18: Example of a code change generated on open-source code.

G Comparison With Static Analysis

Table 6 describes 6 different common sub-optimal vector-reserve patterns and lists whether or not static analysis are able to resolve them. 5 out of the 6 are not resolvable with Clang-Tidy and none are optimized by CppCheck, whereas ECO is able to optimize each one. The table also shows speedup results from ECO optimizations on microbenchmarks, run against varying container sizes (from 8 to 4096 elements). Here we describe each vector-reserve pattern in more detail.

Pattern A: Standard Loop Insertion Clang-Tidy and ECO are both able to optimize loops using standard library vector insertions such as `.push_back`.

Code Snippet 19: Optimization example for Pattern A.

```
dirs.reserve(groups_.size());
for (Group g : groups_) {
    dirs.push_back(GroupDir(g));
}
```

Pattern B: Bulk Move via Algorithms This pattern moves elements into a destination vector using an algorithm wrapper (e.g., `absl::c_move` with `std::back_inserter`).

Code Snippet 20: Optimization example for Pattern B.

```
result_entities.reserve(result_entities.size() + source_entities.size());
absl::c_move(source_entities, std::back_inserter(result_entities));
```

Clang-Tidy fails here because the insertion is encapsulated inside an algorithm wrapper and iterator adapter, leaving no explicit loop in the local AST. ECO is able to recognize the element transfer semantics and recommends reserving.

Pattern C: Iterator-based Assignment on Custom Containers In production, developers frequently populate proprietary containers, such as a protocol buffers in a `RepeatedPtrField`. In the example below, `cache_value` is a protocol buffer.

Code Snippet 21: Optimization example for Pattern C.

```
cache_value.mutable_entities()->Reserve(result.entities.size());
*cache_value.mutable_entities() = {result.entities.begin(), result.entities.end()};
```

Clang-Tidy fails because its analysis rules are hardcoded for standard library types (mainly `std::vector`). It cannot reason about custom APIs or allocations triggered implicitly via assignment operators and initializer lists. By using an LLM, ECO can leverage learned API signatures to suggest the custom container's `Reserve()` method.

Pattern D: Generic Template Sizing & Iterators Generic, templated code is commonly used to write reusable copy utilities.

Code Snippet 22: Optimization example for Pattern D.

```
template <typename Range>
std::vector<Entity> Copy(const Range& source) {
  std::vector<Entity> destination;
  destination.reserve(source.size());
  destination.insert(destination.end(), source.begin(), source.end());
  return destination;
}
```

At analysis time, Clang-Tidy cannot resolve the exact type of the template parameter `Range`. It systematically ignores uninstantiated parameters to avoid risking broken code or generating complex fallback rule paths. LLMs are able to infer the range properties of abstract types and apply block insertions.

Pattern E: Inter-Procedural / Multi-file Size Mappings In complex systems, sizing information is often decoupled and evaluated across functional or compilation unit boundaries.

Code Snippet 23: Optimization example for Pattern E.

```
// Sub-optimal Implementation
void PopulateStats(const std::vector<Entity>& src, std::vector<Entity>& dest) {
  for (const auto& item : src) {
    if (item.isValid) { dest.push_back(item); }
  }
}

// Optimized Implementation
void PopulateStats(const std::vector<Entity>& src, const CollectionStats& stats, std::vector<Entity>& dest) {
  dest.reserve(stats.total_size);
  for (const auto& item : src) {
    if (item.isValid) { dest.push_back(item); }
  }
}
```

Clang-Tidy is limited to single-file compilation units and cannot trace size constraints spanning inter-procedural boundaries. Additionally, conditional loops prevent direct mapping of `src.size()`. With an LLM, ECO can map dependencies across compilation boundaries to recommend a `.reserve()` utilizing the pre-calculated size member (`stats.total_size`).

Pattern F: Custom Pointer Array Buffers This pattern involves custom logging or cache buffers that store object pointers instead of copying full structures. In this case, `buffer` is a custom, dynamically sized data structure that holds a set of pointers, which can be added to it using `Add`.

Code Snippet 24: Optimization example for Pattern F.

```
buffer.Reserve(source.size());
for (auto& item : source) { buffer.Add(&item); }
```

Similar to Pattern B, Clang-Tidy ignores this loop because the container is a custom class and uses a non-standard insertion method (`.Add()`). Clang-Tidy has no semantic awareness that `.Add()` triggers underlying array expansions. LLMs can identify the custom buffer's memory semantics and suggest a `Reserve()` call.

StriaTrace: Efficient Tracing and Diagnosis for Online LLM Inference (Operational Systems)

Haonan Wu[1,2] Yanqing Chen[2] Kun Qian[2] Xue Li[2] Jingbo Xu[2]
Erci Xu[1*] Ennan Zhai[2] Wenyuan Yu[2] Guangtao Xue[1,3] Jingren Zhou[2]

Abstract

Large Language Model (LLM) inference services in production operate under stringent, fine-grained Service Level Objectives (SLOs). Unlike throughput-oriented LLM training, even sporadic performance anomalies during inference can violate SLOs, underscoring the need for improved tracing and diagnosis solutions. However, existing solutions face two primary limitations: (1) existing tracing tools incur prohibitive overhead; (2) training-centric diagnosis tools are ill-suited for capturing sporadic inference anomalies.

To bridge these gaps, we propose StriaTrace, a novel tracing and diagnosis system tailored for online LLM inference. StriaTrace is built upon three principles distilled from production experience: (1) tracing key synchronization points, (2) tracing critical paths, and (3) detailed tracing only during abnormalities. StriaTrace further constructs a dynamic regression-based roofline model and correlation-based diagnosis to identify why each LLM inference abnormality happens. Evaluations show that StriaTrace reduces tracing overhead by 97.8% relative to alternatives. StriaTrace has been widely used in our development, testing, and production release cycles, and has successfully diagnosed hundreds of abnormalities spanning 19 distinct root causes.

1 Introduction

Large Language Models (LLMs) have emerged as a transformative technology, underpinning diverse applications such as chatbots, content generation, code completion, and scientific discovery. Different from classical Internet services (*e.g.,* web-search and e-commerce), running LLM inference focuses not only on satisfying the end-to-end request response time (*i.e.,* Time To First Token, TTFT) but also on optimizing the performance of each generated token (*i.e.,* Time Per Output Token, TPOT). To improve performance, modern LLM inference systems [17,28,40,46,52] employ sophisticated distributed architectures with advanced optimization techniques such as prefix caching, prefill/decode disaggregation [20,37,53], and various types of parallelism strategies [6,15,23,24,36,38,39,41,51].

However, high throughput does not guarantee high Quality-of-Service (QoS). In production, the common Service Level Objective (SLO) of TTFT is 10s, and the SLO for TPOT is 100ms. Our field analysis on a 2K instance cluster shows that, while the majority of requests have a 3.06s TTFT and 24.83ms TPOT on average, the tails (*i.e.,* 99th percentile) exhibit high variance and consistently exceed SLOs. Despite rigorous unit, sandbox, and end-to-end testing typical of large-scale systems, anomalies persist. We attribute these persistent anomalies to two fundamental factors. First, LLM inference is inherently streaming; it thus becomes extremely difficult to reproduce exact online workloads and execution environment in offline testing [11,50]. Moreover, the series of optimizations (*e.g.,* global prefix KV cache and prefill/decode disaggregation), while facilitating the performance of inference service, actually introduce extra complexity along the stack, requiring more effort for diagnosis.

This operational reality necessitates an end-to-end, detailed and continuous tracing system which can capture abnormal runtime events and expedite the diagnosis via automation. Unfortunately, all existing solutions fall short. General-purpose tracing tools from classical distributed systems primarily focus on CPU-related anomalies and lack the telemetry sources needed to capture GPU-centric performance issues. While specialized LLM profiling tools (*e.g.,* TorchProfiler [35] and Nsight [27]) can capture fine-grained execution traces in LLM contexts, they typically introduce significant performance overhead (ranging from 10% to 20%), making them unsuitable for continuous runtime tracing in production under the demanding SLOs.

On the other hand, emerging LLM-specific diagnostic approaches (*e.g.,* Aegis [9], Mycroft [8] and PerfTracker [13]) mainly target the LLM training scenario. They are also ill-suited for inference workloads due to fundamental differences in workload characteristics. First, LLM training is throughput-oriented while inference is latency-sensitive. In LLM training, only significant performance degradation (*i.e.,* persist-

*Corresponding author: Erci Xu, Email: jostep90@gmail.com

ing stragglers) is fatal for overall throughput, and existing solutions are focusing on these issues. However, in LLM inference, sporadic abnormalities can be fatal, directly causing SLO violations and thus impacting end users' experience [42]. The other key difference is that the LLM training workloads exhibit static execution patterns with fixed batch size and sequence length, and existing solutions rely on these characteristics to facilitate the diagnosis and alleviate overhead. However, in LLM inference scenarios, all requests are generated by end users, therefore these proposed diagnosis rules (*e.g.,* fixed-threshold-based straggler diagnosis in Mycroft [8]) are not directly applicable to the dynamic inference workload.

This paper presents StriaTrace, a novel tracing and diagnosis system specifically designed for online LLM inference services. The primary challenge is low-overhead continuous tracing. To address this challenge, we identify the minimal set of information required to pinpoint root causes of various issues in the inference context and distill three key principles for efficient telemetry collection.

First, effective root-cause diagnosis always relies on observing all cross-machine and cross-process interaction points. Guided by this principle, we identify the essential synchronization locations in typical distributed inference workflows, reducing the number of CPU-side instrumentation points from $O(1000)$ functions to $O(10)$ critical sites, significantly lowering CPU tracing overhead (§5.2).

Second, our operational experience in diagnosing real-world inference issues suggests that, leveraging the deterministic sequential dependencies in inference execution, accurate tracing of the critical path alone suffices to infer anomalies in non-critical paths. The extensive use of parallelism strategies and overlapping mechanisms allows us to focus only on changes in the critical path. Leveraging this insight, we optimize GPU-side tracing collection to focus only on GPU kernel execution and memory copy, thereby significantly reducing GPU tracing overhead by up to 97.5% (§5.3).

Third, although traces are generated for all tokens from all requests, only traces captured during ephemeral abnormalities are critical. Therefore, we need localized real-time diagnosis and filtering to further reduce the transmission cost. Building an online real-time diagnosis fitting the inference scenario is another key challenge. To achieve this, we propose a step-level autoregressive roofline model for LLM inference. This roofline model delivers two key benefits: (1) it enables in-situ, distributed anomaly detection directly within the inference process; (2) it enables distributed filtering based on roofline deviations, reporting only anomalous segments to the global analyzer—dramatically reducing data transmission and backend analysis overhead. In the centralized analyzer, correlation analysis is conducted among different types of traces to pinpoint the primary suspects for each abnormality. We further pre-correlate and persistently store the collected raw traces according to inference semantics, thereby avoiding time-consuming repeated memory accesses and on-the-fly correlation at scale (§5.4).

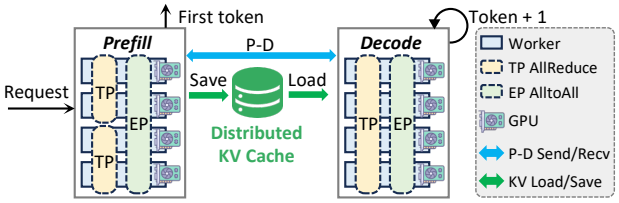

Figure 1: A typical LLM inference workflow with (1) prefix cache, (2) prefill/decode disaggregation and (3) TP+EP.

Our evaluation shows that StriaTrace consistently keeps the tracing overhead to less than 1%, which is 97.8% less compared to existing approaches. StriaTrace has been widely employed in our development, testing and release cycles. StriaTrace has successfully helped us diagnose 19 different root causes of abnormalities and diagnosed several issues that were intractable with conventional tools (§6 and §7). In production, StriaTrace has been running at scale for six months, instrumenting over 1,700 instances across two flagship LLM services and processing upwards of 180 million requests per day. It operates under both TP and DP configurations, and spans monolithic as well as PD-disaggregated deployments. We present the traces and diagnosis results in production in the appendix.

2 Background

Inference workflow. LLM inference follows a prefill-decode workflow. Upon receiving a request, the service initiates the prefill stage to process the input prompt. Then, the first output token is generated and this interval is measured as TTFT. Then, the service proceeds to the decode stage. In each step, the next token is generated based on the current sequence context. At this stage, we measure the TPOT, defined as the inter-token latency between generating token$_i$ and token$_{i+1}$. In production, we typically enforce SLOs of approximately 5-10 s for TTFT and 50-100 ms for TPOT. To better meet the SLOs, we employ a combination of techniques illustrated in Figure 1 and discussed as follows.

Distributed prefix KV cache. The core idea is to reuse KV cache that shares the same prefix across multiple requests. Before prefill, each request attempts to load its matching prefix from a distributed KV cache, while newly generated KV cache during prefill is written back. This approach requires synchronization and data transfer across processes and machines, and substantially improves TTFT.

Prefill/decode disaggregation. This architecture partitions serving instances into distinct prefill and decode pools. After a request completes prefill, the resulting KV cache and the request are transferred to a decode instance. Since prefill is compute-bound while decode is memory-bound, separation enables independent resource allocation and scheduling for each phase.

Inference parallelism. Model parallelism, specifically Tensor Parallelism (TP) and Expert Parallelism (EP), is commonly used in practice. In TP, each Attention or Feed-Forward Network (FFN) layer is partitioned across workers; each worker executes a portion of the computation and synchronizes results with each other. In EP, each token's computation is routed to a subset of experts, and the outputs are subsequently aggregated.

3 Motivation

3.1 Pervasive Performance Degradation

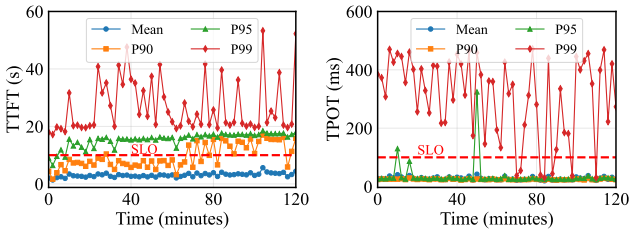
Despite the optimizations in §2, we observe that the average TTFT and TPOT remain within acceptable bounds but the tails of both can still experience severe SLO violations. Figure 2 shows the distribution of TTFT and TPOT from average to 99th percentile in a large-scale commercial LLM chatbot hosted on our platform. Specifically, this inference service contains more than 2K instances and processes 14M requests every day. There are 5.34% of requests violating the TTFT SLO and 1.18% of tokens violating the TPOT SLO.

In this paper, the tail latency is defined by *system-induced*, rather than the semantic variance. A long-tail therefore refers to a latency deviation when executing the *same computational workload* compared to its historical distribution. For instance, a prefix cache miss can drastically enlarge TTFT. However, from the inference engine's perspective, a cache miss simply entails a larger number of tokens to be actually computed during prefill. The resulting TTFT elongation due to increased computation workload is not considered a long-tail. Once semantic variance is factored out, the remaining system-induced tail latency directly manifests as stalls in the TTFT and TPOT.

The criticality of mitigating tail latencies cannot be overstated. Most LLM inference services are human-interactive, *e.g.,* chatbots, AI assistants and coding. Even occasional SLO violations are easily perceived by customers and lead to user-experience degradation. Such degradation severely impacts user retention, resulting in millions of dollars in revenue loss. However, taming tail latencies is non-trivial. First, Figure 2 shows that the tails of TTFT and TPOT exhibit high variance, *i.e.,* slow tokens can be occasional or even one-off events. In addition, as an online service, the workload is intrinsically dynamic, rendering offline reproduction ineffective. Hence, diagnosing the culprits often requires an intensive manual effort. For example, engineers must hypothesize potential performance issues based on experience, add logging statements at suspected code locations, build and deploy a new release, and then repeat this cycle.

3.2 Limitations of Existing Solutions

Although both industry and academia have proposed numerous diagnostic tools, with some even directly targeting LLM scenarios (*e.g.,* Neutrino [14], Mycroft [8] and Minder [7]), these solutions prove fundamentally ill-suited for production LLM inference.



(a) TTFT. (b) TPOT.

Figure 2: TTFT/TPOT spikes are pervasive in production.

High overhead. As shown in Table 1, several tools [4, 10, 14, 27, 29, 34, 35] are tailored for fine-grained tracing. However, our preliminary attempts at integrating these tools proved unsuccessful. The primary impediment is their prohibitive overhead. For example, Neutrino [14] is the state-of-the-art GPU tracing tool, but it may introduce overhead such as ~5% throughput loss due to the intensive memory I/O. We observed comparable or higher overheads when evaluating TorchProfiler [35], Nsight [27] and PerfTracker [13]. Even single-digit overhead is consequential. Owing to the high CapEx and OpEx of running a GPU-based cluster and the scale of today's LLM inference, a 5% loss can easily translate to a multi-million dollar cost increase. As a result, we restrict the usage of these tools on a subset of severe latency anomalies and facilitate certain offline debugging procedures.

Challenge 1: Achieving always-on tracing with negligible overhead.

Inapplicability to inference. A number of diagnostic approaches [7–9, 13] specifically for LLM training have recently emerged, aiming to pinpoint the root causes through cross-layer information collection and correlation analysis. Nevertheless, these approaches fall short as well. First, training scenarios are throughput-oriented. Consequently, anomaly detection in training targets persistent stragglers rather than the transient latency spikes. This focus, however, makes it ill-suited for tracing inference workloads. For example, Mycroft [8] employs coarse-grained (second-level) thresholds to identify performance degradations, and Minder [7] even takes several minutes to identify abnormalities. Moreover, LLM training exhibits highly regular, repetitive execution patterns due to fixed batch size and static computational graphs, which can be leveraged to identify stragglers via peer comparison within a synchronous data-parallel group. Inference workloads exhibit significant variance in batch size and sequence length, thus precluding such direct comparisons.

Challenge 2: Accurate diagnosis tailored for dynamic and sporadic inference anomalies.

Table 1: Limitations of existing solutions

Solutions	Data Source†	Overhead	Temporal Strategy	Runtime Diagnosis
TorchProfiler [35]	CPU+GPU	10-20%	On Demand	✗
PyStack [31]/py-spy [30]	Only CPU	<1%	Sample	✗
eBPF [29]	Only CPU	10-20%	Continuous	✗
Scalene [4]	CPU + partial GPU	<5%	Sample	✗
Nsight [27]	Partial CPU + GPU	10-20%	On Demand	✗
Neutrino [14]	Only GPU	∼5%	Continuous	✗
Aegis [9]	Only Comm	<1%	Continuous	Training
Minder [7]	Metric	<1%	Continuous	Training
Mycroft [8]	Only Comm	<1%	Continuous	Training

StriaTrace (Our Solution)	CPU+GPU	∼1%	Continuous	Inference

† Complete GPU tracing data can cover Comm tracing data, since all collective communication is launched by GPU kernels.

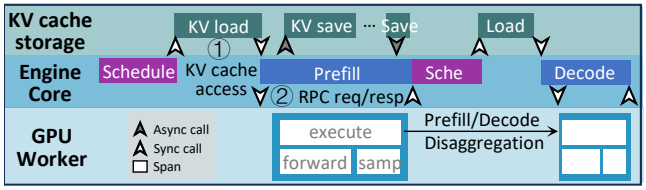

Figure 3: Key synchronization points.

4 Exploring Design Space

To achieve low-overhead and continuous tracing of online inference services, we formulate three design principles grounded in production experience.

Principle 1: Instrument synchronization barriers rather than internal functions. An inference request can traverse complex stages from entry to response. In our profiling, there can be $O(100)$ functions and $O(10K)$ function calls in an inference step (more details in §5.2.1). Tracing each of them would introduce prohibitive overhead. Among these functions, a subset constitutes the key synchronization functions which can be categorized into two types. The first is *inter-process RPC within the inference engine itself*. For example, in vLLM [46], the EngineCore responsible for request scheduling and the GPUWorker responsible for actual computation interact through collective RPC calls (labeled ② in Figure 3). The second is *function calls between the inference engine and external components*. For instance, the engine invokes metadata queries and I/O operations on external KV cache components, as labeled ① in Figure 3. These synchronization points gate the progression of the request to the next stage. Consequently, a core design decision of our tracing system is to instrument at these synchronization boundaries rather than exhaustive profiling.

Principle 2: Prioritize critical path profiling over exhaustive tracing. Even when restricting instrumentation to only synchronization points, exhaustively tracing every event within a request's lifecycle still incurs prohibitive overhead. The root cause lies in the internal concurrency of inference engines. For example, in vLLM, the EngineCore runs multiple concurrent threads: the main inference thread that orchestrates request execution, a dedicated thread for distributed KV cache access, and additional threads for monitoring and metrics collection, etc. Among these concurrent threads, only the main inference thread lies on the critical path that determines the request's completion time. Consequently, our tracing design prioritizes the critical path while discarding detailed tracing for non-critical threads.

Principle 3: Employ anomaly-driven high-fidelity tracing. Approaches employing *full persistence*, *e.g.,* TorchProfiler [35] and Nsight [27], capture all tracing data and lead to a tremendous bandwidth cost (see more details in §6.2). Conversely, *summarized/partial persistence*, *e.g.,* PerfTracker [13], Aegis [9] and Mycroft [8], sacrifices full-fidelity information to achieve lower transmission and storage overhead. However, they lack enough information to pinpoint the culprit in the inference scenario (as discussed in §3.2). Our field experience and statistics show that the vast majority of requests exhibit nominal behavior, and only a small fraction of requests are outliers. Therefore, we adopt *selective persistence*, *i.e.,* only retaining fine-grained tracing data for slow requests.

5 Design

We introduce StriaTrace, a low-overhead tracing and diagnosis tool for LLM inference. We detail the instrumentation mechanisms for CPU and GPU in §5.2 and §5.3, respectively. Finally, §5.4 explains how StriaTrace leverages the collected traces to identify performance anomalies.

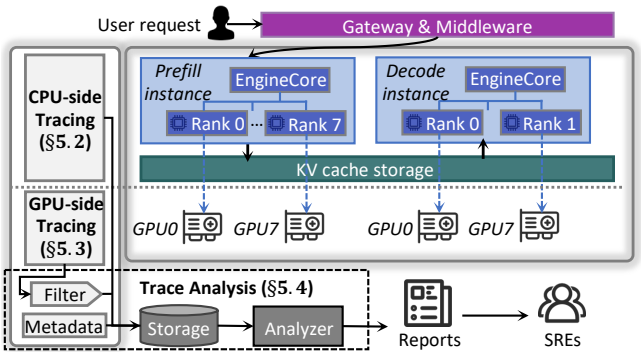

Figure 4: Overview of StriaTrace.

Table 2: Host-side function invocation statistics and instrumentation scope in a single step.

	EngineCore	Worker (P)	Worker (D)
Function types	182	493	284
Function calls	10,000+	3,588	953
StriaTrace spans	13	32	

5.1 Overview

As shown in Figure 4, StriaTrace comprises two components: distributed trace collectors co-located with each serving instance, and a centralized backend for data persistence and analysis. In this paper, a serving instance refers to a vLLM process group on a multi-GPU node.

On the **CPU side** (§5.2), StriaTrace's observability is confined to the vLLM serving instance. For each instance, StriaTrace focuses on the following components: (1) the EngineCore, which handles request scheduling and KV cache management; (2) the parallel ranks (i.e., GPUWorkers), each responsible for token computation on a dedicated GPU. As illustrated in Figure 3, a request's processing flow involves the EngineCore resolving prefix cache and scheduling, followed by RPC dispatch to GPUWorkers for execution, with KV cache I/O interactions with external components. On the **GPU side** (§5.3), StriaTrace operates concurrently on each GPUWorker, capturing kernel executions and memory transfers.

Collectively, StriaTrace records three types of trace data: (1) CPU-side traces, which record the processing latency across system modules; (2) GPU-side traces, which capture hardware-level execution; and (3) essential metadata, including the request ID and the instance IDs traversed by the request to reconstruct the causal chain. These traces are streamed to a centralized analysis backend (§5.4). The backend correlates these heterogeneous streams to reconstruct the complete execution flow of each request. It then leverages a performance roofline model to detect outliers and automatically reports anomalies.

5.2 Host-side Tracing

5.2.1 Coarse-grained Instrumentation

Designed for production monitoring, StriaTrace eschews the exhaustive function-level profiling employed by tools like cProfile [32]. Applying such pervasive profiling to high-throughput engines can incur prohibitive overhead. To quantify the cost, we conduct pervasive profiling on a vLLM instance serving Qwen2.5-0.5B [43]. As shown in Table 2, vLLM's EngineCore executes over 10,000 function calls in a single inference step, while the GPUWorker still triggers thousands of calls during prefill. Consequently, employing pervasive profiling would inflate the latency by tens of milliseconds, which is unacceptable for online inference serving. Following **Principle 1**, StriaTrace employs a hybrid instrumentation strategy to balance visibility and overhead:

Synchronization barrier instrumentation. First, we delineate the critical execution path of the inference engine. Modern inference engines (*e.g.,* vLLM) generally operate on an event-loop mode: cyclically fetching incoming requests, allocating KV cache, and performing per-token inference. Based on this architecture, StriaTrace strategically places tracing hooks at *cross-process synchronization boundaries* along the main loop. Specifically, we categorize these barriers into two types: (1) *Intra-engine cross-process RPCs*: Within vLLM, communication channels among the frontend API server, the EngineCore, and the distributed GPU workers are inherently mediated via Remote Procedure Calls (RPCs). Instrumenting these RPC boundaries naturally covers the inter-process scheduling and orchestration. (2) *Synchronous invocations with external processes*: We also trace mandatory blocking calls to external processes on the main loop. A prime example is the KV cache connector—the dedicated interface class responsible for querying and synchronizing with the distributed KV cache. Targeting these communication boundaries, StriaTrace strictly delimits execution stages and captures blocking latencies without exhaustive profiling.

Semantic span instrumentation. StriaTrace further subdivides the monolithic phases between synchronization barriers into semantic spans. Functionally, a semantic span delimits the execution of a specific logical routine along the inference critical path. In practice, the selection of semantic spans typically aligns with the top-level function invocations between two consecutive synchronization barriers. For instance, we partition the vLLM engine core's execution flow into distinct spans: `schedule` (managing request queues and allocating KV cache), `execute_model` (invoking the forward pass), and `sample_tokens` (generating output tokens based on logits). Crucially, StriaTrace goes beyond mere latency tracking by enriching these semantic spans with runtime context. For example, alongside the `schedule` span, StriaTrace records the batch-level metadata, including the number of

scheduled requests and their respective token status[1]. This context preservation is vital for correlating latency anomalies with workload dynamics. Details of these instrumentation points are provided in Appendix A.

Collectively, these two strategies comprise only dozens of instrumentation points—orders of magnitude fewer than the total function calls in each inference step. This design renders runtime overhead negligible while preserving structural visibility into the system's behavior.

5.2.2 Fine-grained Context Profiling

Through the key instrumentation points in §5.2.1, StriaTrace establishes macro-level observability over the CPU execution. However, when a performance anomaly occurs, this coarse-grained telemetry lacks the fidelity to pinpoint the specific code paths or internal function calls responsible for the anomaly. To bridge this gap, StriaTrace leverages `py-spy` [30], a low-overhead sampling profiler, to capture fine-grained execution contexts. Specifically, StriaTrace operates `py-spy` in non-blocking mode to periodically snapshot the execution state—including thread stacks and Global Interpreter Lock (GIL) ownership—of the vLLM instance. By reading the target process's memory, `py-spy` reconstructs the full Python stack trace without pausing execution or modifying the interpreter state. We configure the sampling interval to 10 ms, sufficient to capture sustained stalls.

A typical application of StriaTrace's `py-spy` integration is detecting GIL contention. Figure 5 visually contrasts a healthy inference step with an anomalous one. In Rank 1 (top), the execution is healthy: the main thread (Thread 1) holds the GIL and executes the `model_forward` logic without interruption, continuously launching GPU kernels (visualized as arrows triggering kernel execution). In contrast, Rank 2 (bottom) exhibits a severe performance degradation. The `model_forward` span is significantly elongated, containing a large "Blocked" gap where no kernels are launched. Without `py-spy`, we can only see a slow `model_forward`, misidentifying it as a computation bottleneck. However, `py-spy` can reveal the true culprit. A background thread (*i.e.,* Thread 2) acquires the GIL, transitioning to the *active+gil* state. Consequently, Thread 1 is forced into an *idle* state, blocked from executing Python bytecode required for kernel launching. As a result, this correlation unambiguously attributes the stall to background thread interference.

5.2.3 Minimizing Runtime Overhead

Having identified the strategic instrumentation points, the subsequent challenge lies in efficiently exporting the telemetry data for further analysis. We initially evaluated vLLM's

[1]Token status encapsulates the input prompt length and the dynamically accumulated decoded sequence length for each request within the batch.

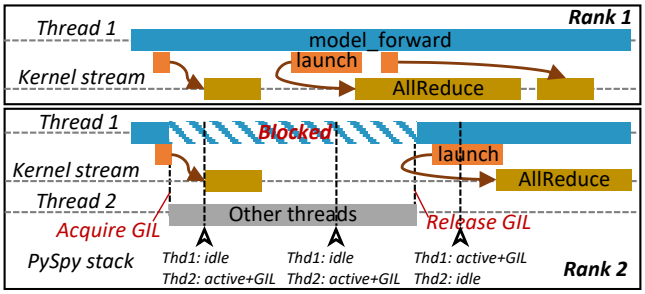

Figure 5: GIL contention between a background thread and the main inference thread.

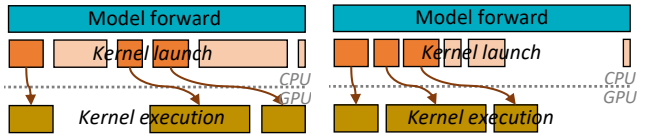


(a) CPU-bound. (b) GPU-bound.

Figure 6: Two canonical performance regimes.

built-in OpenTelemetry (OTel) [29]. As a widely adopted industry standard, OTel defines a unified trace data schema and provides mature middleware for data transmission.

However, practical deployment revealed that the standard OTel Python SDK introduces unacceptable latency jitter. The root cause stems from its *asynchronous batch export mechanism*. Specifically, OTel buffers trace data and spawns a background thread to export the batch via HTTP or gRPC once the buffer fills. Crucially, the serialization (*e.g.,* Protobuf encoding) required for transmission is CPU-intensive and must hold the Python GIL. Consequently, when the background export triggers, it contends with the main inference thread, causing blocking stalls that can exceed 100 ms.

To eliminate this non-deterministic interference, StriaTrace abandons the background export model in favor of a deterministic I/O hiding strategy. Instead of passively waiting for a batch to fill, StriaTrace proactively flushes trace data at precise execution boundaries. Specifically, we exploit the inherent parallelism between the host and the GPU. In vLLM, after the GPU worker issues asynchronous kernel launches, the CPU typically waits for GPU execution to complete. StriaTrace leverages this CPU idle window to perform data export. Hence, StriaTrace can effectively hide the tracing overhead behind the GPU execution shadow, ensuring negligible impact on the critical path.

5.3 Device-side Tracing

5.3.1 Hardware-Centric Instrumentation

Standard profiling solutions within the vLLM ecosystem include Nvidia Nsight Systems and PyTorch Profiler. However, neither is viable for always-on production monitoring due

to prohibitive overhead. The fundamental issue stems from their indiscriminate subscription to the underlying CUPTI (CUDA Profiling Tools Interface) [26] events, the proprietary observability library provided by NVIDIA.

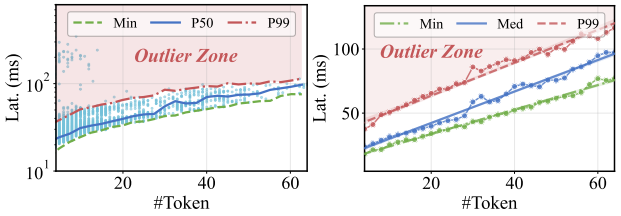
CUPTI provides visibility across the full GPU stack: from software-level CUDA Runtime and Driver APIs to hardware-level kernel execution. Existing tools typically subscribe to all these layers to ensure completeness. In vLLM, however, a single kernel execution is often preceded by a cascade of Runtime and Driver API calls (*e.g.,* argument setup and launch configuration). Capturing this high-frequency API traffic introduces substantial overhead. For instance, TorchProfiler incurs a latency penalty of ∼192%, as it traces both the API calls and the hardware execution.

StriaTrace challenges this "trace-all" convention (following **Principle 2**). We observe that hardware-level information alone is sufficient to reconstruct the critical path of inference. Hence, StriaTrace eschews the tracing of software API calls, focusing on the start and end timestamps of GPU kernels and memory transfers. This design choice drastically reduces overhead while preserving the necessary fidelity for bottleneck analysis. As illustrated in Figure 6, the density of kernel events along the timeline acts as a proxy for the system's bottleneck state: (1) **Scenario 1: CPU-bound (sparse kernels).** As shown in Figure 6a, when the host-side kernel launch is slower than GPU execution, the GPU remains mostly idle, resulting in sparse kernel events. In other words, the bubbles directly reflect host-side bottlenecks, rendering API tracing redundant. (2) **Scenario 2: GPU-bound (packed kernels).** Conversely, as shown in Figure 6b, when kernel execution is slower than the CPU launch, the timeline shows densely packed kernels. The inference engine ultimately stalls waiting for the GPU to complete. Here, the critical path is unambiguously governed by the kernel execution.

In summary, by recording only hardware execution intervals, StriaTrace can unambiguously distinguish between CPU and GPU bottlenecks without paying the overhead of API interception.

5.3.2 Anomaly-Driven Data Retention

While the hardware-centric strategy (§5.3.1) can mitigate runtime interference, it introduces a new challenge. In the vLLM framework, a single inference step typically involves the launch of thousands of GPU kernels. Consequently, recording the complete trace of these events generates a massive telemetry footprint. To quantify this, we profile a vLLM instance serving Qwen3-Coder-30B-Instruct-FP8 [44]. Each GPU worker generates approximately 1,600 kernel records per inference step. With an average step latency of 12 ms, an 8-GPU node produces raw trace data at a rate of 3.54 GiB/min. Extending this to production clusters of 10,000 GPUs, the aggregate bandwidth demand can surge to 590 Gbps. Transmitting and storing this full-fidelity stream is operationally prohibitive.



(a) Latency distribution. (b) Roofline modeling.

Figure 7: Construction of the StriaTrace roofline. (a) Latency distribution versus token count. (b) Modeling the P99 performance boundary via linear regression.

To address this massive footprint, StriaTrace shifts from a "store-everything" to a "store-on-anomaly" paradigm (following **Principle 3**). For production monitoring, detailed GPU kernel traces are redundant for normal inference steps. Consequently, StriaTrace discards kernel traces for normal steps by default, retaining only aggregated metrics. Full-fidelity traces are persisted exclusively when the step is flagged as an outlier by the roofline model (details in §5.4). This anomaly-driven retention strategy reduces the transmission volume to approximately 1.6% of the raw stream.

5.4 Trace Analysis

5.4.1 Adaptive Roofline for Anomaly Detection

To detect performance anomalies, StriaTrace must establish a reliable performance baseline. Simple approaches, such as fixed latency thresholds, fail in this context because the execution time of an inference step varies significantly with its workload (*e.g.,* the number of tokens processed). Consequently, a fixed threshold cannot distinguish between a naturally heavy computation and a true performance degradation.

While theoretical roofline modeling [45, 47, 49] offers a dynamic baseline based on hardware and software configurations, applying it to production environments is operationally intractable. Modern deployments involve a combinatorial variety of model architectures, GPU specifications, parallelization strategies, and serving paradigms (*e.g.,* prefill/decode disaggregation). As these innovations continuously evolve, pre-computing analytical models for every configuration permutation is infeasible.

Instead, StriaTrace employs a data-driven regression approach to construct empirical rooflines tailored to each serving instance. This design is grounded in a key empirical observation: *Inference latency exhibits a strong positive correlation with the number of processed tokens*[2]. This statistical relationship allows us to treat anomaly detection as a regression problem, learning a direct mapping from the token count to

[2]For a *Prefill* instance, this counts the sum of all prompt lengths in the batch; for a *Decode* instance, it equals the batch size.

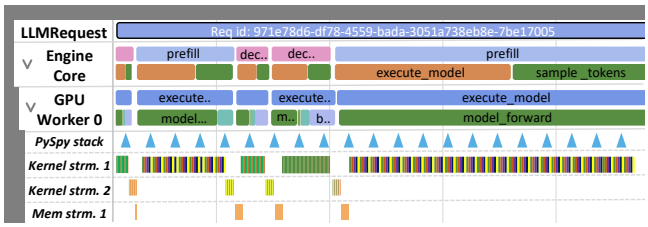


Figure 8: End-to-end trace visualization in the Perfetto UI.

the expected tail latency. Based on this observation, StriaTrace formulates the roofline construction as a data-driven process. The core objective is to determine a dynamic upper-bound for the inference latency, *i.e.,* the *empirical roofline*, by modeling the tail distribution of historical execution data. Figure 7 visualizes this modeling workflow using empirical data captured from a production instance.

Figure 7a plots the distribution of step latency against the number of processed tokens. For each token count (x-axis), we calculate the minimum, median, and P99 latencies from historical data. Two key patterns emerge from Figure 7a. First, the minimum, median, and P99 latency exhibit a strong positive correlation with the token count (x-axis). Second, a subset of samples is distributed far beyond the P99 boundary. StriaTrace defines this high-latency region as the *Outlier Zone*, identifying these specific samples as performance anomalies.

Building on these insights, Figure 7b demonstrates the modeling process. We fit linear regression models to the statistical boundaries derived in Figure 7a. The results show that the P99 latency scales linearly with the token count, achieving an R^2 score of 0.98[3]. StriaTrace adopts this P99 regression line as the empirical roofline. This design allows us to instantiate reliable anomaly detection thresholds using lightweight sampling and robust linear fitting (*e.g.,* RANSAC [12]).

StriaTrace bootstraps the roofline model during the initial serving phase. It collects the token count and latency of each inference step until sufficient data points are accumulated for linear fitting. Subsequently, the system periodically retrains the model during runtime. Furthermore, the construction of the *Prefill* roofline follows this identical "collect-fit-update" paradigm shown in Figure 7.

5.4.2 Hierarchical Analysis and Reporting

Upon detecting a performance anomaly via the roofline model, StriaTrace automatically generates an *anomaly report* for the site reliability engineers (SREs). The anomaly report integrates two components to accelerate diagnosis: *hierarchical telemetry data* and *primary bottleneck suspects*. To facilitate drill-down analysis, StriaTrace organizes the execution context into three semantic layers, mapped to a unified timeline in the Perfetto UI as shown in Figure 8: (1) *Request layer* visualizes the end-to-end lifecycle, identifying queuing delays and overall latency violations; (2) *Framework layer* exposes vLLM internal behaviors, such as scheduler decisions, KV cache block allocation, and worker coordination events. (3) *Kernel layer* provides hardware execution details, visualizing individual GPU kernel executions (*e.g.,* GEMM, Attention) and PCIe/NVLink transfers.

Beyond hierarchical telemetry, StriaTrace performs correlation analysis to highlight primary suspects. Specifically, StriaTrace identifies the dominant span, *i.e.,* the span contributing most to the latency, and correlates it with the `py-spy` trace to pinpoint the executed function, alongside the GIL status to reveal thread scheduling contention. It also flags outliers among GPU kernels. We further illustrate two representative cases in §7.

[3] An R^2 of 0.98 implies that our linear model accounts for 98% of the latency variability, demonstrating exceptional predictive accuracy.

6 Evaluation

We evaluate StriaTrace to answer the following questions:

- Can StriaTrace operate with negligible performance impact on production vLLM serving, while minimizing the telemetry footprint?
- Is StriaTrace effective in detecting performance anomalies and pinpointing their root causes?
- What concrete impact has StriaTrace had on diagnosing performance anomalies in real-world production?

6.1 Setup

Testbed. Our experiments are conducted on a production-grade node. The node is equipped with dual-socket Intel Xeon processors (160 cores total) and 1.3 TiB of DDR5 memory. The server hosts eight NVIDIA H20-3e GPUs (144 GiB memory per GPU) interconnected via NVLink. The system runs Ubuntu 24.04.1 LTS. Our software stack consists of Python 3.12.3, PyTorch 2.7.0, and CUDA 12.8, using vLLM as the inference engine.

Comparisons. We evaluate vanilla vLLM (*Baseline*) against six instrumentation configurations: (1) *NVIDIA Nsight Systems (NSys)*: To control the overhead, we disable the CPU backtracing (see details in Appendix B.1); (2) *PyTorch Profiler (TProf)*: We use the built-in TProf implementation embedded within vLLM (see Appendix B.2); (3) *Scalene*: We configure Scalene with two distinct CPU sampling intervals (*i.e.,* 10 ms and 100 ms, see details in Appendix B.3); (4) *Stria-C:* StriaTrace with only CPU-side tracing enabled; (5) *Stria-G*: StriaTrace with only GPU-side profiling enabled; (6) *Stria*: The complete StriaTrace system with both CPU and GPU instrumentation active.

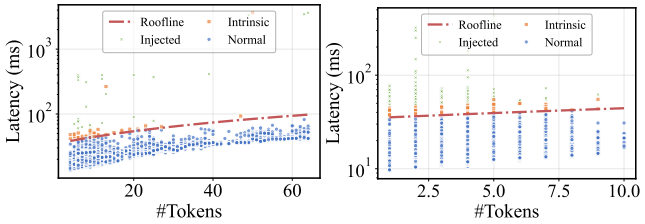
Model and workload. We evaluate StriaTrace using Qwen3-Coder-30B-Instruct-FP8 [44], a state-of-the-art Mixture-of-Experts (MoE) code generation model optimized with FP8 quantization. To strictly mirror our production environment, we deploy this model using a PD disaggregated architecture. We deploy two distinct instances with both instances configured at a Tensor Parallelism degree of 8 (TP=8). These two instances are seamlessly interconnected via our custom distributed KV cache component. For workload generation, we utilize vLLM's native benchmark tool [46] to issue requests with fixed input/output lengths, following a Poisson arrival process at specified rates.

6.2 Overhead Analysis

We evaluate the operational cost of StriaTrace along two dimensions: (1) the *latency penalty* to TPOT and TTFT, and (2) the *telemetry footprint* in terms of storage consumption.

Impact on inference latency. We configure the vLLM benchmark with a fixed request arrival rate of 8 req/s while sweeping the engine's maximum concurrency from 8 to 256. To accurately reflect the performance of the disaggregated architecture, we report the Time-to-First-Token (TTFT) measured at the prefill instance, and the Time-Per-Output-Token (TPOT) measured at the decode instance.

Figure 9a details the TPOT results for the decoding instance. We make three key observations: (1) Existing tools are costly. At a low concurrency of 8, *TProf* incurs prohibitive penalties, inflating the Median and P99 TPOT by 83.6% and 84.1%, respectively. While *NSys* is lighter, it still imposes a non-negligible overhead of 34.3% (Median) and 32.0% (P99). *Scalene-0.1* (default 10 ms sampling interval) also introduces substantial TPOT penalties for both Median (21.4%) and P99 (111.8%). Even when configured with a sparser 100 ms interval, the overhead remains at 18.7% (Median) and 56.9% (P99). (2) StriaTrace's host-side tracing introduces negligible overhead. *Stria-C* introduces virtually no performance regression; the overhead for both Median and P99 TPOT remains strictly below 1% across all settings; (3) GPU overhead amortizes. The cost of full StriaTrace is primarily driven by GPU instrumentation, but this overhead scales inversely with throughput. As the concurrency increases from 8 to 256, the instrumentation cost is effectively amortized, causing the Median TPOT overhead to drop from 5.2% to 0.6%.



(a) Host-side stall. (b) Device-side contention.

Figure 10: Roofline visualization classifying *Injected*, *Intrinsic*, and *Normal* steps under (a) host-side stall and (b) device-side contention scenarios.

Figure 9b depicts the impact on TTFT collected from the prefill instance. Similar to the TPOT results, we observe distinct overhead patterns: (1) *TProf* remains prohibitively heavy. It introduces substantial latency regression, increasing the Median and P99 TTFT by 3.0× and 3.2× over the baseline (at 8 concurrency). (2) *NSys* incurs moderate overhead. Although lighter than *TProf*, it still inflates the Median TTFT by 4.7% and the P99 by 6.3%. (3) StriaTrace demonstrates effective amortization. Consistent with its behavior on TPOT, StriaTrace's overhead on TTFT diminishes as the workload increases. As the concurrency climbs from 8 to 256, the overhead is amortized, dropping from 2.7% to 0.8% (measured in Median).

Tracing data footprint. We measure the rate of tracing data generation (GiB/hour) under a fixed workload of 8 req/s across all instrumentation setups. Table 3 details the tracing throughput for both prefill and decode instances. The results clearly indicate that existing tools incur a substantial data tax. Specifically, for the decode instance, the consumed bandwidth of *NSys* and *TProf* exceeds that of StriaTrace by at least 38×. In contrast, StriaTrace maintains a modest data footprint, making it viable for continuous production tracing.

6.3 Effectiveness of Anomaly Detection

We next evaluate the efficacy of StriaTrace's roofline model in detecting performance outliers. Specifically, we conduct a controlled fault injection campaign on a distributed vLLM cluster (TP=4). After allowing StriaTrace to construct a sta-

Table 4: Abnormalities diagnosed by StriaTrace.

ble roofline under normal traffic, we introduce two types of synthetic anomalies to mimic production failures: (1) *Host-side stall*: We temporarily suspend the execution of a vLLM worker process using the `SIGSTOP` signal; (2) *Device-side contention*: We inject high-priority background kernels that aggressively saturate GPU Streaming Multiprocessors (SMs) using Numba [25]. For each injected fault, we randomize the target worker (or GPU) and fault duration.

Figure 10a and 10b illustrate StriaTrace's roofline during the host-side stall and device-side contention experiments, respectively. Each point represents a single inference step, plotting step latency (y-axis) against token count (x-axis). Using the roofline model together with the injected-failure timestamps, we categorize each step into three classes: *Injected* (steps affected by our synthetic faults), *Intrinsic* (outliers stemming from inherent system variance), and *Normal* (healthy steps). We report the recall on injected faults as our primary metric for assessing detection efficacy. Across both fault types, StriaTrace achieves 100% recall on injected failures, indicating that all injected anomalies manifest as clear deviations from the learned roofline.

6.4 StriaTrace in Production

StriaTrace has been extensively used in the development and testing environments of our inference service, supporting multiple release cycles. Over a six-month deployment, StriaTrace monitors two of our flagship models, encompassing over 1,700 production instances and handling more than 180 million user requests daily. StriaTrace supports diverse parallelization strategies, including Tensor Parallelism (TP) and Data Parallelism (DP), and is deployed across both monolithic and PD-disaggregated architectures. StriaTrace has diagnosed hundreds of abnormalities in production, which can be categorized into three types: (1) hardware issues, (2) configuration issues, and (3) code issues. Crucially, we emphasize that StriaTrace is not designed as a fully automated, end-to-end root-cause oracle. Rather, it functions as a *rapid triage mechanism*. It is designed to provide Site Reliability Engineers (SREs) with rich, fine-grained execution context, thereby reducing the diagnostic search space.

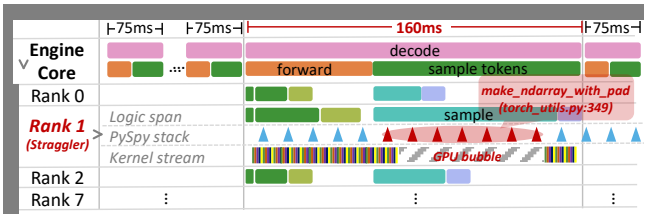
As shown in Table 4, StriaTrace approaches these production issues through two operational paradigms. First, for long-tail latency (*e.g.,* most code-related issues), the degradation explicitly triggers StriaTrace's dynamic roofline model. In these scenarios, StriaTrace executes its complete diagnostic pipeline. By correlating the anomalous semantic span with fine-grained *py-spy* snapshots, the system successfully pinpoints the problematic rank, the specific execution phase (CPU vs. GPU), and the exact line of Python code or CUDA kernel. We detail this kind of case in §7.1.

Second, some anomalies manifest as sustained performance degradations that inherently do not trigger the dynamic roofline alerts. A prime example is when CUDA Graphs are inadvertently disabled (Case 8); this evades roofline detection entirely because the dynamic model constructs its baseline on an already degraded performance state. For such sustained issues, StriaTrace's primary value lies in preserving the execution context. By providing high-fidelity historical traces, StriaTrace empowers SREs with the critical telemetry needed to manually cross-reference contexts and isolate configuration or hardware flaws. We explore this telemetry-accelerated localization in §7.2.

It is important to note that StriaTrace's dynamic roofline model (§5.4.1) is not completely immune to false positives. In our production environment, approximately 7% of the flagged anomalies were eventually classified as natural workload variances rather than true system regressions. For instance, a typical false positive arises from extreme Expert Parallelism (EP) load imbalance. In MoE models, heavily skewed token routing can occasionally cause a specific GPU rank to severely straggle.

7 Case Study

This section details representative cases of diagnosing performance anomalies using StriaTrace. We categorize these cases into two paradigms: (1) *End-to-end pipeline diagnosis* (§7.1) for transient anomalies explicitly flagged by the dynamic roofline model; and (2) *Telemetry-accelerated localization* (§7.2) for broader performance issues where StriaTrace's



```python
def make_ndarray_with_pad(x: list[list[T]], ...):
    ...
    for ind, blocktb in enumerate(x):
        assert len(blocktb) <= max_len
        padded_x[ind, : len(blocktb)] = blocktb
    return padded_x
```

Figure 11: StriaTrace for a 160 ms straggler step. (Top) The end-to-end trace identifies a critical stall on GPU rank 1. (Bottom) The isolated culprit code responsible for the anomaly.

continuous lightweight observability significantly accelerates root-cause identification.

7.1 End-to-End Pipeline Diagnosis

A typical class of performance issues diagnosed by StriaTrace's end-to-end pipeline involves CPU-side logic unexpectedly blocking GPU kernel launches. To resolve these issues, StriaTrace first identifies the macroscopic bottleneck via synchronization barriers and GPU timeline bubbles, and then correlates the anomalous span with *py-spy* stack traces to pinpoint the exact culprit code. These fine-grained contexts are handed over to SREs for final confirmation and mitigation. We illustrate this workflow using a representative production case below, *i.e.,* Case 13 in Table 4.

During a routine production inspection, StriaTrace detected sporadic latency spikes in an 8-GPU decoding instance handling live traffic. As shown in Figure 11, during consecutive decode steps with a stable workload (*i.e.,* no requests joining or finishing), the step latency would occasionally jump from a baseline of 75 ms to over 160 ms. StriaTrace revealed a distributed straggler effect: one of the eight ranks (*i.e.,* Rank 1) was severely delayed, forcing the others into a synchronous stall. On Rank 1, the CPU-side *Logic span* timeline showed that the span named `sample` was abnormally prolonged, and a massive ∼80 ms bubble was observed on the *Kernel stream*. In vLLM, the `sample` is a standard routine that follows the model's forward pass to convert the output logits into token IDs.

The *PySpy stack* of Rank 1 revealed that the vLLM main inference thread (responsible for dispatching GPU kernels) was active and holding the Python Global Interpreter Lock (GIL), implying that the thread was occupied by host-side computations. Furthermore, consecutive stack samples showed the execution was persistently stalled at the `make_ndarray_with_pad` function (see Appendix C.1 for the full stack trace). This function resides in vLLM's `torch_utils.py`, a utility module designed to bridge standard Python data structures with PyTorch tensors.

Then, the SRE team uncovered a subtle memory management bottleneck. Within the token sampling phase, `make_ndarray_with_pad` acts as a conditional branch triggered when users' requests specify penalty constraints (*e.g.,* frequency or length penalties [5]). Its primary function is to pad the historical token sequences of all requests to match the maximum sequence length[4]. The bottleneck originates at line 5 within this function. The `for` loop encompassing line 5 employs native Python list slicing. When operating under a large batch size and extended token lengths, this naive approach leads to two severe consequences: (1) it generates a massive number of temporary Python objects, elevating the risk of GC pauses; and (2) it continuously triggers NumPy's underlying `malloc` and `free`.

To resolve this, the engineering team implemented a custom C++ operator and integrated it into vLLM via Torch JIT [33]. Leveraging direct C++ pointer access to preallocated contiguous memory, this custom operator iterates and pads the sequences entirely at the native C++ layer. This completely eliminates Python object creation and memory allocations. Following this patch, the P99 latency for the `make_ndarray_with_pad` invocation plummeted from 110 ms to 43 ms.

Moreover, StriaTrace's end-to-end pipeline has isolated other straggler effects. For instance, in Case 14, StriaTrace revealed that a background thread managing the KV cache mistakenly executed synchronous operations during block eviction. This implicitly acquired the Python GIL, blocking the main vLLM inference thread. Similarly, in Case 19, StriaTrace correlated an anomalous `sample` span and a massive GPU idle gap with unexpected Triton JIT compilation. The traces demonstrated that a user-defined sampling function, decorated with `torch.compile`, triggered synchronous compiler activities that consumed over 99% of the step's duration.

7.2 Telemetry-accelerated Localization

Beyond the end-to-end diagnosis in §7.1, StriaTrace's continuous observability accelerates the diagnosis of other sustained performance degradations. Below, we present a case illustrating how SREs leverage the fine-grained correlation between StriaTrace's GPU kernel traces and the CPU-side traces to pinpoint the root cause, *i.e.,* Case 17 in Table 4.

During a routine weekly regression test, we observed an unexpected drop in decode token throughput compared to the previous stable release. Since over 400 new commits had been merged that week[5], isolating the root cause via traditional `git bisect` was practically prohibitive. The initial

[4] Sequence length refers to the sum of the initial prompt tokens and the tokens decoded so far.

[5] The weekly average number of commits in our private vLLM repository over the past year is 340.

analysis revealed that, under an identical decode workload, the average decode step latency had inflated from roughly 5 ms to 7 ms. Drilling down into StriaTrace's CPU-side traces, we found that the span named `model_forward` was the sole contributor to this latency increase. In vLLM, this specific span encompasses the critical phase where the GPU worker utilizes CUDA graphs to dispatch kernels for the forward pass.

To pinpoint the exact cause, engineers examined StriaTrace's GPU kernel traces. The data revealed that the GPU execution time inflation was almost entirely attributed to a specific kernel, `16FlashAttnFwdSm90INS1`. This is the critical FlashAttention kernel, invoked dozens of times per decode step to perform the attention forward pass. Crucially, StriaTrace's GPU tracing captures the *mangled name* of each executed kernel. This mangled name embeds not just the function signature, but its exact template instantiation parameters.

By directly comparing the mangled names across the two vLLM builds, a subtle but critical discrepancy emerged: the template arguments had shifted from $(64, 128, 128)$ to $(128, 128, 128)$ (see Appendix C.2 for the full mangled names). These parameters dictate the matrix multiplication tile size used by the GPU thread blocks. The engineering team verified via offline reproduction that on NVIDIA H20 GPUs, the smaller tile size is more optimal, executing in roughly $140\,\mu$s per invocation compared to $210\,\mu$s for the larger size (see Appendix C.2 for detailed settings). Since this kernel executes repeatedly in a decode step, this $70\,\mu$s penalty per invocation accumulated directly into the observed degradation. The fundamental root cause was eventually traced back to a faulty build script. The new vLLM version was shipped with a FlashAttention library compiled with missing template configurations. Consequently, the optimal kernel variant with the 64 tile size was never generated during the compilation. Without the optimal binary available, the FlashAttention runtime silently fell back to dispatching the sub-optimal 128 tile size variant.

Furthermore, StriaTrace's CPU-side telemetry has proven instrumental in diagnosing obscure corner cases. For example, during a recent release rollout, the engineering team reported another unexpected drop in decode token throughput. StriaTrace revealed that *the number of draft tokens proposed by the draft model was strictly less than the number of tokens actually submitted for verification in the subsequent step*. This exposed the silent injection of "ghost tokens", immediately bounding the anomaly to the speculative decoding workflow. Further investigation confirmed this was a secondary bug: a patch intended to resolve a specific EAGLE-3 [19] issue compromised the performance of the N-gram [48] algorithm (detailed analysis in Appendix C.3).

7.3 Experiences & Lessons

Necessity of continuous observability. The rapid development cycles of inference engines dictate that the CI/CD cannot anticipate all performance regressions. Production deployments of vLLM involve a massive combinatorial space of parameters, topologies, and distributed components. Coupled with continuous codebase updates, this sheer complexity makes exhaustive testing in CI/CD practically impossible. Consequently, continuous, *in-vivo* observability is a highly recommended capability for capturing dynamic, workload-dependent anomalies that inevitably emerge in production.

Synergy of cross-layer telemetry. Diagnosing complex anomalies requires both CPU-side semantic context and GPU-side hardware execution details. On the CPU-side, tracking CPU runtime metadata (*e.g.,* dynamic user request parameters and control data) is valuable for isolating logic-level and scheduling bottlenecks. Complementarily, on the GPU-side, extracting mangled kernel names—which inherently encode critical compilation configurations—plays a pivotal role in diagnosing hardware-level anomalies. Correlating these independent dimensions creates a powerful cross-layer synergy that accelerates full-stack root-cause analysis.

Strict hot-path disciplines. In high-throughput inference engines like vLLM, the main inference thread serves as the critical hot path. Any CPU-side stall on this thread directly translates to GPU starvation. Consequently, we recommend that developers follow these guidelines: (1) *Offloading memory-intensive operations to C/C++*: Native Python memory management is inherently opaque. Operations that generate massive temporary objects, such as dynamic list slicing or sequence padding, are highly prone to unpredictable GC pauses. To guarantee latency stability, these logic blocks should be rigorously offloaded to native C/C++ implementations; (2) *Minimizing synchronous interruptions:* Synchronous operations should be introduced with extreme caution. Synchronous calls—such as querying a distributed KV cache, polling remote storage, or waiting on background threads—can inadvertently block the main event loop.

8 Discussion

Tracing coverage vs. overhead. StriaTrace does not blindly sacrifice tracing coverage for low overhead. We discuss this trade-off across the CPU and GPU domains. For CPU tracing, StriaTrace avoids pervasive instrumentation by a hybrid approach. First, it relies on static tracing points embedded in vLLM's critical path. As shown in Table 2, these points cover less than 1% of the total functions. Second, to provide full-stack visibility, StriaTrace employs periodic sampling via *py-spy*. The full-stack sampler remains effective for our target anomalies, *i.e.,*, long-tail latency. Diagnosing sustained performance degradations (*e.g.,* cases in §7.2) presents a more nuanced challenge, as low-frequency sampling might miss

micro-stalls. However, since such sustained issues are highly reproducible, StriaTrace can serve as an initial triage anchor. By preserving the execution scene, StriaTrace narrows the search space, allowing SREs to iteratively inject instrumentation points offline to pinpoint the exact culprit.

On the GPU, StriaTrace is confined to kernel executions. Unlike exhaustive profilers such as *NSys*, we deliberately disable the tracing of CUDA driver and runtime APIs. This is a necessary and unavoidable compromise. Since GPU tracing heavily relies on the closed-source CUPTI [26], tracking high-frequency driver/runtime API calls introduces an untenable overhead. To compensate for this reduced coverage, StriaTrace infers host-to-device interaction bottlenecks heuristically. By analyzing the idle "bubbles" between kernels, SREs can effectively deduce whether a latency anomaly stems from CPU-side CUDA driver overheads or actual GPU anomalies.

Architectural generality and porting effort. In StriaTrace's design, both the CPU-side full-stack sampling via *py-spy* (§5.2.2) and the GPU-side hardware tracing (§5.3.1) are strictly framework-agnostic. These components are applicable to any Python-based inference engine (*e.g.,* vLLM [46], SGLang [40]). The only framework-dependent component—and thus the primary source of engineering effort when porting to a new framework or maintaining across version upgrades—lies in the coarse-grained CPU-side instrumentation (§5.2.1). We emphasize that the manual effort is bounded and manageable. First, regarding cross-framework portability, StriaTrace's instrumentation relies on identifying synchronization barriers along the engine's critical path. Since these points have distinct signatures or structural patterns, they can be efficiently extracted through static code analysis facilitated by modern AI coding agents. Second, regarding temporal maintainability, the critical path of a mature inference engine is inherently stable. While minor feature updates are frequent, the core execution workflow rarely updates. During our six-month production deployment tracking upstream vLLM, the critical path experienced only one major shift, *i.e.,* the transition from synchronous to asynchronous scheduling. Consequently, adapting StriaTrace to engine upgrades requires acceptable effort.

Cross-platform compatibility. Currently, StriaTrace relies on NVIDIA's CUPTI for GPU observability, given that NVIDIA GPUs remain the dominant platform in production-grade LLM serving. However, we acknowledge the growing adoption of alternative accelerators, such as AMD GPUs utilizing the ROCm stack. Porting StriaTrace to AMD GPUs is straightforward due to architectural symmetry. This is facilitated by the availability of ROCTracer [1], an AMD observability tool designed as a near-exact architectural mirror of CUPTI. First, it exposes a standard C library interface, allowing for seamless integration into StriaTrace's GPU tracing module. Second, it reports kernel execution timestamps identical to those of CUPTI, ensuring that the downstream backend analysis logic remains unchanged.

9 Related Work

End-to-end inference profiling. Several frameworks have proposed end-to-end analysis systems for inference scenarios. LLM-Pilot [18] measures inference performance under varying hardware configurations and builds predictive models to estimate performance in new deployment settings. However, it only collects coarse-grained per-request execution time. The ALA framework [2] constructs an analytical model based on collected runtime metrics to perform theoretical analysis and anomaly detection for inference systems. Similarly, ALA relies solely on high-level system metrics.

Training-centric diagnosis. With the rapid evolution of LLMs, there have been numerous studies focusing on locating and diagnosing abnormalities during LLM training [3, 7–9, 16, 21, 22]. However, all these solutions rely on the static training patterns and are ill-suited for dynamic inference workloads. For example, these solutions leverage global barriers in Bulk Synchronous Parallel (BSP) training to distinguish abnormal iterations. In contrast, inference instances process requests independently and asynchronously.

10 Conclusion

In this paper, we present StriaTrace, a tracing and diagnosis system tailored for online LLM inference. StriaTrace employs three principles distilled from production experience to minimize the tracing overhead. Furthermore, StriaTrace introduces a step-level roofline and correlation-based diagnosis for LLM inference abnormalities. StriaTrace reduces tracing overhead by 97.8% compared to state-of-the-art alternatives, and has successfully diagnosed 19 types of issues in production.

Acknowledgments

We sincerely thank our shepherd Hongqiang Harry Liu and the anonymous reviewers for helping us improve our paper significantly. We acknowledge all teams within Alibaba that contributed to the deployment of StriaTrace. APPENDIX

A Host-Side Instrumentation Points

Table 5: **Catalog of instrumented spans in StriaTrace.**

Span Name	Process	Thread
LLMEngine::Request	Client	Main
EngineCore::Step	Engine	Main
EngineCore::Schedule	Engine	Main
EngineCore::Execute	Engine	Main
EngineCore::Output	Engine	Main
EngineCore::CollectiveRpc	Engine	Main
Worker::Response	Worker	Main
ModelRunner::Preprocess	Worker	Main
ModelRunner::Forward	Worker	Main
ModelRunner::Postprocess	Worker	Main
ModelRunner::Sample	Worker	Main
ModelRunner::Draft	Worker	Main
ModelRunner::Bookkeep	Worker	Main
ModelRunner::EpLB	Worker	Main
ModelRunner::Output	Worker	Main
CacheEngine::Load/Save	Worker	Cache Mgmt.

Table 5 provides a comprehensive catalog of the trace points instrumented within the vLLM serving stack. These spans are strategically selected to cover the end-to-end critical path of an inference request, capturing key state transitions from ingress to the model execution backend.

For each instrumentation point, the table specifies: (1) **Span Name:** The semantic identifier used in trace visualization (e.g., `EngineCore::Step`); (2) **Process:** The operating system process where the span originates, specifically distinguishing between the *Engine Process* (responsible for request scheduling and orchestration) and the *Worker Process* (responsible for distributed model execution); (3) **Thread:** The specific execution context, differentiating the compute-intensive *Main Thread* from asynchronous auxiliary threads such as the *Cache Management Thread*.

This mapping enables StriaTrace to reconstruct the causal chain of execution across process and thread boundaries.

B Detailed Instrumentation Configurations

This appendix details the configuration parameters for the profiling tools used in our evaluation (§6.1): NVIDIA Nsight Systems (NSys), PyTorch Profiler (TProf) and Scalene.

B.1 Config of NVIDIA Nsight System (NSys)

We execute NSys using the Command Line Interface (CLI) to capture system-wide execution traces. To strictly control profiling overhead while maintaining essential hardware observability, the key parameters are configured as follows:

- `-trace=cuda,nvtx,osrt`: Enables tracing of CUDA runtime/driver API calls, NVTX annotations (essential for correlating vLLM logical scopes), and OS runtime libraries.
- `-cuda-graph-trace=node`: Since vLLM heavily utilizes CUDA Graphs to reduce kernel launch overhead, this flag forces NSys to expose the internal structure and execution timing of individual nodes within the CUDA Graphs.
- `-backtrace=none`: Explicitly disables CPU call stack unwinding. As discussed in our baseline setup, collecting full backtraces introduces prohibitive runtime overhead, so we disable it to ensure a fair overhead comparison.
- `-sample=process-tree`: Configures CPU instruction sampling across the entire process tree, but strategically downsamples the frequency to a 16 ms period to further minimize host-side interference.
- `-capture-range=cudaProfilerApi`: Restricts the active trace capture strictly to programmatic triggers via the CUDA Profiler API, ensuring we only record stable inference phases and exclude initialization anomalies.

The complete command used to launch NSys in our evaluation is as follows:

```
nsys profile \
--trace-fork-before-exec=true \
--trace=cuda,nvtx,osrt \
--sample=process-tree \
--cuda-graph-trace=node \
--backtrace=none \
--capture-range=cudaProfilerApi \
--capture-range-end=stop \
--sampling-period=16000000 \
--delay 60 \
--duration 100000 \
vllm serve ...
```

B.2 Config of Torch Profiler (TProf)

We utilize the built-in PyTorch Profiler (TProf) natively provided by the vLLM engine. To capture application-level performance data, the profiler is initialized with the following key parameters:

- `activities=[CPU, CUDA]`: Configures the profiler to capture operations on both the host CPU and the GPU device, enabling the analysis of kernel launch latencies and host-device synchronization.
- `with_stack=True`: Records the full Python call stack for every captured operator. This feature is essential for fine-grained root-cause analysis but serves as the primary source of TProf's memory and latency overhead.

The complete parameters used to launch TProf in our evaluation are as follows:

```
vllm serve ...
...
--profiler-config '{"profiler": "torch", "
    torch_profiler_dir": "\path\to\save"}' \
--profile-torch \
--profile-step-start 50 \
--profile-step-end 9999999 \
--profile-prefill-and-decode
```

B.3 Config of Scalene

By default, vLLM's EngineCore utilizes the `spawn` method to initialize distributed GPUWorker processes. However, as of our evaluation (April 2026), Scalene lacks native, comprehensive support for profiling `spawn`ed subprocesses. Consequently, launching vLLM via a standard Scalene command would exclusively profile the frontend API server process, leaving the critical GPU workers—where the actual inference hot paths reside—completely unobserved.

To overcome this architectural limitation, we implemented a custom hook within vLLM's worker initialization phase. Specifically, when the EngineCore bootstraps a worker, we explicitly force the spawned process to execute a Scalene command, thereby successfully bringing the distributed workers into the profiling scope. The complete command used to launch the target processes with Scalene is as follows:

```
scalene run --off \
--cpu-only \
--cpu-sampling-rate 0.1 \
-o path/to/save \
-m vllm.entrypoints.cli.main serve ...
```

The key parameters controlling the profiling behavior are configured as follows:

- `-off`: Starts the process with profiling initially disabled. This allows us to programmatically trigger the profiler only during the steady-state inference phase.
- `-cpu-only`: Explicitly restricts Scalene to CPU-side profiling. This minimizes instrumentation interference on device-side operations, allowing us to evaluate the host-side overhead cleanly.
- `-cpu-sampling-rate`: Dictates the temporal resolution of CPU sampling. In this example, it is set to `0.1` seconds. As detailed in §6.1, we vary this parameter (*e.g.,* `0.01` for 10 ms and `0.1` for 100 ms) to evaluate the trade-off between profiling fidelity and throughput degradation.

C Details of Use Cases

In this section, we provide supplementary details for the production anomalies introduced in §7. For each highlighted case, we expand upon the initial triage by presenting the fine-grained runtime context captured by StriaTrace, the methodology and results of our offline reproduction, and an in-depth root-cause analysis.

C.1 Case 1: Latency spikes in token sampling

Figure 11 shows the culprit code and Table 6 presents the full Python call stack captured by *py-spy* on the straggler rank. The stack reveals that the vLLM main inference thread was persistently stalled at the `make_ndarray_with_pad` function. From the call stack, we can trace the execution flow: the main worker loop dispatches the sampler, which applies penalty constraints to logits. When such constraints are specified, the `make_ndarray_with_pad` function is triggered to pad historical token sequences.

Table 6: Python call stack on the straggler rank.

Function (File:Line)	
make_ndarray_with_pad (torch_utils.py:349)	← Top
make_tensor_with_pad (torch_utils.py:370)	
_convert_to_tensors (penalties.py:54)	
apply_all_penalties (penalties.py:24)	
apply_penalties (sampler.py:364)	
apply_logits_processors (sampler.py:351)	
forward (sampler.py:92)	
_call_impl (module.py:1762)	
_wrapped_call_impl (module.py:1751)	
_sample (gpu_model_runner.py:3412)	
sample_tokens (gpu_model_runner.py:4434)	
sample_tokens (gpu_worker.py:653)	
worker_busy_loop (multiproc_executor.py:858)	
worker_main (multiproc_executor.py:781)	
run (process.py:108)	
_bootstrap (process.py:314)	
_main (spawn.py:135)	
spawn_main (spawn.py:122)	← Bottom

The implementation of `make_tensor_with_pad` (the immediate caller) is shown below; line 349 in `torch_utils.py` corresponds to line 21:

```
def make_ndarray_with_pad(
    x: list[list[T]],
    pad: T,
    dtype: npt.DTypeLike,
    *,
    max_len: int | None = None,
) -> npt.NDArray:
    """
    Make a padded array from 2D inputs.

    The padding is applied to the end of each inner list
         until it reaches
    `max_len`.
    """
    if max_len is None:
        # Unlike for most functions, map is faster than a
             genexpr over `len`
        max_len = max(map(len, x), default=0)

    padded_x = np.full((len(x), max_len), pad, dtype=
         dtype)
    for ind, blocktb in enumerate(x):
        assert len(blocktb) <= max_len
        padded_x[ind, : len(blocktb)] = blocktb

    return padded_x
```

C.2 Case 2: Silent performance degradation due to FlashAttention Miscompilation

C.2.1 Full mangled name of the culprit FlashAttention kernel

Table 7 presents the full mangled names of the FlashAttention kernel captured by StriaTrace across two vLLM builds. The names are nearly identical except for a critical template argument difference highlighted in red. The template arguments encode the tile size configuration: the old build uses $(64, 128, 128)$ which is optimal for NVIDIA H20 GPUs,

whereas the new build uses $(128, 128, 128)$ as a sub-optimal fallback. This discrepancy directly caused the observed latency regression.

Table 7: Mangled names of FlashAttention kernel across two vLLM builds.

Old Build (Optimal):

```

6_tEfNS_4arch4Sm90ELb1ELb0ELb0ELb1ELb1ELb0ELb0ELb
1ELb1ELb1
```

C.2.2 Detailed settings of offline reproduction

To quantify the impact of the tile size discrepancy under production-like setting, we conducted an offline benchmark on the FlashAttention-3 (FA3) kernel. We utilized the `sm_margin` parameter to explicitly govern the Streaming Multiprocessor (SM) allocation. For instance, setting `sm_margin` to 70 restricts the kernel to utilize a maximum of $100 - 70 = 30\%$ of the available SMs, simulating a high-concurrency scenario where SMs are heavily occupied by concurrent tasks. Our benchmark targets the `flash_attn_with_kvcache` function, which internally invokes the kernel introduced in Appendix C.2.2.

As shown in Table 8, under full SM availability, Version 2 exhibited a slight latency regression compared to Version 1 (83.5 µs vs. 73.7 µs). However, under severe SM constraints (`sm_margin`$= 70$), the performance gap drastically widened. Version 1 degraded to 147.7 µs (a 2.0× slowdown), whereas Version 2 suffered a latency spike to 216.8 µs (a 2.6× slowdown).

Table 8: FA-3 kernel latency under different SM availability.

SM Allocation	Version 1 $(64, 128, 128)$	Version 2 $(128, 128, 128)$
Full SM	73.7 µs	83.5 µs
30% SM	147.7 µs	216.8 µs

Root-cause analysis. The root cause lies in the intricate interplay between kernel compilation configurations and GPU hardware limits. The larger tile size $(128, 128, 128)$ in Version 2 dictates higher per-block resource consumption (*e.g.,* shared memory and registers). While the GPU can absorb this pressure when all SMs are idle, it leads to a severe drop in active block occupancy when SM resources are constrained. Consequently, fewer thread blocks can be scheduled concurrently. This case powerfully underscores the necessity of StriaTrace's fine-grained kernel tracing, as such compilation-induced inefficiencies are entirely invisible to standard application-level monitoring.

C.3 Case 3: Diagnosing "ghost tokens" in speculative decoding

As mentioned in §7.2, the engineering team reported a noticeable drop in the decode throughput. StriaTrace's continuous tracing revealed that the median latency of a single decode step had inflated from 7 ms to 9 ms. To understand this 2 ms overhead, SREs delved into the fine-grained CPU-side metadata captured by StriaTrace, *i.e.,* the per-batch scheduling contexts. The trace data exposed an algorithmic anomaly: *during each decode step, the draft token acceptance rate had dropped to nearly zero*. In a standard speculative decoding pipeline, the GPUWorker's draft model proposes a sequence of draft tokens after a forward pass. These tokens are returned to the EngineCore for scheduling and subsequently passed to the target model for verification. However, StriaTrace revealed a critical quantitative mismatch: *the number of draft tokens initially proposed by the worker was strictly less than the number of tokens eventually submitted for verification.* This explicitly confirmed the silent injection of **"ghost tokens"** into the pipeline.

Finally, the SREs confirmed that this was a secondary bug. Previously, the engineering team had encountered an issue where generating JSON-structured outputs under the EAGLE-3 [19] algorithm occasionally produced `NaN` logits. To mitigate this, developers forcefully padded the sequence of draft tokens to a fixed length before returning it to the EngineCore. Unfortunately, this forceful padding logic lacked algorithmic isolation. It leaked into instances utilizing the N-gram [48] speculative algorithm. Consequently, the target model was forced to expend GPU compute cycles verifying these artificially injected, mathematically meaningless padding tokens. This wasted verification compute directly accounted for the inflated step latency and the drop in the token acceptance rate.

Abstract

Many performance issues in large software systems are caused by application-defined resources, such as buffer pools, query caches, and temporary data structures. These resources are managed within the application logic and can strongly affect program execution. However, their resource-specific semantics are often not visible through system-level metrics. As a result, inefficient designs in the management of these resources can cause performance degradation that is difficult to observe and diagnose with existing profilers.

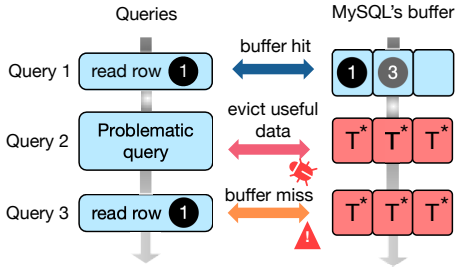
This paper presents *gigiprofiler*, a profiler that diagnoses performance problems caused by application-defined resources. *gigiprofiler* uses a hybrid method that combines LLM-based semantic inference with static analysis: LLM identifies candidate application-defined resources and their usage events from semantic cues, while static analysis validates these candidates against the code. *gigiprofiler* then tracks how each request interacts with inferred resources and records usage events at runtime. *gigiprofiler* detects bottlenecks from aggregate usage events and attributes each resource bottleneck to responsible requests and links the runtime evidence back to code paths to explain how the bottleneck occurs.

We evaluated *gigiprofiler* on 15 real-world performance issues in five widely deployed applications. *gigiprofiler* detects and diagnoses all 15 issues and further uncovers two previously unknown performance issues in MariaDB, both later confirmed by the developers.

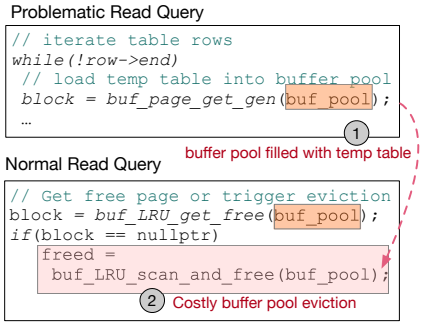
1 Introduction

Diagnosing performance issues in large-scale software is notoriously time-consuming and difficult. A recent survey [4] reports that developers spend nearly 57% of their working hours addressing performance issues. The survey finds that limited visibility into application behavior is a key reason why performance issues are difficult to understand and fix.

Performance issues caused by application-defined resources are especially difficult to diagnose because they introduce a severe visibility gap. Application resources, such as query cache, task queue, or write-ahead logs, are logical abstractions that are defined and used by the application internally. These resources are embedded in application logic and can therefore directly affect program execution and performance. However, their resource semantics, such as how they are allocated, accessed, or scheduled, are often not visible through system-level metrics, such as CPU utilization or memory consumption. As a result, bugs in the application code that manages these resources can cause performance degradation that is difficult for developers to observe and diagnose.



(a) A problematic read query fills the MySQL buffer pool with temporary tables. T^*: intrinsic temporary Innodb table.



(b) Simplified code snippet related to the buffer pool. The elements with orange-colored background represent the buffer pool variable and the pink ones represent slow eviction operations.

Figure 1: (a) Example of performance issue in MySQL buffer pool. (b) The code of the root cause.

Figure 1 shows a real performance bug in MySQL [33, 38]. MySQL uses InnoDB as its default storage engine. InnoDB has a buffer pool to cache data pages accessed by a read query, even if the page contains temporary intermediate results that no other query will reuse. As a result, a query that generates many intermediate results can monopolize the buffer pool and evict useful cached data, forcing other queries to reload pages from disk and causing end-to-end performance degradation. For example, some scan queries produce large intrinsic temporary InnoDB tables to hold intermediate results. When such a query runs, the pages of this temporary table can fill the buffer pool and displace useful cached data.

This performance bug is very difficult to diagnose in practice. Figure 1b shows the bug's code snippet: the buggy scan query repeatedly calls `buf_page_get_gen` function to obtain a large number of buffer pages and writes temporary table data into them. Subsequent read queries thus cannot get a free page from the buffer pool and must invoke a costly `buf_LRU_scan_and_free` function to evict a buffer page and reload useful data. From the code alone, this appears to be a normal buffer write: there are no lock conflicts, long loops, and no explicit error signals that indicate a slowdown. The operating system also does not show memory pressure since the buffer pool is an application-defined resource. As a result, developers have little observable evidence to follow, making the root cause extremely difficult to diagnose.

This lack of observable signals exposes a fundamental limitation in existing profilers. System-level profilers [8, 11, 13, 59] track CPU, memory and lock activity, while code-level profilers search for long loops [18, 43], blocking operations [1, 19, 49, 54], or causal relationships [5, 25, 41]. But performance issues in application resources propagate indirectly through application logic that manages the resource, logic that neither class of profiler observes. In effect, the usage of resource in one request can push later requests onto a much slower execution path, without triggering system events or producing identifiable code patterns such as long loops or hotspots. Consequently, existing profilers surface only weak indirect clues, forcing developers to rely heavily on domain expertise and manual investigation to pinpoint the true root cause.

The key gap is that application resources have semantics that traditional program analyzes alone (static or dynamic) cannot reliably infer. These tools cannot interpret how an application defines, allocates, or competes for its own application resources, making performance issues in application resources difficult to detect or explain.

To make such bugs observable, a tool must expose the interactions between requests and application-defined resources. This is difficult because application resource implementations vary widely across systems and their behavior depends on application-specific semantics not reflected directly in the control or data-flow structure. Our study of 45 real performance issues in application resources shows that, despite various application resource pathologies, four recurring application resource events can always distinguish abnormal usage from normal (Section 2.2 and Section 3.2). Concretely, each event corresponds to a distinct observable interaction with a resource: a task that waits, acquires, accesses, or releases it. We argue that diagnosing application resource performance issues must treat application resource events as first-class signals.

Automatically extracting these usage events requires interpreting both high-level semantics and concrete code behavior. Semantic cues appear in program metadata (names, comments, documentation) that static analysis cannot exploit, but LLMs can. Conversely, confirming that a candidate event truly corresponds to a resource access requires precise control- and data-flow reasoning that LLMs do not provide. We therefore adopt a hybrid design: LLMs identify candidate resources and usage events from metadata, and static analysis validates them against the actual code. This combination increases the coverage and accuracy needed to reliably locate usage events across large codebases.

Building on this hybrid approach, we propose *gigiprofiler*, a diagnosis tool that exposes the internal usage of application-defined resources. *gigiprofiler* identifies application-defined resources, tracks how each request interacts with them, and records usage event sequences during execution. A straightforward way to use usage event sequences is to search for fixed patterns that indicate bottlenecks. However, the hybrid approach may identify incorrect usage events or miss some true events. To make diagnosis robust to incorrect , *gigiprofiler* instead statistically analyzes request-resource interactions, such as how often requests wait for each resource and how often each resource is acquired, to detect bottlenecks. *gigiprofiler* then attributes each bottleneck to responsible requests and performs code-level root-cause analysis to explain which part of the code causes the resource bottleneck.

We applied *gigiprofiler* to five popular large-scale applications. MySQL, MariaDB, PostgreSQL, Apache Web Server, and llama-cpp. To evaluate its effectiveness, we reproduced 15 application resource performance bugs reported in these systems. *gigiprofiler* detected and correctly identified the root cause of all of them. In addition, during the evaluation, *gigiprofiler* discovered two new application resource performance bugs in MariaDB, both of which were confirmed by the developers. *gigiprofiler* is open sourced at `https://github.com/BlizzardLab/OmniProfiler`.

In summary, this paper makes the following contributions.

- We propose a hybrid approach that combines large language models and static analysis to accurately identify application resources and their usage events.
- We design and implement *gigiprofiler*, a performance diagnosis tool that dynamically detects internal-resource performance issues by tracing and analyzing application resource usage.

- We evaluated *gigiprofiler* on five popular applications, demonstrating its effectiveness in detecting 15 real-world internal-resource performance issues and uncovering 2 new performance bugs.

2 Understanding Application Resource Issues

Performance issues caused by application resources are prevalent in large systems. Li et al. [20] found that 22% of 115 performance issues in 20 open-source applications were caused by contention within application resources, and pBox [15] showed that requests frequently interfere with each other through application resources. In this section, we start with a motivating example to show why these issues are difficult to diagnose, and then conduct an empirical study of 45 real-world application resource performance issues to gain insight into the problem's root causes, impact, and guide our solution design.

2.1 Motivating Example

MySQL-75540 [32] is a long-standing performance issue related to the InnoDB UNDO log. Developers have reported that the purge operation can become extremely slow when the UNDO log increases, leading to significant performance degradation [30]. This issue has been discussed in multiple bug reports [29, 31] and community posts [35–37].

The issue comes from a large UNDO log that dominates the InnoDB buffer pool. MySQL uses the UNDO log to maintain older versions of modified rows for transaction isolation. A long-running transaction can therefore cause undo records to accumulate over time. After the transaction commits, these undo records become obsolete and the purge thread must load and clean them through the buffer pool. When the UNDO log is large, this cleanup process can consume many buffer-pool pages, remove useful cached pages, and cause a significant drop in throughput for other transactions. As shown in Figure 2, the MySQL's end-to-end throughput decreases from about 700 QPS to nearly zero when the purge thread starts.

Debugging this issue is challenging because the purge thread does not block other transactions directly on the UNDO log, and the buffer-pool contention is hidden from system-level metrics. The InnoDB buffer pool is a pre-allocated memory region managed by MySQL. Therefore, even when many buffer pool pages are occupied by UNDO-log cleanup, the operating system only observes normal memory usage rather than contention inside the buffer pool. As a result, during the debugging process, multiple incorrect hypotheses were proposed. For example, some developers initially suspected heavy disk I/O under concurrent updates because the system appeared overwhelmed by disk activity [28]. The true root cause was identified only after years of investigation, through careful examination of the source-code and manual tracing of the UNDO-log usage.

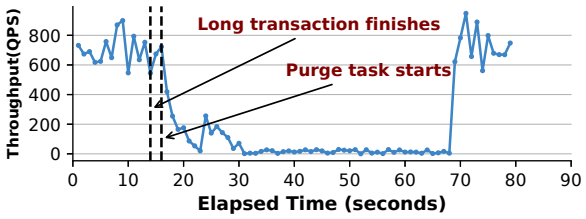


Figure 2: A throughput drop when the purge thread cleans up the huge UNDO log.

```
1   /******** Purge coordinator thread ********/
2   uint trx_purge_attach_undo_recs (node, index, entry) {
3     ...
4     while (n_pages_handled < batch_size) {
5       rec = trx_purge_fetch_next_rec(trx_id,...);
6       ...
7       purge_group.add(rec);
8     }
9     purge_group.assign(thread);
10    ...
11  }
12
13  // Gets the record in an undo log.
14  trx_undo_rec_t* trx_undo_get_rec (page_id, page_size,...) {
15    ...
16    undo_page = trx_undo_page_get(page_id, page_size, ...);
17    ...                    (1) Get a page from buffer pool
18    rec = trx_undo_page_get_first_rec(undo_page, page_no, offset);
19                           (2) Read undo log from page
20    if (rec) {
21      return (rec);
22    }
23  }
```

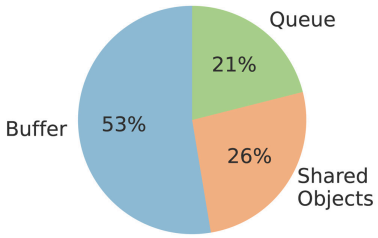
Figure 3: Code snippets showing how the UNDO log fills up the buffer pool during the purge operation.

Figure 3 shows the code relevant to the root cause. When the purge thread processes undo records, it fetches batches of undo pages into the buffer pool. With a large UNDO log, this batching is repeated many times. As a result, the purge thread evicts useful cached pages needed by other queries (step 1 in Figure 3) and keeps many undo pages in the buffer pool (step 2 in Figure 3). This frequent buffer-pool turnover slows down the system.

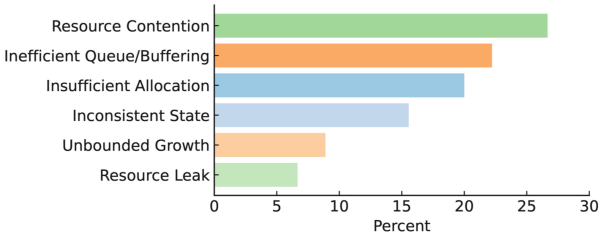
Existing performance debugging techniques have difficulty in locating the root causes: an over-sized UNDO log causes the cleanup process to consume buffer-pool pages. Profilers [19, 57] that track OS-level activity can observe indirect symptoms, such as increased disk I/O or longer execution time, but they cannot directly link the slowdown to the UNDO log and the lack of timely UNDO log truncation. Static analysis tools [18, 43, 44] lack the application-specific semantic context needed to understand how UNDO log, purge thread, and buffer pool interact to degrade performance.

2.2 Empirical Study

Application-defined resources are logical abstractions created and managed by the application code. They may use underlying system resources, such as memory, threads, or synchronization primitives, but their semantics are defined by the application. Performance issues caused by application-defined resources are difficult to diagnose because we lack



(a) Application resource Type.



(b) Root cause Type.

Figure 4: Application resource type and root cause distribution.

a systematic understanding of what kinds of application resource developers define, why they are mismanaged, and what recurring pathologies they exhibit. To fill this gap, we conducted an empirical study of 45 real-world performance issues caused by application-defined resources.

Methodology: We collect performance issues from three widely used large software systems: MySQL, PostgreSQL, and Elasticsearch. These systems contain millions of lines of code and cover two major classes of data-intensive systems: databases and distributed search engines. For each software, we manually examined bug reports and forum posts whose titles or descriptions contain terms such as "slow" or "hung", and select cases whose root causes are related to application-defined resources.

We exclude cases where the synchronization is the direct root cause, such as lock contention or deadlock. However, we keep the cases where contention comes from how an application-defined resource is managed, even if the resource is protected by locks. We keep these cases because diagnosing them requires understanding why the resource becomes monopolized, whether the monopolization is expected, and how the resource-management logic causes other requests to wait. Therefore, in those cases, identifying the contended lock alone does not explain the root cause.

Diverse Resource Types and Root Causes: Our study shows that performance issues are caused by a variety of application-defined resources. Across the 45 issues, we identified 38 distinct application-defined resources, including query caches, UNDO logs, write buffers, and write-ahead logs. A key finding is that the same application-defined resource can be implemented very differently across systems. For example, both MySQL and PostgreSQL implement a UNDO log abstraction. However, MySQL implements UNDO log as linked

Root Cause Category	Total Cases	Matched Cases
Resource contention	12	12
Inefficient policies	10	8
Insufficient allocation	9	7
Inconsistent state	7	5
Unbounded growth	4	4
Resource leak	3	3
Total	**45**	**39 (87%)**

Table 1: Mapping the 45 studied cases to the pathology patterns in our analytical model.

log records, whereas PostgreSQL stores old row versions directly in tables.

We categorize these resources into three broad types. Figure 4a shows their distribution. *Memory-related resources* are resources that provide application-level storage abstraction, such as query caches, read buffers, and shared memory. *Shared state objects* are shared application objects whose state affects the performance of many requests, such as tables, indexes, and logs. *Internal queues* are resources that order, schedule, or coordinate work inside the application, such as task queues and thread pools.

Figure 4b summarizes the root causes of the cases. Performance problems come from six categories: contention for application resources (26.7%), inefficient queuing or buffer-management policies (22.2%), insufficient resource allocation (20%), inconsistent software state (15.6%), unbounded resource growth (8.9%), and resource leaks (6.7%). Despite the diverse root-cause types, these performance issues share a common characteristic: they happen when application-specific resource-management semantics are violated under certain workloads or execution paths. When an application implements a resource, the resource implicitly carries semantics about how it should be managed. For example, the MySQL's buffer-pool implies that no single query should monopolize buffer-pool pages. Violating these semantics can cause the resource to be mismanaged and degrade performance.

Classification of Application-Resource Pathologies. We further analyze the studied cases to answer a central question: given that performance issues in application-defined resources come from application semantics, do these semantic violations share recurring failure patterns? Examining the source code of the 45 cases, we find that application-defined resources can be modeled by a simple but expressive *acquire-use-release* lifecycle, similar to the lifecycle of OS resources. A request obtains a resource, uses it to perform work, and eventually releases it. Deviations from this lifecycle give rise to common pathologies:

- **Resource Contention**: a request monopolizes an application resource, forcing other requests to acquire it through a slow or expensive path, or wait for a long time.
- **Inefficient Policies**: suboptimal eviction, batching, or scheduling policies cause a request to hold a resource that it rarely uses.

- **Insufficient Allocation**: a request receives too few resource units and repeatedly reuses a small share of the resource despite sufficient overall capacity.
- **Unbounded Growth**: an application-defined resource keeps growing unbound.
- **Inconsistent State**: incorrect creation or use of a resource leaves the system in a state that later prevents progress or causes performance degradation.
- **Resource Leaks**: an application resource leaks.

Table 1 shows that 87% of cases align with these pathology patterns. The remaining cases have policies that are too complex to fit into a category.

The general characteristic of these pathologies is that they violate application specific resource-management semantics. Moreover, their performance impact is context-dependent: a given resource usage pattern degrades performance only under particular workloads or execution paths.

2.3 Limitations of Existing Solutions

Traditional performance profilers and debugging tools diagnose bottlenecks by tracing system-level events and inferring relationships such as causal paths [5, 11, 19, 41, 59]. However, these approaches are insufficient to diagnose application-resource performance issues. Application-defined resources do not provide a unified interface that existing analyzes can directly use to construct wait-for dependencies, causal paths, or other diagnostic relations. For example, relational debugging [41] models fine-grained runtime events as relations and uses statistical A/B testing to identify relations that are likely to explain performance differences. However, it requires the relevant events to be visible to the profiler. Without knowing the internal application-defined resources, relational debugging is unable to find the root causes

A straightforward way is to report every function that modify the application-resource at runtime, but this would generate unaccepted overhead. Moreover, application-defined resources have diverse semantics and characteristics, and the OS or runtime lacks the application-specific knowledge needed to interpret their usage patterns.

Another potential solution is to combine LLMs with static analysis to detect potential application-resource pathologies. The pathology patterns in Section 2.2 can guide this process: an LLM can map a pathology to concrete code constructs, and static analysis can validate whether the corresponding resource-usage pattern exists in the code. However, these patterns are context-dependent. Static evidence alone cannot tell whether a pattern actually hurts performance in a running workload. Thus, LLM-based semantic inference and static validation must be combined with dynamic profiling to diagnose application-resource performance issues.

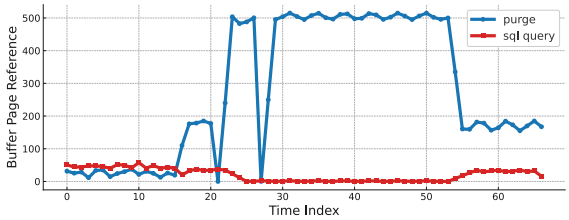


Figure 5: MySQL's buffer-pool page usage over time, split between the purge thread and all other queries.

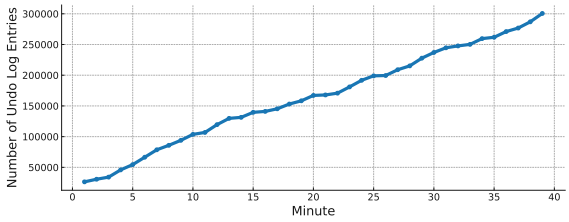

Figure 6: Growth of undo-log entries over the past 40 minutes.

The pathology study guides *gigiprofiler*'s design. It shows that diagnosing application-resource pathologies does not require tracking every internal state change of an application-defined resource. Instead, observed pathologies can be captured using a compact application resource event interface: `WAIT`, `ACQUIRE`, `USE`, and `RELEASE`.

2.4 *gigiprofiler* on the Motivating Example

To show how these application resource events help diagnose real performance issues, we apply *gigiprofiler* to the motivating example of Section 2.1.

We first reproduce the issue by creating a table with 1,000 records and running a long transaction that is active for several hours. In parallel, we issue repeated small write transactions that update the same row, causing undo records to accumulate while the long transaction is active. When the long transaction finally commits, the purge thread begins cleaning the accumulated UNDO log, and triggers the performance degradation shown in Figure 2.

gigiprofiler identifies the InnoDB buffer pool as an application-defined resource. It then identifies `trx_undo_page_get` as an `ACQUIRE` event for this resource and `trx_undo_page_get_first_rec` as a `USE` event, corresponding to lines 17 and 19 in Figure 3. *gigiprofiler* instruments these events, along with the corresponding `WAIT` and `RELEASE` events, and records that request triggers each event during execution. *gigiprofiler* applies the same event-identification process to the UNDO log. After instrumenting the usage events of both the buffer pool and the UNDO log, *gigiprofiler* records the request triggers each event during execution.

Figure 5 compares the `USE` events of the buffer pool triggered by the purge thread and by normal queries, measured as the average number of `USE` events per second. The purge thread dominates the usage of the buffer pool, indicating con-

tention for the buffer pool pages. *gigiprofiler* further identifies that most of these pages are used to store undo records, linking the buffer pool contention to the UNDO log resource. Figure 6 shows the growth of the UNDO log over time. *gigiprofiler* tracks `ACQUIRE` and `RELEASE` events for the UNDO log and estimates the size of the UNDO log as the difference between the number of `ACQUIRE` and `RELEASE`. This unbounded growth explains why the purge thread later consumes many buffer-pool pages and identifies the UNDO log as the root cause of the performance degradation.

2.5 Lesson from Our Initial Attempt

Although application resource usage events provide a useful abstraction for diagnosis, identifying them from code is challenging. Our initial attempts to use LLMs revealed significant limitations. We developed a prompt-based LLM pipeline that provides the model with the definition of application-defined resources, the roles of usage events, and concrete examples. Although this pipeline could identify many application-defined resources and usage events, its precision was low and is difficult to increase simply by improving the prompt.

We identified four key challenges. First, scaling LLM-only analysis to large systems is impractical: these systems contain millions of lines of code, exceed the model's context window, and require many expensive model calls. In our experience, scanning MySQL with GPT-5.2 took 3 days and cost about $1,000. Second, identifying application usage events often requires control and data-flow information, which is rarely available in comments or documentation. Third, comments and documentation can be ambiguous, misleading, or even absent. For example, `is_active` is only a checking function, but its comment includes the phrase "get the status of bin_log," causing the LLM to mistakenly mark it as a `USE` event. Fourth, even when comments are clear, LLMs may still make incorrect inferences or hallucinate resources that do not exist.

These limitations show that resource identification should not be treated as a monolithic LLM task. LLMs provide broad semantic coverage, but their output is inaccuracy; static analysis provides precise code reasoning, but lacks the semantic context. *gigiprofiler* avoids this trade-off by integrating both. The LLM extracts semantic cues, and static analysis validates these candidates using control-flow and data-flow information. This hybrid, agentic design grounds LLM cues in actual program behavior, reducing false positives and enabling accurate identification of application resources and their events.

3 Design of *gigiprofiler*

In this section, we describe the design of *gigiprofiler*. Our empirical study showed that performance issues in application resources can be captured by specific patterns of pathological resource usage and that neither static analysis nor LLMs alone can reliably identify application resource usage. These insights guide the design of *gigiprofiler* 's agentic static analyzer. We begin by introducing the four resource-usage events that *gigiprofiler* instruments, then describe how the agentic static analyzer identifies and validates application resources and their usage events, and finally explain how *gigiprofiler* profiles and analyzes the behavior of application resources at runtime.

Event	Parameters	Description
`WAIT`	(resource_id, `wait`)	Task spends `wait` time on the slow acquire path.
`ACQUIRE`	(resource_id, `units`)	Task obtains `units` number of the resource.
`USE`	(resource_id, use_type, target_id)	Task uses resource by read/write, optionally involving another resource `target_id`.
`RELEASE`	(resource_id, units)	Task releases `units` number of previously acquired resource

Table 2: Event types and parameters used to instrument application-defined resources.

3.1 *gigiprofiler* Workflow

We developed *gigiprofiler* to identify application resources, trace their usage, and diagnose the root causes of performance issues in application resources. Figure 7 shows its workflow. *gigiprofiler* has two phases: an offline static-analysis phase and a dynamic profiling phase. In the static-analysis phase, an agentic static analyzer identifies application resources and their usage events. Software comments, naming conventions, and documentation are preprocessed into structured metadata and provided to an LLM agent, which proposes candidate resources and events. Static analysis then validates these candidates using control-flow and data-flow information, removing false positives and producing a precise list of resources and operator functions.

In the dynamic profiling phase, *gigiprofiler* instruments the application to trace application resource events during a buggy execution. *gigiprofiler* records usage events and value samples for each resource, and the collected traces are analyzed offline to detect contended resources and identify pathological usage patterns. This integrated profiling and analysis provides developers with an explainable code-level diagnosis of performance issues in application resources.

The deployment workflow. *gigiprofiler* is designed as an on-demand diagnostic tool. The static-analysis phase runs once for each application version and produces a reusable list of application resources and usage events. The dynamic-profiling phase is activated only when a performance issue is observed, which keeps runtime overhead negligible during normal operation.

3.2 Application Usage Events

gigiprofiler models application resources using four usage events: `WAIT`, `ACQUIRE`, `USE`, and `RELEASE`, which is derived from

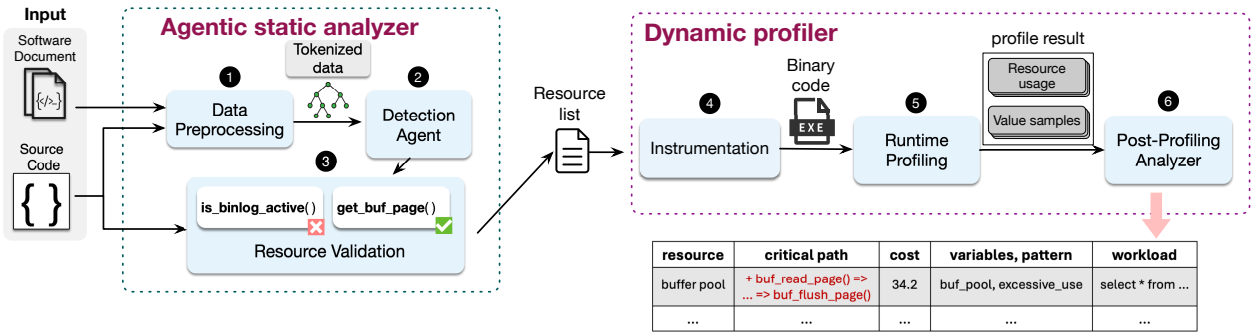

Figure 7: An overview of *gigiprofiler*.

```
/* Get a buffer page */
buf_block_t* buf_LRU_get_free_block(
    buf_pool_t* buf_pool) {
  …
loop:
  block = buf_LRU_get_free_only(buf_pool);
  get(block, 1);
  if (block) {
    return block;
  } else {
    block = buf_LRU_scan_and_free(buf_pool);
  }
  …
  goto loop
}
```

```
/* Free a buffer page */
bool buf_LRU_free(…){
  bpage = buf_pool->LRU
  while (!freed) {
    freed = buf_LRU_free_page(bgpage);
    free(bpage, 1)
    bpage = get_prev(bpage);
  }
  return (freed);
}
```

sql/buf0lru.cc

```
/* Evict a buffer page to get a new page*/
buf_block_t* buf_flush_page_from_LRU(
    buf_pool_t* buf_pool) {
  for (bpage = buf_pool.start(); bpage!=null;
        bpage = buf_pool.next()) {
    …
    if(freed = buf_flush_page(bpage)) {
      break;
    }
    …
  }
  wait(bpage, time);
  return freed;
}
```

sql/buf0flu.cc

```
/* Write to a buffer page */
buf_block_t* trx_undo_get_rec() {
  …
  undo_page = trx_undo_page_get(page_id, …);
  …
  rec = trx_undo_page_get(undo_page);
  use(undo_age,"write",rec)
  …
}
```

sql/trx00undo.cc

Figure 8: Example of tracing buffer pool usage in MySQL.

our empirical study. The API is listed in Table 2. These events provide a unified abstraction for how tasks interact with diverse application resources. `WAIT` records the time a task spends on a slow acquisition path; `ACQUIRE` denotes when a task obtains a unit of the resource; `USE` denotes operations performed using the resource, such as reading or writing; and `RELEASE` denotes when the resource is returned. Although simple, this model captures the pathological patterns observed in our study: contention appears as prolonged `WAIT` events, inefficient policies manifest as resources that are frequently `ACQUIRE` and held for long periods without corresponding `USE` events, insufficient allocation emerges as repeated `ACQUIRE` attempts, and unbounded growth or leaks surface as unmatched `ACQUIRE`/`RELEASE` pairs.

Instrumentation is fully automated: once the agentic static analyzer identifies the code locations corresponding to `WAIT`, `ACQUIRE`, `USE`, and `RELEASE` events, *gigiprofiler* injects lightweight probes at those locations using an LLVM pass. No developer effort or manual annotation is required. Figure 8 shows the instrumentation points that *gigiprofiler* insert into the MySQL buffer pool. The `ACQUIRE` event is implemented as the `get` API, which *gigiprofiler* inserts in `buf_LRU_get_free_block()` after a buffer page has been obtained from `buf_LRU_get_free_only()`. If no free page is available, MySQL chooses an old page via `buf_flush_page_from_LRU()`, and *gigiprofiler* records a `WAIT` event to capture the time spent on this slow-acquiring path. When a page is returned to the buffer pool in `buf_LRU_free()`, *gigiprofiler* emits a `RELEASE` event via the `free` API. Finally, when `trx_undo_get_rec()` writes the undo log to a buffer page, *gigiprofiler* logs a `USE` event to record that the page is being used to store undo records. Together, these events allow *gigiprofiler* to reconstruct how tasks acquire, wait for, use, and release buffer pool pages.

3.3 Finding Application Usage Events

3.3.1 Organizing Input Data

Identifying application-defined resources and usage events in a large scale system is challenging. Large-scale software design consists of dozens to hundreds of resources and spans millions of lines of code. Feeding the entire codebase to an LLM as plain text would cause the LLM to lose essential software context, such as control-flow and cross-file relationships that are needed to identify application resources accurately. A straightforward approach is to split the codebase into smaller chunks and run the LLM iteratively, but naïve chunking breaks the structural relationships between files, classes, variables, and functions. The semantic context needed to recognize how resources are defined and used. Thus, *gigiprofiler* requires a more systematic method for organizing and presenting the software context to the LLM.

To preserve context while searching large codebases, *gigiprofiler* organizes metadata into a hierarchy of file → class → variable → function → source code. The LLM agent traverses this hierarchy, pruning branches early when a higher-level node is unlikely to represent a resource. This structure preserves cross-file context and enables efficient, targeted queries despite LLM context-length limits.

Figure 9 shows a snapshot of the hierarchy structure of *gigiprofiler* for MySQL. It is implemented as a restricted directed acyclic graph that enforces a fixed parent–child order from the file to the class/struct variable, to the member variable in the class or structure variable, to the function descrip-

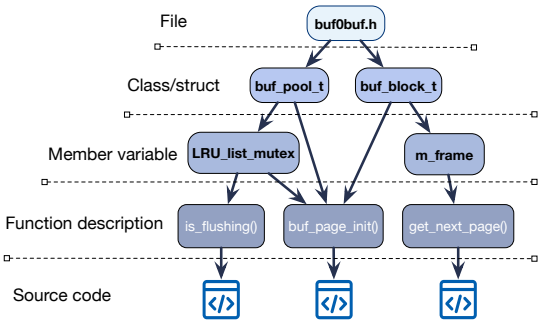

Figure 9: Example of hierarchy structure for MySQL.

tion and finally to the source code. Each node stores relevant metadata, such as names, types, and associated comments or docstrings, to preserve semantic context. A pre-processing module constructs this DAG by parsing the source code and documentation to extract metadata and connect nodes based on data dependencies.

3.3.2 LLM agent

Once the codebase is organized into the hierarchy, the LLM agent must identify candidate application-defined resources and usage events efficiently and accurately. A straightforward approach is to traverse the hierarchy node by node, but this approach is inefficient. First, it may visit many nodes that are clearly unrelated to any resource. Second, the same node can be visited multiple times through different paths. For example, in Figure 9, both `buf_pool_t` and `buf_block_t` may lead the traversal to the function `buf_page_init`.

To avoid redundant and unnecessary queries, *gigiprofiler* uses a top-down traversal with a two-phase reasoning process. Our insight is that application-defined resources are usually represented as class or structure instances, or as variables, whereas usage events are implemented in functions. Therefore, the agent first queries the LLM on high-level class, structure, and variable nodes to identify candidate application-defined resources and then uses these candidates to filter out unrelated function nodes. Because function and source-code nodes contain far more tokens than higher-level metadata nodes, this approach significantly reduces offline analysis time and LLM cost without sacrificing coverage.

The first phase is performed on both the class and variable layers. Figure 10 shows a snapshot of the prompt used by our LLM module to identify the application resources. The prompt contains a short task summary and step-by-step checks that guide the detection agent in deciding whether the variable represents an application resource. We categorize resources into two types: *exclusive resources*, which are accessed by at most one thread (or owner) at a time (e.g., an UNDO log instance tied to a transaction) and *shared resources*, which are concurrently accessed by multiple threads (e.g., buffer pools and work queues).

After identifying candidate application-defined resources, the agent invokes a lightweight data-flow analysis to find

 # Task summary:
You are a class analyzer that analyzes whether a class may represent a key resource in MySQL according to the name of the class and some documents about the functionality of the class.

 # Instruction:
An application-defined resource is a logical software resource whose use can affect performance. Resources are typically accessed across multiple functions and may be acquired, used, or released according to application-specific semantics.
Your goal is to:
1. Infer the high-level purpose of the given class, structure, or function using naming conventions, comments, and metadata.
…
 # Examples:
…

Figure 10: Prompt snapshot for the first phase

functions that use these resources. If a function uses multiple resources, the agent groups it as a function-to-resource pair and analyzes them together, which avoids repeated LLM queries on the same function .

For each selected function, the agent prompts the LLM to determine whether the function contains any of the four usage events. If the function signature and description provide sufficient evidence, the agent makes a candidate decision at the metadata level. Otherwise, the agent inspects the function's source-code node for additional context. To help the LLM interpret the function in context, the agent also provides call-stack information and the source code of related functions when available. If the agent cannot confidently determine whether an operation is a valid usage event, it marks the operation as a candidate and defers validation to the static analyzer.

3.4 Validation of Resource Usage Events

After the LLM agent identifies candidate resources and usage events, the static-analysis module validates whether a candidate event actually waits for, acquires, uses, or releases the corresponding resource. This step is critical because the LLM agent has low precision: without validation, false usage events would be instrumented, and later mislead dynamic diagnosis.

A fundamental challenge is that checking a candidate event requires validating a semantic property that standard program analyzes cannot easily decide on. Existing LLM-assisted static-analysis pipelines often use control-flow or data-flow analysis to validate standard program. However, validating a resource-usage event requires more than such structural consistency. For example, validating that a function is an `ACQUIRE` event for the buffer pool requires checking whether the function actually obtains a buffer pool page and passes it to the caller that will use it to store some internal data. There is no data flow analysis can observe this pattern.

To tackle this challenge, *gigiprofiler* translates each semantic event into a set of necessary code behaviors that the event should exhibit.For example, an `ACQUIRE` event should satisfy three necessary code behaviors: (1) it obtains a resource unit from the resource, (2) it passes the unit to the caller or the

Algorithm 1: Validation for get and wait event

Input : Resource candidates R, Usage events E, Target Function F
Output : Validated resources and events

```
1  foreach candidate (R,E,F) do
2      if E.type == get then
3          CheckAcquire((R,E,F))
4      else if E.type == wait then
5          CheckAcquire((R,E,F))
6  Function checkAcquire(R,E,F):
7      tainted ← GetAllTaintedVar(F,R);
8      if IsResourceWritten(F,tainted) then
9          mark E as invalid acquire;
10         return;
11     if ! IsResourceReturned(F,tainted) then
12         mark E as invalid acquire;
13         return;
14     if ! HasLookupPattern(F,tainted) then
15         mark E as invalid acquire;
16         return;
17     mark E as valid ACQUIRE;
```

Algorithm 2: Validation for release and use event

Input : Resource candidates R, Usage events E, Target Function F
Output : Validated resources and events

```
1  foreach candidate (R,E,F) do
2      if E.type == release then
3          CheckRelease((R,E,F))
4      else if E.type == use then
5          CheckUse((R,E,F))
6  Function CheckRelease(R,E,F):
7      tainted ← GetAllTaintedVar(F,R);
8      sites ← FindReleaseSites(F,tainted);
9      if sites is empty then
10         mark E as invalid release;
11         return;
12     if HasUseAfterRelease(F,tainted,sites) then
13         mark E as invalid release;
14         return;
15     if ReturnsReleasedValue(F,tainted) then
16         mark E as invalid release;
17         return;
18     mark E as valid RELEASE;
19 Function CheckUse(R,E,F):
20     tainted ← GetAllTaintedVar(F,R);
21     if TouchesResource(F,tainted) then
22         mark E as candidate USE for dynamic validation;
23     else
24         discard E as spurious;
```

task that will use it, and (3) it does not modify the variable of the application resource. These behaviors are necessary for an ACQUIRE event. *gigiprofiler* then converts these behaviors into static analysis checks, such as checking whether function F's return value comes from resource variable R. Here, F, R, and the event type are provided by the LLM.

For an ACQUIRE(get) event, *gigiprofiler* checks three properties. First, the function should not modify the resource variable during acquisition because the application resource must be read-only during acquisition. Second, the function's return value must be derived from the resource variable; otherwise, it is not actually "getting" a resource unit. Third, the function should search for the resource through iteration, hashing, or indexed access. The Algorithm 1 shows the core logic. The analyzer taints the resource variable, propagates the taint through dependent values (line 7), and verifies that all tainted values are read-only(line 8). It then checks whether the return value is tainted (line 11) and whether the function performs a search over the resource (line 14).

A WAIT event represents the slow path to acquire an application resource. Statistically, its code structure is the same as the ACQUIRE event but includes an additional delay or retry loop. *gigiprofiler* performs structural validation using the same rules as ACQUIRE and relies on the dynamic profiling phase to determine whether the path is truly slow. If the dynamic profiler does not observe a slowdown, the WAIT event is ignored.

For a RELEASE event, the static analyzer verifies that the function exhibits a release-like effect. Concretely, the function should invoke a known release primitive (e.g., a freelist insertion, LRU return, or deallocation routine), after which the resource variable must not be used on any execution path. Thus, *gigiprofiler* enforces a no–use-after-release rule (Line 12 in Algorithm 2). Because static analysis may miss indirect or dynamic uses, the no–use-after-release rule is also enforced during the dynamic profiling phase, which confirms whether the released resource is ever touched again at runtime. The release operation must also transfer the resource back to the application rather than returning the released object to the caller (Line 15 in Algorithm 2).

For USE event, static analysis only marks the resource as potentially used. Dynamic profiling later verifies whether the resource was acquired by the same task before being used and the function is using the resource.

Scope of validation. The static validation module is not intended to be a complete or sound detector of usage events. Its role is to improve the precision of LLM-inferred candidates. The LLM first identify which program variable is the application resource and which event type the function may represent. Given these candidate functions and variable, static analysis checks whether the function exhibits code behaviors that are necessary for the claimed event type.

This LLM-provided candidate is what makes validation practical. Without this candidate, the static analyzer would need to apply all all checks to all variables, all functions, and

all event types, which would be impractical for large-scale software and would produce many false positives.

3.5 Dynamic Profiling

After the software is instrumented with application-resource event hooks, *gigiprofiler* executes the software using a workload that reproduces the buggy execution. During runtime, *gigiprofiler* only records lightweight event information and defers expensive computation to the post-profiling analysis. Each event is logged with a timestamp, resource ID, thread ID, event type, and event-specific parameters, and is stored in a lightweight thread-local ring buffer to avoid costly inter-thread communication on the critical path. *gigiprofiler* periodically and asynchronously flushes the local buffers to the disk. In addition, *gigiprofiler* integrates with *perf* to periodically sample hardware counters, system-resource usage, and application call stacks.

3.5.1 Post-Profiling Validation

Some usage event's rule cannot be validated statically. The post-profiling validation filters these events using the runtime event trace. The validation first checks whether events follow the expected lifecycle order. Within a request, an application-defined resource should follow the expected event order: `ACQUIRE` $\rightarrow$ `USE` $\rightarrow$ `RELEASE`. That is, a resource should be acquired before it is used, and released only after its last use. Across requests, a `WAIT` event should correspond to a conflicting holder of the same resource. The expected order is: $\texttt{ACQUIRE}_{r_1} \rightarrow \texttt{WAIT}_{r_2} \rightarrow \texttt{ACQUIRE}_{r_2}$, where request or task r_1 acquires the resource first, and request or task r_2 waits before later acquiring it. Events that violate these ordering rules are discarded as invalid usage events.

The post-profiling validation then checks the event-specific runtime behavior. For a `WAIT` event, *gigiprofiler* verifies that the event corresponds to a real delay in the slow acquire path. For a `USE` event, *gigiprofiler* check that the instrumented code actually reads or writes the associated resource unit at runtime. For a `RELEASE` event, *gigiprofiler* checks that the released unit is touched by the release function and is not used again by the same request after release. These runtime checks remove false events that pass static validation.

3.5.2 Diagnosing Performance Issues

Even after static and runtime validation, some false application resource events may remain, and some true events may be missed. This makes traditional wait-for analysis unreliable if it treats every event as exact. Directly applying traditional trace-based analysis to such traces can be unreliable. For example, a false `WAIT` event may create a wrong wait relation, while a missing `ACQUIRE` event after a true `WAIT` may make the wait time to be longer than it actually is.

gigiprofiler therefore diagnoses performance issues using aggregate request-resource statistics rather than individual event matches. For each resource, *gigiprofiler* aggregates event signals across requests and functions and computes four per-task metrics. First, *waiting time* measures how long a task spends on the slow acquire path, using timestamps from `WAIT` and `ACQUIRE` event pairs. Second, *utilization* measures how frequently an acquired resource is actually used, computed as the ratio of `USE` to `ACQUIRE` events. Third, *hold time* measures how long a task holds a resource, computed as the time between `ACQUIRE` and `RELEASE`. Fourth, *acquire frequency* measures how often a task repeatedly acquires resource units, computed as the number of `ACQUIRE` events per second.

After computing these metrics, *gigiprofiler* detects pathological usage patterns as follows. If a resource has high aggregate waiting time across requests, *gigiprofiler* classifies it as resource contention. If a task holds a resource for a long time but rarely uses it, indicated by long hold time and low utilization, the pattern is classified as an inefficient policy. If a task repeatedly acquires small resource units despite high utilization, indicated by high acquire frequency, the pattern is classified as insufficient allocation. If `ACQUIRE` events are not matched by `RELEASE` events after a task finishes, *gigiprofiler* identifies a resource leak. If the aggregate gap between `ACQUIRE` and `RELEASE` events continues to increase with time, *gigiprofiler* identifies unbounded growth.

After identifying a bottleneck resource and the tasks responsible for this performance issue, *gigiprofiler* performs root cause analysis to explain why the performance issue occurs at the code level. This step is critical for developers as it pinpoints the specific code paths that trigger the pathological behavior of the resources. *gigiprofiler* performs a static backward analysis based on the usage events of the misbehaving task, tracing the control and data-flow dependencies to locate the operations that initiated resource acquisition, prolonged hold time, or prevented release. Because *gigiprofiler* also records value samples for variables associated with each event, the analysis can highlight values when pathological behavior occurs. To ensure actionable explanations, *gigiprofiler* focuses this backward analysis on code sites that determine how the resource is held, used, and reclaimed, which are precisely the decisions that lead to contention, insufficient allocation, inefficient policies, or leaks. These locations are flagged as the root cause and reported to developers.

3.6 Implementation

We implement *gigiprofiler* as a combination of Python-based analysis components, an LLVM-based static analyzer, and a C++ runtime profiling library. The data preprocessing module is implemented as a Python script that parses source code and documentation. The LLM agent is implemented as a Python orchestrator. It traverses the hierarchy, maintains traversal state, issues LLM queries for selected nodes, and invokes

lightweight static-analysis routines to connect candidate resources to related functions. The underlying LLM is configurable and can be replaced without changing the rest of the *gigiprofiler* pipeline.

The *gigiprofiler* static analyzer is built on top of LLVM [21]. The *gigiprofiler* profiler is implemented as a C++ library that can be linked with the target software. It injects lightweight profiling hooks at validated event locations and records event traces during execution.

4 Evaluation

We evaluate *gigiprofiler* to answer the following questions: (1) How accurately does *gigiprofiler* identify application-defined resources and their usage events? (2) Can *gigiprofiler* detect and localize real-world performance issues in application resources? (3) Can *gigiprofiler* explain these issues by pinpointing their code-level root causes? (4) What is the runtime overhead of dynamic profiling?

We evaluated *gigiprofiler* on five popular, large-scale applications: MySQL, PostgreSQL, MariaDB, Apache Web Server, and llama.cpp. These systems have up to 2 million source lines of code. *gigiprofiler* scans each system and automatically instruments its APIs without requiring manual annotation. All experiments were conducted on servers equipped with 10-core Intel Xeon E5-2640 CPUs, 64 GB of DRAM, and a 480 GB SSD, with Ubuntu 20.04 as the operating system. The main evaluation uses GPT-4o as the underlying LLM model, which was the newest GPT model available when the experiments were conducted. Unless otherwise specified, all results in the evaluation use this GPT-4o.

4.1 Diagnosing Root Cause

To evaluate the effectiveness of *gigiprofiler*, we collected 15 real-world cases of performance issues in application resources. These issues were collected from the official bug-tracking systems of each application, community forums such as StackOverflow and developer posts on social media. As summarized in Table 3, the selected performance issues span a diverse set of resources and performance issue patterns, providing a comprehensive benchmark for evaluation.

For each performance issue, we prepared a reproduction script to trigger the issue. We compare *gigiprofiler* against three baselines: *perf*, a widely used system-level profiler; *PCatch* [19], a performance-bug detection tool for identifying cascading performance issues; and *Perspect* [41], a a relational debugging tool that automatically pinpoints the root causes of performance problems by analyzing statistical changes in the relations between fine-grained runtime events. Both *PCatch* and *Perspect* require program-internal events as input, such as synchronization operations or selected program variables. To provide these inputs without manually specifying application-defined resources, we use SyncFinder [54] to identify application-specific synchronization primitives as input to both systems.

Id.	App	Resource	Root Causes
c1 (link)	MySQL	UNDO log	Unbounded Growth
c2 (link)	MySQL	Table metadata	Resource Contention
c3 (link)	MySQL	MDL	Inefficient Policy
c4 (link)	MySQL	Buffer pool	Resource Contention
c5 (link)	MySQL	Buffer pool	Resource Contention
c6 (link)	MariaDB	Foreign keys	Inefficient Policy
c7 (link)	MariaDB	Queue	Insufficient allocation
c8 (link)	PostgreSQL	MultiXact cache	Resource Contention
c9 (link)	PostgreSQL	pgss	Resource Contention
c10 (link)	PostgreSQL	Shared memory	Inefficient policies
c11 (link)	PostgreSQL	Write Ahead log	Inconsistent state
c12 (link)	PostgreSQL	Reorder buffer	Resource Leak
c13 (link)	Apache	Buffer	Inefficient policies
c14 (link)	Apache	Thread pool	Insufficient policies
c15 (link)	LLAMA	Result queue	Resource Contention

Table 3: Description of 15 *real-world* application resource performance issues.

As shown in Table 4, *gigiprofiler* successfully find the true root cause(s) as the top candidate in all 15 cases. Three cases have multiple root causes, and *gigiprofiler* correctly ranked all of them ahead of unrelated candidates. The analysis process was also fast. On average, *gigiprofiler* takes 95.15 seconds to detect an issue and identify the root cause.

In comparison, *perf* failed to detect the issues in 10 out of the 15 cases. In the 5 cases where performance problems were reported, the true root cause function was ranked very low, making it difficult for developers to locate root causes. PCatch also failed to detect 10 of the 15 cases. it missed all shared resource performance issues as they do not block other requests through synchronization. The Perspect detected 4 of the 15 cases. Perspect detected 4 of the 15 cases. The reason is that Perspect need the normal and buggy executions to determine which relations are abnormal. But in our evaluation, we only provide the reproduced buggy execution because *gigiprofiler* does not require a normal run. As a result, the Perspect can not performance differential analysis correctly.

We provide a case study to show how *gigiprofiler* detects and diagnoses performance issues in application resources:

Case 10: Send Buffer Exhaustion. Apache has a bug where the server continues writing to the send buffer even after the client has stopped receiving data. This behavior gradually fills the buffer with unneeded data, exhausting the buffer pool and blocking new writes. Because the send buffer is managed as an application resource, both *perf* and *PCatch* fail to detect the issue. By contrast, *gigiprofiler* exposes the buffer resource and identifies prolonged waiting times when tasks attempt to acquire free buffer space. Moreover, *gigiprofiler* finds that the data written in the buffer was never used by any client. This direct linkage between prolonged waits and low resource utilization enabled *gigiprofiler* to locate the Apache overuse of the send buffer.

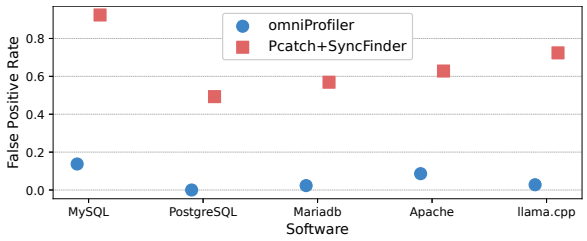

Figure 11: False positive rates across five software.

4.2 Detecting New Performance Issues

To further demonstrate *gigiprofiler* 's effectiveness, we monitored new bug reports from the five evaluated applications. We specifically focused on performance issues with unknown root causes and without clear system-level signals. For each report, we constructed a reproduction script and applied *gigiprofiler* to the corresponding application. During this exercise, *gigiprofiler* successfully diagnosed two new cases of performance issues in application resources. In both cases, the diagnoses were confirmed by developers:

MDEV-34989 [27]. After executing a `SELECT` statement, subsequent `INSERT` operations in the same table would hang for an extended period. *gigiprofiler* identified that the root cause is that if the table is empty, the `SELECT` query holds the table's metadata for too long. This prevents the `INSERT` thread from acquiring the `TABLE_SHARE` resource. The developers confirmed the diagnosis and released a fix.

MDEV-34836 [26]. In a Galera cluster, a read query would unnecessarily hold a parent table while operating on a child table. As a result, a DDL transaction on the parent table would mistakenly operate on the query. However, since the query actually accesses the child table, it would block the DDL transaction on the parent table. *gigiprofiler* identified the root cause by finding that the query that held the parent table never actually accessed it. The developers confirmed this diagnosis and addressed the bug.

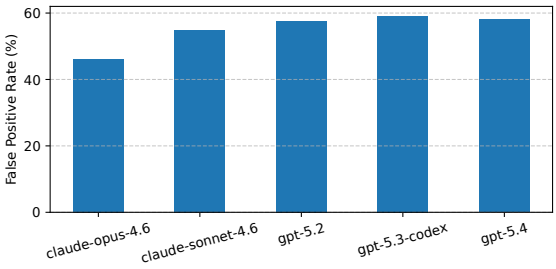

Figure 12: False positive rates across five LLM model

4.3 Accuracy of Finding Software Resources

The precision of identifying application resources is critical for the effectiveness of *gigiprofiler*. To evaluate this, we run the *gigiprofiler* in the five software and manually inspected the accuracy of identifying all the application resource usage events. We compare *gigiprofiler* with SyncFinder+PCatch, the state-of-the-art static analysis tool to identify waiting events in the application code.

As shown in Figure 11, *gigiprofiler* consistently achieves low false-positive rates in the five applications. Even for MySQL, which has the largest codebase in our evaluation, *gigiprofiler* achieves a 13.6% false-positive rate in identifying application-resource usage events. In comparison, the static analysis approach has much higher false-positive rates.

4.4 Sensitivity to different LLM model

Because *gigiprofiler* can use different LLM as the underlying model for its LLM agent, we evaluate whether the coverage and precision of the identification are sensitive to the choice of LLM. We run the LLM agent on MySQL using five different models, including recent GPT and Claude models, e.g., GPT-5.4 and Claude-Opus-4.6, as well as code-agent models(gpt-5.3-codex). To isolate the sensitivity effect of the LLM, we only evaluated the LLM agent without static validation. We manually inspect the identified resources and usage events to determine which candidates are true positives and false positive. For each candidate event, we review the source code to confirm whether the function actually accesses the corresponding application-defined resource.

Figure 12 shows the false-positive rate of each model. All tested models have high false positive rates, ranging from 45% to 60%. The GPT models show similar false-positive rates. The result suggests that the precision problem is not specific to the GPT-4o model used in the main evaluation. Claude-Opus achieves the lowest false-positive rate, but it also identifies fewer candidates(as shown in Sec 4.6)

4.5 Ablation Study on *gigiprofiler* workflow

gigiprofiler uses three modules to improve the accuracy of identifying application-resource usage events: LLM agent, static validation, and post-profiling validation. We conduct

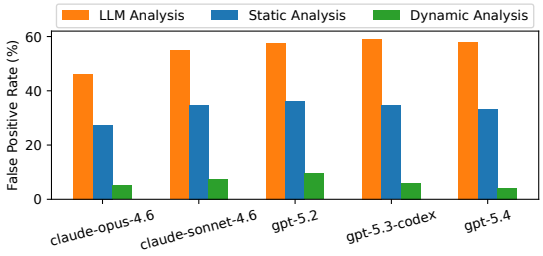

Figure 13: False positive rates in different phases of *gigiprofiler* workflow.

an ablation study to quantify how each module reduces false positives in the identified events. For the LLM agent and static validation, we compute the false-positive rate over all identified events. For post-profiling validation, however, runtime evidence is available only when a workload triggers the corresponding events. We therefore run a set of standard *sysbench* workloads together with our reproduction scripts to cover as many resources as possible, and compute the false-positive rate only over the events observed during execution. We run this study on MySQL using five different LLMs.

As shown in Figure 13, the LLM agent alone produces high false-positive rates, ranging from 45% to 60%. Static validation reduces these rates by 22% on average. Post-profiling validation further reduces the false-positive rate by 24%.

4.6 Coverage of Application Resources

We evaluate whether *gigiprofiler* misses application-resource usage events. Obtaining ground truth on how many application resource events are in a large-scale system is difficult because application-defined resources are not explicitly enumerated in any documentation.We therefore conduct two complementary evaluations. First, we cross-check using the manually validated SyncFinder+PCatch results from Section 4.3. Second, we performed an exhaustive case study on the MySQL buffer-pool subsystem, where we manually enumerate resource-usage functions and events for a small set of well-defined resources.

Cross-check with PCatch. In MySQL, *gigiprofiler* identified 154 usage events but missed 23 valid events found by SyncFinder+PCatch, a false negative rate of 13.0%. These missed events come from two main sources. First, the LLM misses some usage points when comments are absent. Second, the static analyzer misses some resource-access patterns that do not match its validation rules. In comparison, SyncFinder+PCatch misses around 100 usage events found by *gigiprofiler*, a false negative rate of 66.7%.

Case Study: Buffer Pool in MySQL. To obtain a more detailed coverage estimate, we performed a case study on the MySQL buffer-pool subsystem. We focus on three core buffer-pool resources, `buf_pool_t`, `buf_block_t`, and `buf_page_t`. We exhaustively enumerate functions that involve these resources and manually label their usage events. This scope is limited to the buffer-pool subsystem, but gives us a precise ground truth to analyze the events *gigiprofiler* tend to miss.

Model	Missed Events					Missed Functions
	ACQUIRE	USE	WAIT	RELEASE	Total	
Opus-4.6	12	36	38	1	87	25
Sonnet-4.6	10	35	26	1	72	21
GPT-5.2	11	30	29	1	71	26
GPT-5.3-codex	14	35	32	0	81	25
GPT-5.4	11	38	29	0	78	24
Average missing rate	22.7%	24.0%	23.2%	6%	23.0%	12.1%
Total Event	51	145	133	10	339	200

Table 5: Coverage study for the MySQL buffer-pool subsystem. The `ACQUIRE`, `USE`, `WAIT`, and `RELEASE` columns break down the missing events by event type.

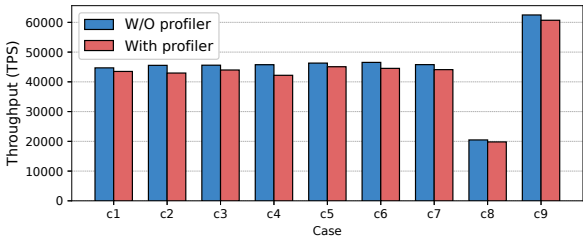

Figure 14: Overhead under 6 cases.

As shown in Table 5, the buffer pool subsystem contains 339 events that span 200 different functions. On average, *gigiprofiler* misses about 23% of events and 12% of functions in the tested LLMs. Among the different models, Opus-4.6 misses the most events, missing 25% of events. We manually checked all missed events and found that most missed events are caused by misclassifications of the event type. For example, If the LLM mis-classifies an event that should be `ACQUIRE` as a `USE` event, the candidate will be checked using the wrong event rule and get rejected. As a result, the true `ACQUIRE` event is missing from the final set of events.

4.7 Runtime Overhead

Finally, we evaluated the runtime overhead of *gigiprofiler*. Because *gigiprofiler* activates its tracing only when a performance issue is triggered, measuring overhead on a generic workload, where tracing is inactive, can not provide a meaningful comparison. We therefore report overhead on 9 of the 15 reproduced issues. We exclude cases 10, 11, and 15 because they lead to CPU hangs making end-to-end performance comparison meaningless. Case 12 is a leak that does not produce measurable throughput degradation. Cases 13 and 14 occur in a web-server setting, where additional client-side instrumentation is needed to trace the overhead.

Figure 14 shows the throughput across the 9 measurable cases. *gigiprofiler* incurs consistently low overhead, averaging 3.7% and never exceeding 7.8%. The observed overhead primarily comes from tracing resource-usage events and writ-

ing them to a ring buffer. Because the current implementation records every event, sampling or batching could further reduce overhead with minimal impact on diagnostic accuracy.

5 Related work

Diagnosing performance bottlenecks in large-scale software systems has been a critical challenge. Existing performance analysis tools can be broadly categorized into general profilers, causality analysis tools, and application-specific methods.

Performance Issue Detection. Profilers [3, 5, 7–9, 11, 13, 14, 39, 57] are fundamental tools for detecting performance problems and identifying associated symptoms. These tools focus on revealing performance-intensive events (e.g., functions, loops, or resource usage) but leave developers to manually infer the underlying reasons for resource contention. Statistical debugging [41, 43, 48] analyzes application-level events to detect performance anomalies. These tools effectively correlate specific code behaviors with performance degradation, making them particularly suitable for identifying issues related to custom synchronization logic or other application-specific patterns. However, interpreting the results of statistical debugging typically requires significant manual effort, as developers must deduce why certain predicates correlate with poor performance. In contrast, *gigiprofiler* identifies application resource usage patterns and directly links these patterns to performance anomalies at runtime, which allows *gigiprofiler* to clearly explain the root causes of performance problems involving resource misuse, thereby reducing the manual investigative effort required by developers.

There are also tools tailored for debugging specific types of performance problems using predefined patterns. For example, loop-oriented debugging tools [34, 44] target performance degradation caused by inefficient or excessive loop iterations, while memory leak detectors [22, 47] focus on identifying and diagnosing memory issues. In contrast, *gigiprofiler* is designed to serve as a general-purpose diagnosis tool, capable of addressing application resource misuse.

Causality Analysis. Numerous techniques have been developed for causality analysis in performance debugging [2, 17, 25, 40]. For example, Argus [50] introduces causality graphs annotated with strong and weak edges, enabling prioritization of relational analyses for complex systems. Similarly, Pensieve [58] demonstrates how runtime logs, combined with static analysis, can reconstruct causal paths and uncover performance bottlenecks. Value-assisted profiling [49] enhances performance diagnosis by capturing and analyzing variable value patterns during execution. While these methods are effective in analyzing runtime interactions and identifying causal dependencies, they rely heavily on existing logs and annotations, which are often unavailable or incomplete for application-defined resources.

LLMs for Software Analysis. Modern large language models have revolutionized code-related tasks, including code generation [10], program repair [12, 42, 51, 52, 55], automated testing [6, 16], and specification generation [23]. Despite their advancements, LLMs face challenges in interpreting application-defined semantics due to their inherent variability.

Recent works [24, 45, 46, 53, 56] combine LLMs with program-analysis techniques for tasks such as binary-code understanding, decompilation, specification generation, and static checker synthesis. These systems use a "propose and validate" approach: it first allows LLMs to propose candidate and then uses program analysis validates these candidates. *gigiprofiler* differs from these systems in two ways. First, *gigiprofiler* targets application-specific resource semantics that can not be validated by standard program analysis. For example, ReSym [53] uses pointer analysis to check the consistency among recovered variables and symbols of the data-structure. In contrast, *gigiprofiler* must decide whether a program variable is a resource defined by the application and whether a function is semantically an event for that resource. There is no standard static-analysis rule for making this semantic judgment. Second, *gigiprofiler* targets large-scale server systems. Existing LLM-assisted approaches that analyze small code fragments do not scale well to large-scale system. They can miss cross-file context, require many expensive LLM calls, and produce low-precision results when the resource semantics depend on broader application logic.

6 Conclusion

Performance issues in application resources are a major source of hidden slowdowns in modern software, yet they remain difficult to detect and diagnose because their effects do not manifest through system-level signals. This paper introduced *gigiprofiler*, a diagnosis tool that exposes the behavior of internal resources in an application by identifying resources defined by the application, tracking how tasks wait for, acquire, use and release them, and describing slowdowns to the underlying code paths. *gigiprofiler* combines LLM-based semantic inference with static analysis to automatically recover resource-usage events across large and heterogeneous codebases, and instruments lightweight runtime tracing to detect pathological usage patterns. Our evaluation on five large applications shows that *gigiprofiler* accurately diagnoses the root cause for all 15 reproduced real-world performance issues in application resources and detected two previously unknown issues confirmed by developers.

Abstract

Shell scripts are pervasive, acting as the glue between commands and subprocesses that are written in a variety of languages and perform complex, system-wide effects. Given the black-box nature of these subprocesses, all work that optimizes script performance until now has relied on handwritten annotations that describe subprocess effects. In this paper we introduce hS, a system that brings *out-of-order, speculative execution* to scripts that invoke subprocesses without requiring any user input or annotations about them. hS speculatively executes command instances—typically simple commands, pipelines, or small synchronization regions—dynamically detecting their effects: blocking unsafe ones, like network accesses, and selectively committing independent effects, like file writes, given no conflicts. On a wide range of real-world scripts, hS offers up to 9.3× speedups compared to bash, and up to 7× speedups over PaSh—all while not requiring any developer involvement or command annotations.

1 Introduction

Shell programming is as prevalent as ever, consistently ranking among the top ten programming languages and growing in popularity more quickly than other established languages such as C and Python [24]. Shell programs are often used for various analytics [50, 61], bioinformatics [8, 23], and other performance reliant applications [4, 55, 63]. This has recently led to significant academic activity aimed at accelerating shell scripts through parallelization [29, 54, 62], distribution [42, 50], and other forms of scaleout [18, 35, 55]. This academic work on the shell relies on command annotations to optimize commands, which are either crowd-sourced or baked into each system. Unfortunately, existing approaches face two significant challenges: (1) annotations are restrictive, and (2) they focus primarily on data parallelism.

Existing tools such as PaSh [29, 62] and POSH [50] only optimize fragments of shell programs for which their command annotations fully specify the parallelizability, input order, and side effects of each command. While it is plausible to have a blessed set of annotations for GNU Coreutils or `util-linux`, we cannot hope to have annotations for every command a script might invoke. Some scripts compile and run their own commands—it is unreasonable to assume that *those* commands will be annotated! Relying on annotations significantly reduces the scope and applicability of shell tooling, which is the main way to compose tools written in different languages and frameworks [23, 49]. The usage of shell to compose domain-specific programs are precisely where existing tooling falls short.

Furthermore, existing tools are limited to *order-preserving* data parallelization to avoid introducing concurrency bugs—for example, PaSh and POSH explicitly treat composition primitives, like `;` and `if`, as synchronization barriers and will not typically optimize across any control flow.[1] However, not all order need be preserved! A standard optimization that is done by many modern compilers and architectures is out-of-order execution, where code is reordered, sometimes in a speculative way, and dependencies are dynamically tracked to guarantee that the out-of-order execution will have the same semantics as the original.

In this paper, we propose hS, a novel system that enables out-of-order optimizations in the shell in a fully transparent way: hS executes script regions speculatively out-of-order *without any developer input or annotations*. These regions are the executable units exposed by the shell program's structure—typically simple commands or pipelines, rather than individual Unix processes. In contrast to all prior work, this enables hS to support scripts that compose arbitrary binaries, like bioinformatics tools. hS achieves this: (1) by *dynamically* capturing each region's file-system dependencies and other effects using system-call tracing, reordering the region in the script speculatively at runtime; and (2) by *conditionally* committing or

* Equal contribution.
† Now affiliated with Columbia University.

[1] PaSh does some basic pipelining on loops without carried dependencies.

reverting the effects of a region using lightweight sandboxing techniques.

Orchestrator (§3): Out-of-order execution is challenging to apply correctly as subtle changes can alter the behavior of the original script. The relevant soundness property is *observational equivalence*: the original program and the reordered program must behave the same from the perspective of the user. To ensure that hS's reordering is sound, it implements a novel state-machine-based algorithm that tracks and respects conflicting command dependencies. We use the Alloy [27] model checker to ensure that our algorithm yields observationally equivalent runs that are safe (no deadlocks; dependencies are respected) and sound (speculated commands are committed in the correct, sequential order).

Executor (§4): Speculative execution requires controlling a command's effects on the surrounding system. hS achieves that using a combination of process-level sandboxing and tracing that can contain, block, and selectively defer an individual command's effects. If all of a commands effects are deferrable, e.g., file writes and shell variable assignments, hS can speculate it, containing all its reads and writes, and later commit its effects if it doesn't depend on other previous commands. Even though commands with non-deferrable effects, e.g., network accesses, cannot be speculated, hS still guarantees correct execution by blocking their effects and executing the commands exactly once, without speculation.

Optimizations (§5): Speculative execution can lead to redundant recomputation when mis-speculating, *i.e.*, if a dependency indicates that some speculative run of a command is invalid, we must throw away its results. To improve efficiency, hS introduces a set of domain-specific optimizations that reduce the number of mis-speculations by predicting the starting state from which to speculate commands. First, hS reasons about the shell language directly, eagerly and efficiently evaluating pure assignments without any need to speculate. Second, hS is optimistic, speculating each command in the freshest, potentially uncommitted file-system state, while eagerly stopping speculations that have conflicts.

hS is able to optimize the execution time of arbitrary shell scripts without any user input or command annotations. On a diverse set of 49 real-world shell scripts, some of which have already been optimized to exploit command independencies by their authors, hS achieves a geomean 2.6× speedup (up to 9.3×) over Bash. hS also achieves significant speedups over the prior state of the art, PaSh [29, 62] (geomean: 2.4×, max: 7×), while not requiring any command annotations to enable optimizations, thus being able to support a wider variety of scripts with custom and domain specific commands and utilities. Finally, to show that our techniques are applicable more broadly to scripts that use subprocesses, we develop a Python frontend for hS that can optimize a restricted fragment of Python programs that invoke subprocesses (§6). On a set of 5 real-world Pythons programs hS manages to achieve

Figure 1: The core of a bioinformatics script for RNA sequence processing [23].

speedups of up to 8.4× over standard Python execution.

Availability: hS is open source and available at https://github.com/binpash/hs.

2 Speeding Up Everyday Data Processing

We first explain how hS speeds-up shell scripts using an example: a bioinformatics script that processes RNA sequencing data from mouse samples, taken from the TERA-Seq toolkit [23] (Fig. 1). The script preprocesses genomics data `(1)`, aligns RNA samples to reference genomes or transcriptomes `(2)`, and conducts post-alignment analysis `(3)`.

The script leaves a lot of performance on the table by not taking advantage of various optimization opportunities. First, each sample could be processed independently: for example, alignment's `(2)` two steps (`c`, `d`) are independent and can be performed in parallel. Additionally, some processing could start earlier: the script starts building the SQLite databases `(3)` only after *all* alignments complete (`c`, `d`), even though it would be safe to start building the database for a sample (`g`, `h`) as soon as that sample is aligned.

Optimization Challenges: Identifying independent execution optimization opportunities in shell programs is not trivial. One must accurately understand each command's behavior and the implicit data dependencies between commands. Individual shell commands are black boxes, written in arbitrary languages, sometimes with unavailable or inscrutable source code. Often, commands have implicit dependencies; for example, `samtools index` generates an index file that is not mentioned in its arguments, but whose name is based on the

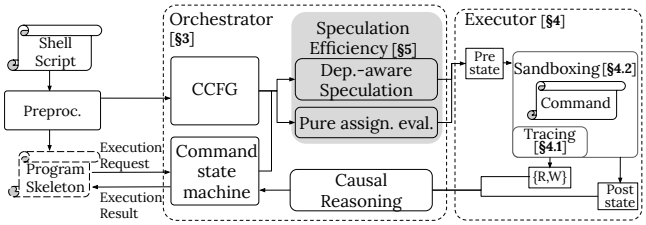

Figure 2: High-level architecture of hS.

input file's name. Even if programmers know all commands' dependencies, independent execution has to be embedded in the script logic, a process that is tedious, error-prone, and complicates development and maintenance.

The state-of-the-art tools for parallelization of shell scripts, PaSh [29] and POSH [50], cannot exploit these opportunities—neither offers any benefits on this script (PaSh takes 7918s vs Bash's 7914s). In their default configuration, neither tool can reason about or optimize invocations to domain-specific tools like `fastq-sanitize-header`, `minimap2`, and `samtools` as there are no annotations to characterize their behavior. As we show in §7.2, even conservative annotations for a representative TERA-Seq workflow are insufficient to expose substantial PaSh speedups without domain-specific split/merge support.

2.1 Overview of hS

To understand how hS is able to correctly and effectively optimize scripts, we overview the system architecture (Fig. 2) in the context of a single iteration of a fragment of the analysis stage of the bioinformatics script (Fig. 1(3)). Before any iterations, the analysis stage runs `./prep_db.sh` (e). Then, for each iteration's sample, it will index that sample's alignment (g) and generate a SQLite database for that sample (h).

Preprocessing: hS uses script rewriting [29] to transform the input script into two objects: a *program skeleton* and a *command control-flow graph (CCFG)*. The program skeleton is run by the real shell interpreter, while the CCFG is managed by hS's orchestrator. The program skeleton preserves the original script's control structure, but replaces executable regions with stubs that communicate with hS's orchestrator. We call each concrete execution of such a region a *command instance*. Despite the name, a command instance is not necessarily a single Unix process: it may be a simple command, a pipeline, or a small shell region needed to preserve explicit synchronization. The CCFG abstracts the script by tracking these regions and how they relate with respect to control flow. In our example, the CCFG (Fig. 1 (top left)) puts (e) first, followed by a loop that contains sequences (g) and (h). Regions in loops can map to multiple command instances in the concrete execution—one per loop iteration.

Command Control Flow Graph (§3 Orchestrator): hS's *orchestrator* is a server that responds to execution requests from the hooks in the program skeleton. The orchestrator manages the CCFG to decide which command instances to execute, possibly speculatively. Sequential execution would run the next instance in the CCFG once the prior instance completes; hS's orchestrator speculates by executing instances further ahead in the CCFG.

Shell construct handling: hS's preprocessing pass is syntax-directed: it keeps the shell in charge of the script's control structure, and exposes executable regions to the orchestrator. A pipeline such as `A | B | C` is one command instance: shell pipe semantics are preserved inside the sandbox, while hS tracks and commits the aggregate dependencies and effects of the whole pipeline. Similarly, a background/wait pattern such as `A & B & wait` is treated as a shell-synchronization region, so hS does not reorder `A` and `B` with respect to each other or check their internal conflicts separately; only the region's combined effects are checked against earlier and later command instances.

Control constructs determine which command instances are reached. Conditionals, cases, loops, short-circuit operators, groups, subshells, and redirections remain in the program skeleton and are evaluated by the shell in the original order. The CCFG exposes possible future instances to the orchestrator, including loop iterations, but a speculative result is committed only when the skeleton later requests that concrete instance and its shell and file-system starting states are compatible. Commands that cannot safely be executed outside the skeleton—for example shell control-flow builtins such as **`break`**, **`continue`**, **`return`**, and `exit`, or commands with non-deferrable effects—are marked unsafe and executed once by the skeleton, acting as speculation barriers. Finally, a nested hS invocation is treated like any other subprocess by the outer hS: the outer execution remains governed by the same dependency and effect checks, but it may expose less parallelism than a single run with one global CCFG.

Command dependencies and effects (§4 Executor): Instead of running each command in order, hS's orchestrator speculatively executes subsequent commands (like (g) and (h)) earlier than in sequential execution. Correct execution depends on only committing the results of commands unaffected by out-of-order execution. The orchestrator commits the effects of speculative executions if previous commands did not affect their execution—*i.e.*, if the speculated commands didn't depend on effects of prior commands. hS is able to speculatively execute commands without jeopardizing execution correctness by tracking each command's *dependencies—i.e.*, what it reads from—and by containing and deferring its *effects—i.e.*, what it writes to. hS does that using its *executor* (§4), which tracks dependencies and effects on two types of state: (i) the shell state (*incl.* environment variables and shell configuration), and (ii) the file system state (*incl.* files, terminals, and file descriptors). The executor identifies command dependencies in a completely black-box

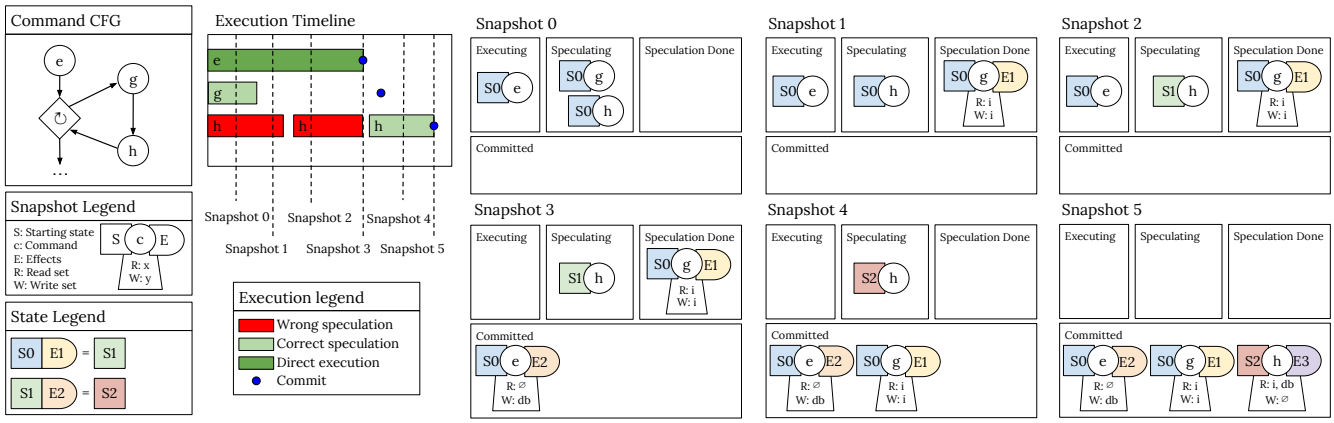

Figure 3: Example hS execution on fragment (3) (Fig. 1). **Top left**: Command control-flow graph and execution timeline; CCFG nodes denote executable script regions, and each concrete execution of such a region is a command instance. **Bottom left**: Legends. **Right**: Each snapshot represents the state of the orchestrator (§3) at a point in the execution timeline.

manner using system call tracing (§4.1) and contains effects using lightweight sandbox techniques, namely OverlayFS and namespaces (§4.2). While hS is able to optimize the execution of commands with effects that are *deferrable*, e.g., file writes and shell variable assignments, it guarantees correct execution even in the presence of non-deferrable effects, e.g., network accesses—when a command performs such an effect, hS blocks it and marks the command as unsafe for speculation, later issuing it for normal execution.

2.2 Speeding up the Script

We will now walk through an execution of hS on a fragment of the RNA processing script (Fig. 1(3)). Figure 3 shows a sequence of execution snapshots and the timeline. Execution starts with snapshot 0, where (e) is issued for normal execution while (g and h) are issued for speculative execution.

Execution snapshot 1: For this example, we assume that building the index (g) completes before the database preparation (e) (Fig. 3, Snapshot 1). When a command completes execution, the executor passes the command's traced dependencies and contained effects to the orchestrator. Here, (g)'s dependencies are the files that it read from, including `$SM/Genome.sorted.bam`, and its effects are that it generates the index file (abbreviated to *i* in Fig. 3) in either `$SM/Genome.sorted.bam.bai` or `$SM/Genome.sorted.bam.csi`. Note that these files aren't explicitly referenced in the command arguments, but implicitly chosen by `samtools index`—which one is chosen depends on the size of the input genome.

Execution snapshot 2: In the meantime, the `samtools view` command (h) has been speculatively executing in a state that does not include the indices generated by (g). At some point, hS will observe a system call by (h) that tries to read these indices and fails, since its computation *implicitly* relies on them. Upon discovering this dependency between (g) and (h)—(g) writes a file that (h) reads—the orchestrator determines that (h) has been mis-speculated, since (h) would only run after (g) in a sequential execution, but hS has run it earlier. The orchestrator then drops the effects of (h), and re-speculates it on top of the (as yet uncommitted) effects generated by g.

Execution snapshot 3: After the database preparation completes (e), the orchestrator can immediately commit the results of (e) to the live system—(e) was the first command, so there can be no mis-speculation or dependency violations. Even so, (e)'s effects are still recorded for later reasoning.

Execution snapshots 4 and 5: The effects of (e) include writes to `$dbdir/sqlite.db`, meaning that (h) will need to be re-speculated once more—the second command in its pipeline reads from `$dbdir/sqlite.db`. The orchestrator observes that (e) and (g) are completely independent, and it can immediately commit the speculated results of index building (g) (Fig. 3, Snapshot 4). Since every prior command has committed when (h)'s third execution completes, the orchestrator can directly commit (h) when it completes (Fig. 3, Snapshot 5).

Pure assignments (§5.1): Note that the assignment (f) between (e) and (g) is *not* part of the CCFG. While assignments can have dependencies (globbing) or external effects (*e.g.*, command substitutions `$(...)`), many of them do not. hS identifies assignments without effects—*i.e.*, *pure* assignments—and simply includes them in the starting speculation state of all following commands. This optimization significantly reduces CCFG size and speculation overhead.

Zooming out: Having examined a single iteration of the `for` loop, we now consider the entirety of the post-processing stage (Fig. 1(3)). Again, we assume that (g) completes before (e). hS uses a configurable speculation window to limit how many commands can be speculated at any time. For example, with a speculation window of two, we will have three com-

mands in execution: (e) executing directly, and (g) and (h) in speculation. When (e) commits, a slot in the speculation window opens up and the orchestrator continues speculation following the would-be sequential execution of the program, by speculating (g) in the next iteration of the loop, even though the prior iteration has not completed.

Dependency-aware speculation (§5.2): When two commands in speculation have recorded dependencies, such as (g) and (h), they should not be speculated starting from the same state. hS avoids such mis-speculations by employing a *dependency-aware speculation strategy* (§5.2): we only start commands speculation after all the (discovered) dependencies finish, and we create a speculative starting state that combines the effects of all previously speculated commands.

Summary: Through speculative execution and the aforementioned optimizations, hS optimizes shell programs by executing independent script segments out-of-order, trying to take advantage of the latent parallelization opportunities. In our example script, hS achieves a 4.5× speedup over sequential execution using Bash (§7).

3 Orchestrator

The orchestrator (Figure 2, middle) manages speculation by keeping track of the command control-flow graph (CCFG) and all command instances in the script. The orchestrator uses the CCFG to look ahead and speculate commands, such that it can return pre-computed results to the program skeleton, achieving effective parallelization. At the same time, it keeps track of commands with unsafe behavior and dependencies across command instances to make sure that they are executed and committed in a safe order. In this section we describe the orchestration algorithm, which uses a state machine (Figure 4) to track the execution state of each command instance.

3.1 Orchestration Algorithm

The orchestrator manages two data structures: the *command control-flow graph* (Fig. 3, top left) and the *set of command instances* (Fig. 3, snapshots). The CCFG is generated from the source program, relating each executable region back to its position in the program skeleton. As introduced in §2, each command instance corresponds to one concrete execution of such a region. In loops, a single CCFG region may therefore have several command instances in the set, one per iteration. A command instance keeps track of: (1) the command's current speculation state (§3.1); (2) the results of speculation, if any; and (3) the command's read and write sets.

State machine without speculation (Ⓡ, Ⓔ, Ⓒ): Each command instance is associated with a *command state* (Fig. 4). To explain command states, we start by considering a sequential orchestrator that doesn't speculate but simply executes a command instance whenever the program skeleton requests

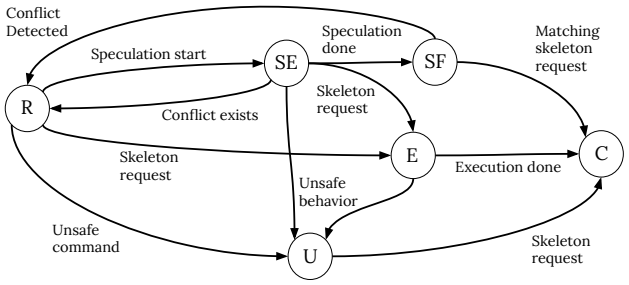

Figure 4: State machine for each command instance.

its execution. At first, every command instance is in Ⓡ, the 'ready' state. When execution begins, the program skeleton requests the execution of the first command instance in the script. The orchestrator then sends the first command instance to the executor, marking it as Ⓔ, the 'direct-execution' state. When the first command instance terminates, the orchestrator commits its saved results, moving the command to Ⓒ, the 'committed' state, responding to the skeleton that it is done. As the program skeleton continues, it makes another execution request—this time, for the second command instance. The orchestrator executes it, running it in the most recent state, *i.e.*, the state after the first command instance has committed, and then commits the results, at which point the skeleton requests the execution of another command until all of them are done executing in the correct, original, sequential order.

Unsafe commands (Ⓤ): Some commands—shell control-flow utilities, like `break`, or commands with non-deferrable effects, like network accesses—cannot be speculated and need to be run *exactly* once by the program skeleton. The orchestrator dynamically detects such commands (§4) and moves them to Ⓤ, the 'unsafe' state. When a command *C* is determined to be unsafe, the orchestrator waits until the program skeleton requests the execution of *C*, at which point it informs it to execute the command itself, in the context of the original script. Upon receiving the next execution request, the orchestrator will move the Ⓤ node into Ⓒ, indicating the command has been executed and its effects are globally visible.

Speculative states (Ⓢⓔ, Ⓢⓕ): Having understood a sequential orchestrator, we now introduce speculation and the remaining states. A speculating orchestrator finds the next command in the CCFG in the Ⓡ state, sends it for speculative execution (§4), and transitions it to Ⓢⓔ, the 'speculatively executing' state. An instance in Ⓢⓔ can make one of three transitions: it can complete its execution, in which case the orchestrator records the result and moves it to Ⓢⓕ, 'speculation finished'; it can be marked as unsafe and transition to Ⓤ; or, the program skeleton can send a request for this instance after speculation has started. When the skeleton sends a request for a command in Ⓢⓔ or Ⓢⓕ, the execution takes a different path depending on whether the speculation starting state is equivalent to the current, real system state or not.

System states and compatibility: Before describing the two paths, we describe what system states are. The system state contains two components: (1) the shell state (*incl.* shell variables, functions, *etc.*), and (2) the filesystem state (*incl.* all files, directories, metadata, *etc.*). The shell state a set of key-value pairs [17, 29] and so comparing two of them amounts to checking for differences point-wise. Comparing filesystem state involves two challenges: (1) representing and storing the *entire* contents of the filesystem is not efficient, and (2) even though there might exist a difference between two states, it might not be relevant for the command instance in question.

File system states as write sets: To address the first challenge, hS represents the FS state as the effects of a command on the file system, namely only the values of the files in its write set (instead of the FS complete contents). For example, the resulting file system state for the command `echo "hello" >f1.txt` only contains the value of file `f1.txt`. hS manages to get such a fine-grained representation of the file system state through its executor (§4).

State equivalence: For the second challenge, consider script `echo "hello" >f1.txt; touch f2.txt`. Even though the output filesystem states after executing these two commands differ—the former has an updated `f1.txt` and the latter read `f2.txt`—there is no dependency between them. To address this, the orchestrator keeps track of all commands reads and writes through the executor (§4) and continuously checks if there are any dependencies. Suppose we are executing a two-command program where the second command reads the results of the first, e.g., `echo "hi" >f1.txt; cat f1.txt`. If we speculatively start executing both programs in the initial filesystem state, `cat` will not see the final correct state of `f1.txt`. When the orchestrator discovers that `echo` writes to `f1.txt` and `cat` reads from `f1.txt`, the dependency is recorded and the orchestrator cancels `cat`'s speculative execution (ⓈⒺ or ⓈⒻ), and moves it back to Ⓡ.

Handling conflicts during speculation: When the orchestrator receives a request for a command instance in ⓈⒺ or ⓈⒻ, it checks if the starting speculation state conflicts with the current real-system state, given the command instance's dependencies. If there is a state conflict, we have mis-speculated and the command instance needs to transition back to Ⓡ. If the states are compatible, we can commit the results of the command instance. An instance in ⓈⒺ will transition to Ⓔ and keep executing until it hits Ⓒ; an instance in ⓈⒻ can be committed immediately, transitioning to Ⓒ directly.

Avoiding speculation across Ⓤ commands: hS does not generate tracing directly in program skeletons (§4.1), so it is impossible to determine the write sets of Ⓤ commands. To ensure that execution is correct, every execution of a Ⓤ command invalidates all later command speculations, transitioning them back to the Ⓡ state.

Orchestrator correctness: We built a model of the orchestrator's core logic in Alloy [27], and we used its bounded model checking capabilities to check several key properties: (1) the orchestrator eventually terminates (no deadlocks); (2) file system dependencies are respected, *i.e.*, a command will be rerun if a command preceding it writes to a file it reads from; and (3) the final command commit order is equivalent to the sequential execution order. The checks are performed over a bounded model with a finite number of files and commands, under the assumption that all commands eventually terminate with arbitrary read/write dependencies.

Speculation policy: hS uses a configurable *speculation window* to limit the amount of speculation. When the window is full, i.e., the number of commands in the ⓈⒺ or ⓈⒻ state are equal to the window size, the orchestrator cannot issue new command instances for speculative execution. Finally, there are points where hS has to pick between more than one command instance to speculate next, e.g., branches of a conditional—a problem akin to branch prediction. This choice does not affect correctness, but it affects performance. hS currently has a fixed policy for these predictions, e.g., loops will keep iterating and conditionals will take the else branch, and we leave a better policy as future work.

4 Executor

The executor's main goal is to identify, contain, and when possible defer effects that commands make to the surrounding state to enable speculation. Before we describe the two key orchestrator components, tracing and sandboxing, we describe which events can be deferred and which can only be blocked.

Deferrable: These effects can be identified by the executor, contained, and deferred to enable speculative execution. These effects include shell state changes (*i.e.*, variables, current working directory, shell options, and open file descriptors), as well as changes to regular files, directories, and a small set of pseudo-files without state (*e.g.*, `/dev/null`).

Non-deferrable: These effects cannot be deferred, but can be detected and blocked, allowing the orchestrator to mark the culprit command as unsafe for speculation and execute it normally without speculation—the rest of the commands can still be safely executed as described in Section 3.1. These effects include network interactions, IPC, and signals.

4.1 Tracing

hS's executor traces system calls to detect all effects. For deferrable effects it traces all path-related system calls and returns a list of paths that the command reads from and writes to. This information is then used by the orchestrator to determine the file-system dependencies. To improve efficiency, hS does not trace all read and write calls, but considers a file to be accessed the moment it is *acquired*, *i.e.*, when its path is passed as a parameter to system calls like `open`, and `rename`. hS uses

seccomp-BPF for `strace` [40] to avoid context switching on untraced system calls.

Path dependencies: hS determines read and write dependencies over paths and not files. For example, an `ENOENT` (no such file) error on a `stat` system call counts as a read to the path even though it didn't read any file. This is because if any previous command creates a file in that path, the result of `stat` will change, affecting the command.

Parent directories: Parent directories require special handling due to the way modifications affect their children. More specifically, a write effect (*e.g.*, `rename`) at the parent directory may alter the child paths without specifically targeting them. Therefore, the tracer treats any effect on a path as read effects on all its parent directories as well, such that the read-write conflict can correctly capture this indirect influence.

Symbolic links: Special care needs to be taken when tracing the creation and use of symbolic links. A symbolic link involves two paths: a link path and a target path. The *creation* of a symbolic link (`symlink`, `symlinkat`) is not affected by the file-system state at the target path. Therefore, although the target path is an argument to the system call, it does not count as either read or write to the path. The *use* of symbolic links, on the other hand, should be treated as *reading* the link path in addition to the effect on the target path. This is because changing to the link path will lead to changes in the outcome of the system call (*i.e.*, opening a different file).

4.2 Sandboxing

hS's sandbox supports two types of deferrable effects: file-system effects and shell-state effects. It handles file-system effects with OverlayFS [7], creating a private view of the file system and storing side effects into separate directories. The shell-internal states are handled by creating a separate shell process and running additional setup and recording utilities at the start and end of the command. Non-deferrable effects are blocked using Linux namespaces [38]; after they are detected with tracing, hS marks such commands as unsafe.

Shell state handling: The shell state includes the (1) current directory, (2) variable and function definitions, (3) shell options, (4) active trap handlers, and (5) opened file descriptors. The executor needs to correctly set up these components when executing any command instance. At the beginning of each runtime hook invocation in the program skeleton, the shell state is recorded, and sent to the orchestrator, which then passes it to the executor. After a command instance finishes execution, the shell state is recorded and sent back to the program skeleton, which then applies the new shell state at the end of the runtime hook invocation.

File system effects: OverlayFS is a union file system that stacks one or more *lower layers* (*i.e.*, 'lowerdirs') and an *upper layer* (*i.e.*, 'upperdir') into a single, merged view. OverlayFS searches for a path starting from the highest layer, meaning that each higher layer shadows lower ones by adding or removing files from them hS isolates commands by setting their root directory to be OverlayFS's merged view using `unshare` [41]. The upperdir records all file-system writes in the sandbox and isolates them from the surrounding system. To commit a write, hS traverses the upperdir and copies the changes back to the real file system. A subtle challenge that hS needs to address is that OverlayFS disallows any pre-existing mount point that cannot be unmounted by the current user to be part of a lowerdir [28]. hS addresses this issue by using mergerfs [1] to shadow these mount points.

Challenge: file descriptors: A challenge that hS needs to address is tracking changes to open file descriptors, i.e., `stdin`, `stdout`, `stderr`, and other files opened with the `exec` command. This differs from the individual command's output redirections, which are already handled by the sandbox's overlay. These file descriptors are opened for the shell program itself, and usually stay opened until the entire program exits. Capturing and controlling the state of file descriptor for every kind of file is beyond the scope of this work, especially those that interact with users or devices. hS supports file descriptors if they are sequentially read from or written to. When recording the state of the file descriptors, hS reads from `/proc` to determine the file descriptor's permission, file path, and current offset. For `stdin` and read-only file descriptors, hS re-opens the corresponding files and uses `lseek` to set the correct offset. For `stdout`, `stderr`, and write-only file descriptors, hS opens a new empty file for each to record the written content. When committing, hS appends the newly written content to the corresponding opened files. Since all the files are re-opened inside the overlay in a separate process, their effects are also isolated from the rest of the system.

If two file descriptors are aliases of each other (*e.g.*, the shell program is run with `2>&1`), their write effects should not be recorded separately; otherwise the intended interleaving of output will be broken. In such cases, hS detects aliasing of file descriptors with the `kcmp` system call, and sets up the aliasing inside the sandbox with proper `exec` redirection, instead of opening separate record files.

Blockable effects: hS uses namespaces and `unshare` to disallow all blockable effects. Linux namespaces [38] are designed to isolate *any* globally visible state changes introduced by a process. Under a non-malicious setting it is reasonable to assume that no unintended effects escape their namespace. hS sets up fresh network, pid, and user namespaces so speculated processes cannot interfere with the outside world through network, signals, and other process control features provided by the operating system. The `/proc` filesystem and a limited set of `/dev` devices are remounted within the namespace to avoid exposing control to other processes or devices.

5 Improving Speculation Efficiency

A key challenge that needs to be addressed by hS is managing mis-speculation. To address that, hS deploys two optimization techniques, pure assignment evaluation (§5.1) and dependency-aware speculation scheduling (§5.2).

5.1 Pure Assignment Evaluation

hS treats any difference in shell state as a conflict, meaning that all shell state changes invalidate all speculated (SE) and (SF) commands. This leads to significant wasted resources, especially in programs with multiple variable assignments.

To address this challenge, and avoid re-executing commands unnecessarily, hS identifies and evaluates pure assignments on the starting shell state. Pure assignments are just variable assignments where the right-hand side does not perform side effects, *e.g.*, `(f)` in Fig. 1. The insight that hS exploits is that pure assignments do not need to be speculated at all, they can simply be run. Furthermore, they can be identified using a simple syntactic pass, ahead of time, during preprocessing. By evaluating pure assignments, the speculator both reduces the number of failed speculations (since the starting shell state of commands is computed correctly), and increases the number of speculated commands that take more time to execute (since pure assignments are no longer considered candidates for speculation).

5.2 Dependency-aware Speculation

To maximize the possibility of correct speculation and minimize resources spent on mis-speculation, we deploy a two-part strategy to make smart speculation decisions about file-system states in hS.

Eager conflict detection and timely restart: Instead of receiving the read-write sets of a command instance after it has completed execution, hS consumes tracing information (§4.1) in a streaming fashion, continuously checking for file-system conflict between executing and speculating commands. Whenever such conflict is discovered, the target command, which is always in (SE) or (SF) state, will be stopped, and reset into (R) state. On top of that, such dependency is recorded by hS. Whenever a command finishes speculation, hS looks up the recorded dependencies, and restarts any commands that have a dependency to the finished one. At this point the following strategy comes into effect.

Opportunistic speculation chaining: Since conflicted speculations are reset to (R) state eagerly, preceding commands that are able to stay in (SF) state are more likely to be committed. Therefore it is beneficial to take their state changes into consideration when launching new speculation. More specifically, suppose a command C_2's only file-system dependency is another command C_1, which just finished speculation. Instead of starting from the current file-system state S, hS starts new speculations on a "predicted" state that contains the effects of C_1. In the case that C_1 is successfully committed, C_2's speculation will not have conflict with the new real file-system state, which will be equivalent to its starting state. In the general case, hS chains all preceding uncommitted effects in (SF) states into the starting states of new speculations. hS implements this state chaining, by layering multiple lower directories into the overlay 4.2, allowing commands to run on an environment with the freshest file-system state available to hS, without it yet being committed in the underlying system.

6 Implementation

The hS implementation comprises 2.4k lines of Python for the preprocessor, orchestrator, executor, 478 lines of shell code for the sandboxing and wrappers, and 285 lines of Alloy for the orchestrator model (§3.1).

Python frontend: As a proof of generality beyond the shell, we also prototype a Python frontend for hS, targeting Python programs that invoke subprocesses, e.g., using `subprocess.run`, to implement their functionality. The frontend is the only thing that changes to support Python, and the orchestrator (§3) and executor (§4) can be used as is. The frontend is not meant to be comprehensive and is currently only able to optimize a limited fragment of Python applications for which (1) the subprocess calls can be easily extracted, i.e., they can be syntactically identified in the program execution, and (2) the subprocess arguments can be easily computed without any side-effects. The frontend currently assumes that a Python program does not include any control flow that affect which external commands run besides for loops, that all the functionality happens in a single `main` function, and that all file system effects go through an external command rather than builtin functions like `sys.write`. Supporting the optimization of arbitrary Python applications goes beyond the scope of this paper and would require significant improvements on Python program analysis that are not possible with the current state-of-the-art. The implementation of the Python frontend consists of an additional 547 lines for a Python-specific preprocessor and runtime.

7 Evaluation

To evaluate hS, we have collected a wide variety of shell scripts from the wild (§7.1), on which we run experiments highlighting various dimensions of hS's performance and correctness. We examine hS's overall performance (§7.2), by comparing it to Bash and PaSh [29, 62] on all the scripts in our suite. We also measure the amount of redundant resource usage of hS due to mis-speculations (§7.3). We then evaluate the overheads of hS's executor using various benchmarks (§7.4),

Table 1: Summary of all benchmarks used to evaluate hS, showing the number of scripts, lines of code, input size, execution time with bash, and source.

	Bench. Set	Scripts	LoC	Input	Exec. Time	Source
1	TERA-Seq	9	2k	177G	25m-8h	[23]
2	Genomics	1	22	97G	1.3h	[8]
3	Sklearn	1	102	0.8G	7m	[4]
4	DGSH	10	308	14G	<1s-40m	[55]
5	NLP	23	204	78G	10s-20m	[9]
6	NOAA	1	20	80G	40m	[63]
7	Unix50	1	58	23G	40s	[46]
8	COVID-mts	1	49	14G	6m	[61]
9	LogAnalysis	1	25	3G	17m	[50]
10	WebIndex	1	67	8G	6m	[62]
11	µbenchmarks	3	82	—	—	custom

as well as its performance under varying window sizes (§7.5). Finally, we evaluate the performance of hS's Python frontend comparing it to standard Python execution on a set of real-world Python programs (§7.6).

Setup: All experiments were conducted on CloudLab [13] `r6525` machines equipped with two 32-core AMD EPYC 7543 CPUs running at 2.8GHz with 256GB of DDR4 RAM, and NVMe SSD storage. The OS was Ubuntu 22.04.2 LTS was kernel version 5.15.0-122-generic, Bash version 5.1.16, PaSh version 0.12.2, and Python version 3.10.12. Docker (27.3.1) was used for the experimental environment. hS is configured with a speculation window of 30 unless noted otherwise, and PaSh is configured with width of 30.

7.1 Benchmarks

For our evaluation we have collected a variety of real-world scripts from the wild (Table 1). Our benchmark selection is complementary to recent shell benchmark characterization efforts such as Koala [33]; we include benchmarks used by prior shell-optimization systems and add domain-specific, long-running workflows such as TERA-Seq to stress scripts with custom tools and implicit dependencies.

TERA-Seq [23] consists of real-world workflows for RNA sequencing that use domain-specific tools and are applied to a multi-GB dataset. These applications run for multiple hours and are on the critical path of bioinformatics research so the authors have already optimized them using `&` and `wait` to exploit command independence and parallelization.

Genomics [8] is a single script that processes 97GB of NGS data, producing chromosome-specific, indexed BAM files, making use of nested loops to iterate across samples.

Sklearn [4] runs a regression model on the kdd99 [57] datasets using custom commands that wrap Scikit-Learn [48].

DGSH [55] contains a collection of shell scripts for text processing, compression, code metrics, log analysis, and git repository analysis. We transliterate the original scripts from the dgsh-dialect to be POSIX-compliant.

NLP [9] contains 23 shell scripts from UNIX-for-poets that perform various text processing tasks using UNIX and Linux utilities. Their input is a set of 120 books amplified to 100× their original size.

NOAA [63] processes multi-year temperature data across the US during the 2000s, consisting of more than 100k compressed files with up to 500MB size. We replace instances of iterations using `seq` and `xargs` with equivalent **`for`** loops.

Unix50 [46] includes classic and recent (circa 2019) scripts making heavy use of UNIX and Linux built-in commands. We evaluate hS on a cumulative script that contains all 36 scripts together on an input of 21GB.

COVID-mts [61] analyzes public transit data during the COVID-19 pandemic, consisting of five pipelines that process 10GB of input data (originally 3.4GB) using UNIX and Linux utilities. We combine the five pipelines into a single script.

LogAnalysis [50] analyzes 2.8GB of web server logs from the World Cup '98 website [2] over a period of 53 days. We extended the original pipeline [50] to handle compressed data and to process multiple log files.

WebIndex [62] is a large, multi-stage script for crawling and indexing Wikipedia. The script uses various utilities like `pandoc` [34] and `awk` to convert HTML to text and extract metrics. We evaluate the script on a fraction of the original input (7280 files, out of approximately 1.5 million).

7.2 Overall Performance and Correctness

Results (Fig. 5): We evaluate hS compared to Bash and PaSh on the 10 benchmark sets, totaling 49 shell scripts and 2.9k LOC. We omit PaSh bars for the full TERA-Seq suite because a meaningful PaSh comparison requires workflow-specific annotations and, for the dominant stages, domain-specific split and merge operators. To investigate this, we manually annotated a representative TERA-Seq workflow, 5TERA3, with conservative PaSh input/output annotations and ran a comparison. PaSh produced output matching Bash, but did not improve performance. Profiling showed that the safely annotatable FASTQ preprocessing work accounts for only 1.6% of profiled time, while SQLite/database mutation and SAM/BAM processing dominate; accelerating those stages would require database partition/merge support or SAM/BAM-aware splitters, not just command annotations. Each bar shows the speedup of hS and PaSh over bash. Across *all* benchmark sets, hS achieves a geomean speedup of 2.6× over Bash, (min: 0.14×, max: 9.3×). Across all benchmarks other than TERA-Seq, PaSh achieves a geomean speedup of 1.2× (min: 0.2×, max: 10.8×). hS slows down 7 scripts compared to bash (DGSH 3, 4, 6, 9, 10, NLP 9, WebIndex), out of which 5 take less than 10 seconds to execute with Bash (DGSH 3, 4, 9, 10, NLP 9). hS is slower than PaSh for only 4 scripts that take more than 10 seconds to execute (DGSH 5, 6,

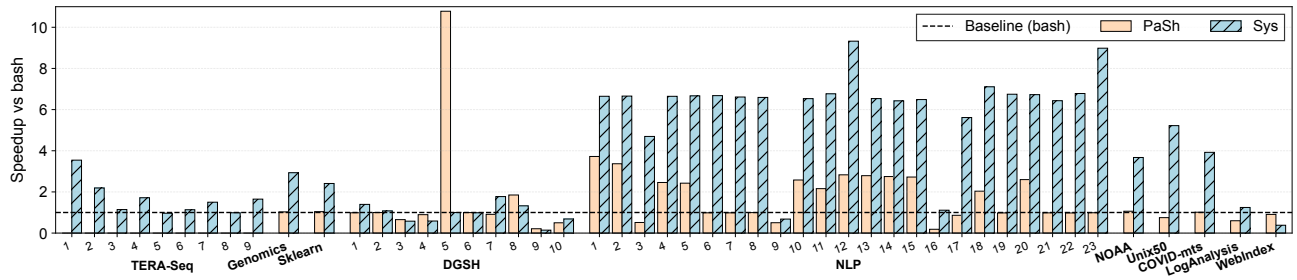

Figure 5: hS performance. hS and PaSh speedup over Bash for Tab. 1 rows 1–10.

8, and WebIndex). For all compared runs, we check that hS's output and exit status match Bash and, when included, PaSh.

Discussion: hS improves execution time on most scripts compared to Bash and PaSh, without any static knowledge about commands and without any input from the user. Importantly, hS manages to improve the performance of 7 out of 9 TERA-Seq scripts (geomean: 1.5×, max: 3.5×) even though their developers had already attempted to optimize them by uncovering parallelization and out-of-order execution opportunities using `&`. This shows that hS can be useful even for scripts that have already been optimized to exploit command independence. The scripts that hS slows down compared to Bash or PaSh either (1) have a short sequential running time below 10s and therefore hS's overheads dominate execution time (DGSH 3, 4, 9, 10, NLP 9), (2) perform many file accesses (WebIndex) (details in §7.4.2), or (3) exhibit strict dependencies across commands and pipelines (DGSH 5, 6, 8). For example, the DGSH 5 script performs a fully-dependent workflow, it finds words in a document (tokenizing, sorting, and removing duplicates) and then spellchecks them against a dictionary, leaving no room for out-of-order execution and so hS performs similarly to Bash (522s vs 523s, respectively). In contrast, PaSh manages to accelerate this script by leveraging its command annotations to exploit data parallelism in the same document, which is not in hS's scope. hS manages to accelerate scripts by exploiting available command invocation independence (across commands that read from or write to different files), for example in Genomics it manages to exploit the fact that different chromosomes can be processed independently. hS achieves that without any static knowledge about the commands in a script, and therefore can also accelerate scripts with domain-specific tools that PaSh cannot optimize.

7.3 Mis-speculation Statistics

We evaluate the amount of redundant resources that hS uses when it mis-speculates a command instance and then has to reexecute it. We measure the time spent on a command by recording the start and end time of each command instance (speculative) execution, then compute the time spent on mis-speculations over the total execution time of all commands.

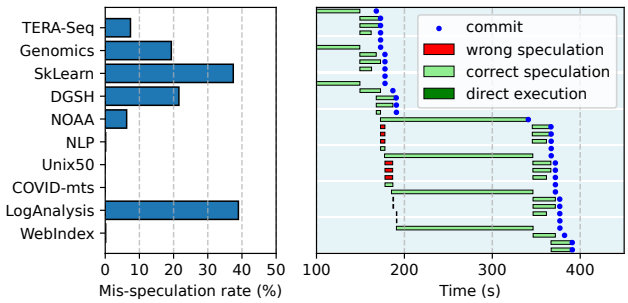

Figure 6: **Left:** Rate of mis-speculation. Percentage of how much execution time hS spends on reexecutions. **Right:** Fragment (100-450s) of Genomics execution in hS. Each row represents a command being executed, different blue regions are different iterations of a loop.

Note that the measured time is not equivalent to CPU time, since a command might have internal parallelization and potential resource contention with other commands.

Results (Fig. 6, left) and Discussion: Wasted execution time due to mis-speculation ranges from 0–39%, with an average of 17% across all scripts. Some scripts (Unix50, COVID-mts, NLP) have minimal dependencies and therefore observe minimal mis-speculation. Some scripts (TERA-Seq, NOAA, WebIndex) have dependencies but mis-speculations can be determined quickly due to eager dependency detection (§5.2), leading to a small amount of wasted execution time 0.1–8%. Finally, some scripts (Genomics, DGSH, LogAnalysis, Sklearn) have dependencies that can only be determined after spending significant time executing their commands, leading to more wasted execution time 19–39%. Sklearn and LogAnalysis both lead to significant mis-speculation because they introduces file-system writes at the end of some of their commands, preventing hS from detecting conflicts earlier.

Zooming in (Fig. 6, right): We show a trace from a Genomics execution with hS. After a quick setup, the script enters a loop, where iterations are independent, but for each iteration the first command is a dependency for all the rest. As the figure shows, subsequent commands in each iteration start

as mis-speculation at first, but are quickly terminated since hS can eagerly detect dependencies (§5.2) hS only reschedules these commands after the first command finishes. All in all, hS is able to speed up this script by 2.9× while only wasting 8% of its total execution time in mis-speculations.

7.4 Executor Overheads

We evaluate the executor's overheads using our benchmark suite and various microbenchmarks.

Constant overheads: We evaluate the constant overheads of hS's executor (*incl.* sandboxing, tracing, and parsing) by executing 1024 `echo` commands with and without sandboxing. On average hS's executor adds an overhead of 217ms per command, out of which 120ms is from sandboxing, a modest overhead considering that it focuses on optimizing programs with long executing commands.

7.4.1 hS overheads

Benchmark	Overhead
Genomics	5.5%
Sklearn	2.4%
DGSH	7.7%
NLP	18.1%
NOAA	49.0%
Unix50	31.8%
COVID-mts	3.0%
LogAnalysis	34.0%

We evaluate the overall overheads of hS's tracing, sandboxing, and orchestration by executing 8 benchmark sets (Tab. 1, rows 2–9) with speculation window 0, meaning that hS executes one command at a time.

Results and Discussion: Overheads of hS compared to Bash range from 2.4% to 49.0%, with an average of 23% across all scripts. Some benchmarks like Unix50, and LogAnalysis have high overheads because they execute a large number of short commands, which are more expensive to sandbox. Tracing and sandboxing introduce higher overheads for I/O intensive workloads (e.g., NOAA) and lower overheads for CPU-intensive ones (Sklearn and COVID-mts).

7.4.2 I/O-heavy overheads

We evaluate hS on two artificial, I/O-heavy workloads to stress test its overheads: one workload writes a large file using `dd` [36], and the other creates a large number of small files.

Results (Fig. 7): For a large output file, hS's performance is 3.2–3.4× slower than Bash, most of which comes from sandboxing (3.0–3.4×), while tracing and parsing add negligible overhead. For many small files, hS's performance is 6.2–7.2× slower than Bash, with tracing causes 310% overhead, while parsing and sandboxing incur smaller part of the overhead 120–130% and 140–200%, respectively. hS's running time is slightly faster than the sandboxing time because tracing and parsing are pipelined.

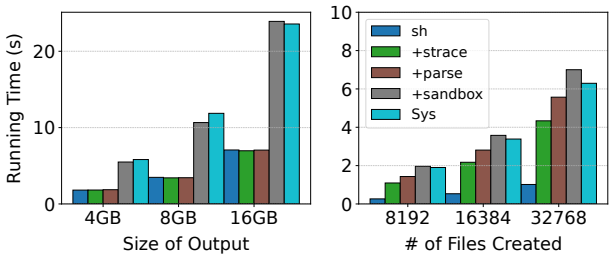

Figure 7: hS overheads on two I/O-heavy workloads.

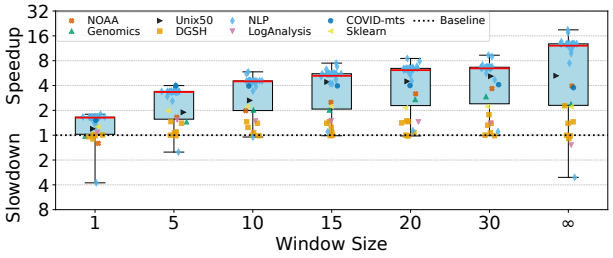

Figure 8: hS performance with varying window sizes.

Discussion: hS can incur substantial overheads on I/O-heavy workloads, both with the increasing size of written output, as well as the increasing number of accessed files. These are due to (1) the additional I/O overhead of moving the files out of the sandbox (between drives), and (2) the overhead of tracing a large number of `open` system calls.

7.5 Varying Window Sizes

We finally evaluate how different speculation window sizes, i.e., how many commands can be speculated concurrently, influence hS's performance. We run the scripts that take longer than 20 seconds out of 8 benchmark sets (Tab. 1, rows 2–9). We vary the speculation window size from 1 to an infinite window size (speculate all subsequent commands).

Results (Fig. 8): Increasing the window size from 1 to 15 improves performance across all sets, from 1.6× to 5.24× on average. Beyond this, benchmarks exhibit distinct behaviors: NLP continues scaling, reaching up to 9.1× on average at infinite window size; LogAnalysis peaks and then degrades due to excessive speculation (33% at infinite window size); and the rest initially benefit but quickly plateau.

Discussion: Optimal window size depends on script complexity, parallelizability, and available CPU cores. Several of our benchmarks benefit from larger windows due to abundant parallelism, *e.g.*, NLP scripts with completely independent loop iterations. The benchmarks that plateau execute fewer commands or are inherently less parallelizable. Finally, some scripts with many short-running commands do not benefit

Table 2: Summary of all Python benchmarks used to evaluate hS and their characteristics. Exec. Time indicates the execution time of the script with standard Python and Speedup indicates the speedup of hS.

	Benchmark	LOC	Input	Python Time	hS Speedup
1	BioAlign [59]	27	1.6M	3h11m	1.75×
2	ProteinInt [26]	122	3.5G	5h7m	2.25×
3	AudioProc [32]	22	28G	4m23s	3.99×
4	VideoProc [67]	32	648G	14m50s	2.76×
5	MRIanalysis [53]	161	25G	2h44m	8.40×

from larger window sizes due to resource saturation, *e.g.*, LogAnalysis invokes more than 700 commands, saturating the 128 threads of the execution machine.

7.6 Performance on Python programs

We evaluate the performance of hS and its Python frontend by comparing its execution time with standard Python execution on a set of real-world Python scripts. We configure hS with a speculation window of 16.

Benchmarks: We use a set of 5 real-world Python programs to evaluate hS's Python frontend (see Tab. 2 for a summary). The programs perform a variety of tasks, two bioinformatics workflows, an MRI image analysis, and audio and video processing; and are taken from a variety of sources including a textbook, an online forum, and a serverless benchmark suite. We did minor modifications to the programs to simplify the frontend: (1) invocations to external processes through a wrapper were inlined to directly call `subprocess.run`; (2) file-manipulation functions, e.g., `sys.write` were replaced with external processes calls so hS's executor could track their side-effects; and (3) user defined functions were inlined in main. BioAlign was also modified to disable JVM's performance logging to enable parallelization (see "Discussion").

Results (Tab. 2): We show the performance of hS compared to standard Python execution. Scripts have varying execution times, ranging from 4m to 5h when executed without hS. hS achieves a geomean speedup of 3.26× (min: 1.75×, max: 8.40×) across the benchmarks.

Discussion: hS improves the execution time across all Python scripts against baseline Python without any user input. For example, in MRIanalysis, hS manages to identify the speculation opportunity across independent loop iterations and achieves a speedup of 8.4×. In ProteinInt hS only achieves a 2.25× speedup because the script is bottlenecked by indexing a reference genome before the parallelizable loop.

Furthermore, hS's dependency tracking enables safe optimizations and performance debugging for target applications. When we first ran BioAlign with hS, we observed a .5% slowdown compared to the baseline. Inspecting hS's dependency logs allowed us to identify and fix a hidden but unnecessary write-write conflict (all JVM instances write perf. monitoring data in `/tmp/hsperfdata`) by passing a JVM flag that disables these logs. This experience shows that hS's tracking facilitates performance debugging and achieves benefits without risking changing a program's behavior—which could happen if one manually reordered invocations that were mistakenly thought to be independent.

8 Related Work

Performance optimizations for shell scripts: Recent work achieves significant speedups on shell scripts through parallelization [20, 29, 55, 62] and distribution [42, 50]. A key component of all these systems is a just-in-time compilation infrastructure [19, 29] that optimizes scripts at the right time, despite them being highly dynamic. hS builds on this just-in-time infrastructure, but extends it with context-passing, side-effect-management, and dependency reasoning to enable speculative execution. All of these systems require annotations for all commands present in a pipeline to enable optimization; hS, on the other hand, can optimize scripts without any user input, by understanding command behavior at runtime through tracing and isolation.

Runtime frameworks for shell scripts: Recent work that improves various aspects of shell scripts has identified the benefit of harnessing runtime execution information through tracing. Riker [11] enables incremental execution for shell scripts that describe software builds by tracing their execution and using the trace to identify the minimal set of commands to re-execute when the script changes. Dozer [22] translates shell scripts to Ansible commands for better maintainability by tracing the system calls of a target script and finding comparable traces in its library of Ansible commands. Autobash [58] helps users debug system configuration errors by tracing command execution to infer state deltas, with which it is able to detect predicate violations and perform rollbacks [44].

Explicit dependency encoding: Workflow and build systems [15, 21, 25, 31, 56] explicitly express dependency graphs by manually encoding all input and output dependencies of each step. Encoding dependencies statically and ahead-of-time yields better program schedules, but (1) requires users to provide *all* dependencies or suffer from stale or incorrect results, and (2) cannot express the high dynamism prevalent in shell scripts. Our approach addresses both these challenges.

Speculative execution: Speculation and rollback are not new ideas, with an extensive history from computer architecture to the application level, *e.g.*, for system configuration [44] or security checks [45]. In some of these proposals speculation is enabled by modifying the application (*e.g.*, Undo [6]), while others support arbitrary black-box applications [44, 45, 58]. Thread-level speculation is a widely

studied technique for extracting parallelism from applications at runtime by speculatively executing parts of them in different threads and rolling them back if dependencies are violated [14, 60]. Spidermine [64] optimizes programs through speculative prefetching by dynamically identifying sites of frequent reads. We build on these ideas, tightly coupling with the shell's language and semantics reducing overhead and the amount of tracked information: instead of considering the whole script as a black-box application, we use the script semantics to separate it into logical application components (command invocations).

Containment and tracing: There has been significant work on extending filesystems with sandboxing and transactions, some examples include: MBOX [30], a sandboxing mechanism; Amino [65], a transactional filesystem; SandFS [3], a filesystem with sandboxing support; filesystems that support snapshots, such as ZFS [5] and BTRFS [51]; and TotalCOW [66], which aims to improve the treatment of copy-on-write pages in Linux. All of this work is orthogonal and complementary to hS, since it could be used instead of or in addition to OverlayFS to improve hS's performance.

Shell script semantics: Finally, recent work has tried to study the semantics of shell scripts, either through collection of real-world shell uses [12], or through formalization [16, 17]. hS draws inspiration from these works to reason about the correctness of its optimizations and uses the parsing infrastructure developed by Smoosh [10].

9 Discussion

Limitations: There are some effects that hS's executor cannot currently identify, block, or revert precisely. First, our implementation blocks, but does not precisely detect, IPC, signals, and effects through device files [43]. These effects are restricted by IPC, pid, and mount namespaces respectively, but precisely classifying them requires more elaborate system-call tracing and, for device-file accesses, comparison with mount structures. Second, hS cannot detect, block, or revert effects through memory-mapped I/O or file systems with external effects, such as NFS [52]. Third, hS does not currently support pseudo-files for GPU devices. Although GPU runtimes typically provide process-level memory isolation, they rely on `ioctl` calls that create persistent state and perform IPC between GPU-using processes, which is not straightforward to detect and block [47]. hS also does not support scripts whose core logic depends on time, including wall-clock time or file access times [39]; executing such scripts with hS may change their results.

hS's dependency abstraction is path-based. It handles parent-directory effects and symbolic-link use conservatively, but it does not canonicalize all path aliases, such as hard links, complex bind mounts, or `/proc/self/fd`-style paths, into a single inode-level identity. Scripts whose correctness depends on such aliases being recognized as the same underlying file are therefore outside hS's current guarantees.

A separate limitation concerns scripts that impose higher-order semantic requirements on file accesses, *e.g.*, `apt`'s use of files as locks [37], or programs that coordinate through shared on-disk caches such as compiler caches, package-manager state, SQLite databases, or generated bytecode caches. These cases can require application-specific merge or locking semantics that are not captured by bulk OverlayFS commit.

hS also does not provide opacity for speculative executions: a speculated command may observe a state that is not globally reachable in the sequential execution, and could therefore crash, loop, or generate excessive output before being discarded. Production deployments could add explicit time, memory, and output quotas to bound such behavior.

10 Conclusion

This paper proposes hS, a system that can automatically exploit latent parallelism in shell scripts using out-of-order speculative execution. hS represents a significant improvement over the state of the art because it can support and optimize scripts with arbitrary executables without any form of user input or command annotations.

A Artifact Appendix

Abstract

The artifact for hS is an archived release of the implementation and evaluation materials for speculative shell execution. It includes the code, artifact-evaluation instructions, automation scripts, precomputed paper results, and dataset manifest.

Scope

The OSDI '26 evaluation grants only the Artifacts Available badge. The artifact therefore first supports checking that the implementation and supporting materials are public and permanently archived. The same instructions also describe optional functional and reproducibility paths: installing hS, running tests, regenerating plots from precomputed results, and rerunning selected benchmarks on suitable hardware.

Contents

The archived release of hS contains the source tree (`hs`, `scheduler/`, `executor/`, `preprocessor/`, `jit_runtime/`, `model-checking/`, `test/`, `report/`, and `python_hs/`); the `try` submodule; setup/archive helper scripts; precomputed results and plotting inputs under `artifact/paper-results/`; and dataset locations in `artifact/datasets.md`, as well as detailed instructions to set up and use the artifact.

Hosting

The stable artifact URL is the Zenodo archive: https://doi.org/10.5281/zenodo.19832407. The corresponding GitHub artifact-evaluation branch is https://github.com/binpash/hs/tree/osdi26-ae. The main development repository is https://github.com/binpash/hs.

Requirements

The quickstart in `INSTRUCTIONS.md` targets an Ubuntu-like Linux host (Ubuntu 20.04 or newer preferred), Python 3.12 or newer, permission to install APT packages, and `sudo`/root access for the tracing, cgroup, OverlayFS, and filesystem facilities used by hS and `try`. The setup script initializes dependencies and builds helper binaries. Full benchmark reruns require multicore machines with at least 1TB of disk space, and optionally privileged Docker access.

Incr: Faster Re-execution via Bolt-on Incrementalization

Yizheng Xie* Evangelos Lamprou* Jerry Xia* Nikos Vasilakis
Brown University

Abstract

While most software development is incremental, most execution environments are not: even small program modifications fail to take advantage of prior executions, at worst requiring full re-execution of all computational stages in the modified program. Such full re-execution decelerates software development and debugging, especially in dynamic polyglot environments such as the Unix and Linux shell. This paper presents INCR, a system that accelerates the re-execution of unmodified shell programs by automatically incrementalizing their execution. INCR analyzes and tracks interdependencies to detect and store key intermediate results, reusing them on subsequent re-executions whenever possible. INCR's effect analysis supports correct re-execution even for non-idempotent computations, and several static and dynamic optimizations reduce the runtime and storage overheads of incrementalization. Applied to diverse real-world scenarios, INCR accelerates re-execution by an average of 34.2× and a maximum of 373.3×—all while requiring no developer annotations or code modifications and remaining behaviorally indistinguishable on over 10,000 test cases.

1 Introduction

Nearly all software development is incremental: layers of modifications, additions, replacements, and deletions are applied iteratively to morph a program toward its intended goal. Such incremental development is particularly common today in data science [41, 60, 83], machine learning [10, 30], exploratory computing [24, 66, 79], and interactions with large language models [28, 67]. It is also the standard approach in dynamic, interactive environments such as the Unix shell, which is used for understanding, exploring, and gradually refining software systems, the opaque components comprising them, and the input they operate on [31, 43, 77].

Unfortunately, these environments do not support efficient re-computation when parts of a program change. Such changes, irrespective of their size, fail to take advantage of past executions—requiring a full re-execution of all the computational stages in the modified program. Even small refinements can result in long waiting cycles, especially on large datasets where re-execution might take the majority of the time. As the program grows, the longer it runs—and the slower it becomes to further iterate, discover errors, hand-tune, debug, and eventually ship.

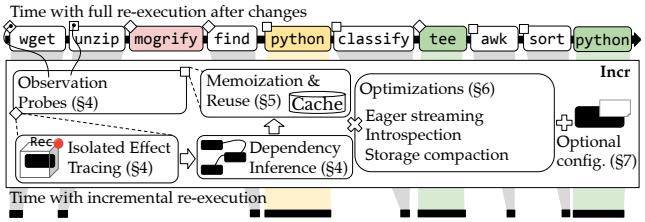

Fig. 1: **INCR overview**. INCR accelerates re-execution in modified shell programs by bolting onto otherwise unmodified execution environments. Upon re-execution, it reuses prior results to avoid redundant computation. Colors indicate types of incrementalization: + additions, − deletions, and ~ in-place modifications.

This paper introduces INCR, a system that accelerates re-execution by bolting incremental re-computation onto unmodified shell programs. Once enabled during development, it trades a small overhead during the first execution to accelerate subsequent re-executions. INCR operates in two phases: the analysis phase, which collects and analyzes program dependencies; and the incrementalization phase, which extracts information about modifications and, combined with the earlier analysis, accelerates subsequent re-executions of modified programs. INCR supports full POSIX *and* Bash semantics, including modifications to command arguments, flags, data flow, control flow, environment variables, and external resources, ensuring behavioral equivalence even for non-idempotent operations. When ready to ship, INCR can be disabled to avoid unnecessary runtime overheads in production environments.

INCR's analysis and incrementalization phases discover and

*Equal contribution

exploit process-level data and control dependencies across commands, automatically detecting, analyzing, and storing effects at runtime (§4). In subsequent runs, INCR determines which parts of a shell program are unchanged and safely reuses their outputs (§5). Several additional optimizations, such as eager stream processing, introspection, and storage compaction, lower runtime and space overheads (§6), making incrementalization practical for real-world workloads (§8). While no user input is necessary, INCR can leverage crowdsourced partial annotations for POSIX, GNU Coreutils, and third-party commands from earlier research [42, 71, 84], as well as developer-specified configurations to enable finer-grained incrementalization or eliminate dependency analysis in parts of programs that will not change (§7).

INCR has been applied to 14 real-world scenarios that include debugging, data exploration, interactions with LLMs, and other common tasks (§8). With no developer input, INCR accelerates re-executions by an average of 34.2× and by up to 373.3× by trading in space (avg: 6.05× of the original input size, max: 55.44×). While INCR slows down the first (typically short) execution by an average of 101.05%, mostly due to dependency tracking, additional optimizations reduce this overhead to 43.55%, raising average re-execution speedup to 38.64× and the maximum to 377.65×. INCR's behavior and outputs are indistinguishable from the underlying shell interpreter across all real-world scenarios and 10,279 out of 10,282 (99.9%) tests from the standard Bash test suite, including unusual behaviors rarely seen in practice.

The paper starts by exemplifying INCR on a real-world workload (§2), followed by its execution model (§3) and key contributions (§4–7):

- Fine-grained dependency tracking via lightweight interposition probes that capture interactions across the filesystem and shell environment (§4).
- Correct incrementalization via memoization of dependencies and effects, including both transient data streams and side effects, and safe reuse of prior effects (§5).
- Diverse runtime optimizations, such as eager stream processing, introspection, and compaction, that make incremental execution practical (§6).
- An optional tuning interface that accepts crowdsourced annotations and developer configurations to enhance, disable, or relax parts of incrementalization (§7).

The paper then characterizes INCR on real-world programs (§8), discusses related work (§9), and concludes (§10). Appendix A presents the paper's software artifact.

2 Applying INCR During Development

Fig. 2 shows a real shell program used to digitize images of hieroglyphs collected during an archaeological expedition [3]. The script (1) fetches the images collected during the expedition; (2) unpacks the images into a local directory; (3) iterates over the images; (4) segments each image into hieroglyph regions using Meta's Segment Anything Model [45]; (5) applies a hieroglyph classifier to each segment; and (6) outputs the formatted mappings between image filenames and their classified segments to the `db.txt` file.

```
1  wget 'http://inst.edu/dpt/images.zip'
2  IMGS=${IMGS:-images}
3  unzip images.zip -d "$IMGS"

Fig. 2: **Hieroglyph classification script**. A script that segments, classifies, and visualizes images of hieroglyphs. Highlighted lines indicate modifications made during development: `+` additions, `-` deletions, and `~` in-place modifications. Primed line numbers denote updated versions of earlier lines. Numbers denote modification order; equal numbers belong in the same iteration.

Developing this script involved several modifications, four of which are highlighted in Fig. 2: removing a redundant image resizing step (ln.4, ln.6, #1), changing `awk` to include image paths in the output (ln.11, #2), making the outer loop process images in all subfolders (ln.5, #3), and plotting the classification results (ln.10, ln.13, #4).

Problem: Re-executing the entire script after each modification takes up to 15 minutes, dominated by the segmentation and classification stages.

Incrementalization—re-executing only the parts of the script necessary to reflect each modification—can significantly accelerate re-execution. To achieve incrementalization, a developer could *manually* insert `tee` commands and **`if`** guards (lns. 5–12) to memoize intermediate results and reorganize the script to reuse those intermediate files. However, this approach requires significant effort and can introduce subtle errors, as manual partial re-execution may use stale intermediate results. Furthermore, this approach does not help with change #3, which expands the input image set, and is cumbersome to apply with changes #1 and #4, which

modify the program in non-trivial ways.

Key challenges: There are several challenges in automating the incrementalization of shell programs. First, Fig. 2's script contains opaque, heterogeneous commands with complex and often implicit interdependencies. For example, `plot.py`, introduced in modification #4, consumes `classes.txt` (produced in ln. 10) and thus depends on the outputs of all prior stages (lns. 5–9). Commands also interact with external resources and the execution environment. For instance, `segment.py` (ln. 6) reads images from the `$IMGS` directory (defined in ln. 2) and depends on several Python packages loaded by the `python` interpreter. In addition, such dependencies are typically implicit and dynamic (*e.g.*, `$IMGS` may be externally set). Therefore, the script's behavior can change with its surrounding context.

Second, these commands generate arbitrary side effects, including modifications to the filesystem and transient input/output streams that flow through pipelines and cannot be easily reused across runs. For example, modification #4 alters the pipeline by inserting a `tee` command (ln. 10), which consumes the output stream produced by earlier commands. The `tee` command then emits two effects: one written to disk as `classes.txt`—later consumed by the newly added `plot.py` command (ln. 13)—and another directly streamed to the next command `awk` (ln. 11).

Finally, commands exhibit diverse execution patterns that can make incrementalization via tracing and caching inefficient. For instance, modification #3 changes the set of images the **`for`** loop will iterate over; this changes the set of images processed but does not invalidate memoized results for some commands inside the loop, as they can be reused for the unchanged images. Memoization of command effects can incur substantial storage overhead, particularly for large artifacts produced by commands such as `unzip` or `segment.py`.

Applying INCR: Developers enable INCR during development to automatically incrementalize scripts and disable it when ready to deploy. This workflow for Fig. 2's script is:

```
$ incr dpt.sh                    # Enabling INCR
$ incr dpt.sh ... incr dpt.sh    # #1 #2 #3 #4
$ ./dpt.sh                       # Ready to ship!
```

To solve the earlier challenges, INCR probes the script's execution at runtime to track command dependencies (§4), memoize their intermediate effects (§5), and reuse them when relevant state is unchanged. It first parses the script, inserts *interposition probes* at all command invocations, and executes the transformed script using the underlying shell interpreter. These probes wrap each command and observe its execution: each probe creates an isolated environment for its command to run in, tracks its `stdin` and filesystem dependencies, and memoizes its input/output streams and filesystem effects. During re-execution, each probe compares the current dependencies to those stored and decides locally to re-execute its command if it detects any changes; otherwise, it skips execution and emits its memoized effects. As INCR's probes operate at runtime, they can observe dynamic changes to variables (which may depend on external state) and control flow.

Modification #1 removes the redundant `mogrify` command that resized images before segmentation and makes the `segment.py` command resize images internally instead. Upon re-execution, INCR replays `wget`'s and `unzip`'s effects—their dependencies are unchanged and INCR is not invoked with `-N`, which would re-execute all network-effectful components. It then detects that `segment.py`'s input and invocation have changed; INCR thus re-executes `segment.py` normally, but its output, containing normalized coordinates, has not changed. Then, the probes surrounding `classify.py` and `awk` detect that their environment, inputs/outputs, and filesystem dependencies are unchanged, so INCR skips their executions and emits their memoized results.

Modification #2 includes two changes to the `awk` command: adding classification confidence (`$6`) and the image path (`i`) to its output. The `awk` command's probe detects that its arguments have changed and re-executes it. The downstream probes detect `awk`'s output changes and re-execute their corresponding commands. All prior stages (lns. 5–9) reuse their memoized results.

Modification #3 filters out irregular files in the `$IMGS` directory using `find`. The probe on `segment.py` retrieves and emits memoized results for images it has processed before; otherwise, it executes the command normally.

Finally, modification #4 includes several changes that add a plotting section to visualize the classification results saved by `tee`. On re-execution, INCR skips all unchanged stages before `tee`. Then, INCR detects that `tee` does not alter the input to the `awk` command, and thus continues to reuse memoized results for all subsequent stages—executing only the new `plot.py` command.

Results: INCR improves time spent across all re-executions from 1h25m to 20m41s, resulting in a 4.1× speedup. Modifications #3 and #4, which include exploration of already-processed data, enjoy 91.2× and 119× speedups, respectively. If annotations were used, INCR would achieve an additional 5% speedup by skipping dependency tracking on `awk` (§7).

3 Execution Model

To provide practical incrementalization for real shell programs, INCR does not incrementalize all observable behavior nor does it re-execute all commands when their environment exhibits *any* observable change. Instead, it groups all possible component effects and behaviors into five classes (Tab. 1): (1) *memoizable* effects, which INCR can record and apply identically to the component that originally performed them; (2) *detectable* effects, which it observes to infer dependencies but which it does not memoize; (3) *blocked* effects, which will fail during a command's execution and thus typically surface as errors indicating to the user that INCR cannot be

used for part of the script; (4) *ignored* effects, which INCR's current implementation does not support; and (5) *out-of-scope* behaviors that are fundamentally outside INCR's goals and assumptions.

Memoizable effects are effects which INCR can both detect precisely during tracing and replay exactly during reuse. These are a command's interactions with standard streams, its exit status, and local filesystem effects on regular files, directories, symbolic links, hard links, named pipes when used unidirectionally, including their permission metadata changes. Examples of such effects are writing to `stdout`, moving a directory from one path to another, and creating a symbolic link. Commands whose effects primarily fall into this class include `grep`, `cp`, `mv`, `ln`, `gcc`, `pwd`, and `jq`.

Detectable effects are effects which INCR can observe during tracing but cannot precisely replay, and for which it therefore conservatively re-runs the command when it detects such effects. These include all memoizable effects, the process's environment variables, filesystem effects on character devices, block devices, and sockets. INCR's `-N` flag (§5) extends this set to clock system calls, network system calls, and entropy-supplying system calls. Examples of commands whose effects primarily fall in this class include `wget`, `curl`, and `shuf`. If all components in a shell program only perform effects in this class, INCR can guarantee correct re-execution.

Blocked effects are effects that (attempt to) cross the boundaries of INCR's probes during execution. INCR blocks these effects because its underlying probe environment [50] requires `user`, `mount`, and `pid` namespaces to instantiate a private filesystem view and correctly interpose on the `/proc` filesystem. For instance, sending a signal to a process outside the same process sub-tree, *i.e.*, outside the probe, will fail—with the signal never reaching its intended target. Commands that spawn subprocesses meant to outlive their original runtime will not be reflected outside the probe environment. A large number of process- and job-control commands such as `kill`, `jobs`, `bg`, and `fg` are implemented as shell built-ins, which INCR does not probe and can thus perform their effects freely. Other blocked behaviors include concurrent access to shared state across probe environments, such as command `a` producing files that command `b` consumes concurrently in `a | b`. Command effects do not inherently belong in this class; rather they are specific to cross-command interactions that will be blocked by INCR's underlying semisolation mechanisms. Blocked effects can be safely allowed using INCR's configurations (§7).

Ignored effects are effects that can be observed or blocked by INCR, but are not supported by the current prototype. These effects are assumed to not affect a component's observable behavior and include querying the current system state—*e.g.*, host and kernel identity, scheduling state, and system-wide resource statistics—POSIX message queues, semaphore sets, and shared memory segments. For example, `hostname`'s `stdout` will be replayed even if the system's hostname changes across re-executions. Example commands in this class include `uname`, `getpriority`, `sysinfo`.

Out-of-scope behaviors include timing-sensitive components whose behavior depends on the precise elapsed time; INCR-aware components that change their behavior when they detect they are executing inside probes; non-deterministic components seeded by state undetectable by INCR; ones not terminating, *e.g.*, daemons; and ones that interact with system state outside system-call tracing, *e.g.*, by changing kernel state via module loading. These behaviors will require new insights and approaches that are very different from the ones INCR takes. Examples of commands include `systemd-detect-virt`, binaries seeded by `RDRAND`, `at`, `insmod`, and polling loops built around `sleep`.

Table 1: **Effect classes.** INCR's implementation distinguishes between several classes of effects described below.

Class	Example effect	Commands
Detectable	perform network communication	`wget`, `curl`
Memoizable	create or overwrite a regular file	`cp`, `echo`, `mv`
Blocked	signal a non-child process	`pkill`
Ignored	query system hostname	`hostname`
Out of scope	wait for a given amount of time	`sleep`

4 Dependency Tracking

This section describes how INCR acquires fine-grained information about command dependencies.

Inserting interposition probes: Shell programs feature complex control flow and interaction with the environment, complicating the extraction of command dependencies and their effects. INCR performs all dependency tracking at runtime, following a component-centric approach: it isolates each command's effects and tracks its dependencies individually (Fig. 3). It allows tracking commands on a per-effect basis (§5), enabling far more precise memoization and reuse than probing the script as a monolith.

INCR first parses the shell script using `libbash`, which exposes Bash's parsing subsystem as a library. It then walks the program's abstract-syntax tree (AST) and inserts probes as higher-order commands that wrap the original command invocation. For example, INCR transforms the invocation `rm $path` into `./probe rm $path`. The probe overwrites the `$0` variable to point to the original command and then invokes it with its original arguments. Each probe tracks its command's dependencies and memoizes its effects. This includes any subprocesses spawned by the command, meaning that a command such as `xargs` will be incrementalized as a whole.

Probes are only placed at trackable commands, which leaves out shell-defined functions, built-in commands, and other components that cannot be resolved inside the shell (*e.g.*, `alias`). To deal with these shell-specific constructs, INCR ap-

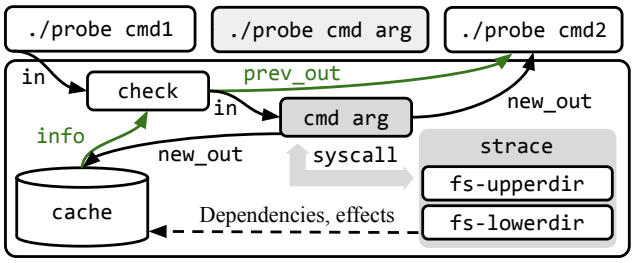

Fig. 3: **Interposition probes**. INCR inserts lightweight interposition probes before each command in a shell program. A command's probe records its dependencies, inputs, outputs, and other effects by tracing its system calls (gray arrows) and memoizing those effects in a cache. On subsequent executions, the probe checks its dependencies against prior runs retrieved from INCR's cache. If they are unchanged, the probe reuses prior results (green arrows); otherwise, it re-executes and re-traces the command (gray arrows).

plies a small set of lightweight syntactic analyses and transformations. In particular, INCR keeps track of and does not place probes on built-in commands (using the closed set given by `compgen -b`), function definitions, `alias`ed invocations, and backgrounded computations (`&` and `coproc`). For other syntactic constructs that create non-trackable side effects, INCR transforms them into equivalent, trackable commands. It converts redirections (`>`, `>>`, `<>`, `>|`, and their number-prefixed variants) into `dd` invocations before inserting probes.

Detecting dependencies: Correct incrementalization requires comprehensive tracking of each command's runtime dependencies.

To precisely capture each command's effects on the filesystem, INCR executes them within a `try` semisolate [50], which provides a private, copy-on-write view of the filesystem. Before each command executes, INCR instantiates a new OverlayFS mount that composes a read-only lower layer (`lowerdir`) with a writable upper layer (`upperdir`) into a unified merged view for each top-level directory in the current filesystem and `unshares` to change the process's root directory to the merged view. To suppress components with unsupported dependencies, INCR also instantiates a `user`, `pid`, and `mount` namespace, blocking non-filesystem cross-process interactions such as signals and shared memory. All modifications performed by the command are captured in the `upperdir`, while the `lowerdirs` offer transparent read-only access to the underlying filesystem. Upon completion, INCR scans the `upperdir` to identify modifications made by the command and commits them from the `upperdir` back to the persistent filesystem. Furthermore, INCR stores the `upperdir` for reuse during subsequent executions (§5).

Scanning the upperdir only reveals write dependencies. To capture read dependencies, INCR monitors system calls made by each command during its execution. To lower overheads, INCR intercepts a subset of system calls within the scope of dependencies it needs to track—specifically, `fork`, `exec`, and all file-related system calls included in `strace`'s `%file` system set. INCR uses `seccomp-BPF` to filter out irrelevant system calls and reduce context switching overhead. The set of observed system calls can be extended to detect other types of dependencies, at the expense of higher tracking overhead.

INCR also tracks environment dependencies such as environment variables and function declarations. These are pervasive in shell scripts as commands often rely on environment variables for configuration (*e.g.*, `LC_ALL` affects `sort`'s ordering behavior). Before executing each command, INCR captures the current environment variables and function declarations in the shell. If this set differs on re-execution, INCR reruns the command. Environment modifications made during execution are handled automatically as INCR captures environment snapshots on a per-component basis.

False and noisy dependencies: Within the execution environment, *false* and *noisy* dependencies may lead to unnecessary re-executions. For example, INCR cannot determine which environment variables a command depends on, because after process startup the environment resides in the process's user-space memory and accesses to it do not go through the system call interface. This forces INCR to conservatively treat all environment variables as dependencies, which may trigger re-executions even when variables that do not impact command behavior change across runs. To mitigate this, INCR implements a distribution-aware filter that discards noisy environment variables. Currently, INCR is aware of noisy variables inside the Debian and Ubuntu distributions, specifically those related to session management and `tty` settings.

5 Memoization and Reuse

This section explains how INCR memoizes command dependencies and effects at runtime and reuses these memoized results when appropriate.

Efficient memoization: INCR stores each command's dependencies and effects collected during effect tracking (§4) in a cache directory on the host system. Commands are indexed by their invocation arguments, environment variables, and `stdin` stream hash. During re-execution, INCR indexes into the cache to check if commands can be skipped and to fetch memoized results.

Each command's probe only has visibility into its own read and write dependencies. After recording them, INCR generates a dependency file. INCR tracks read and write dependencies differently as an optimization, using the insight that components in dynamic runtimes resolve sub-components at runtime, leading to many more read than write dependencies [85]. Write dependencies are tracked using content hashes while read dependencies are tracked using last modification timestamps, which are much cheaper to extract. To check if a write dependency has changed, INCR compares the file's current

hash to its stored hash. This allows INCR to skip re-execution if upstream commands modify a file but produce the same output (*e.g.*, `sort` may produce the same output given different inputs), while also distinguishing between same-content overwrites and appends, ensuring correct reuse for non-idempotent writes. To check if a read dependency has changed, INCR checks if the file's timestamp has changed. However, this over-approximates changes when a command reads a file modified upstream. To mitigate this, INCR avoids updating file timestamps when applying memoized writes, ensuring that commands do not detect spurious timestamp changes.

Furthermore, INCR stores each command's transient data streams, exit code, and filesystem effects alongside its dependency file to memoize its effects. To capture transient data streams, INCR duplicates a command's `stdout` and `stderr` to files within the cache directory at runtime. To capture the exit code, INCR waits for and records the command's exit status after execution. To capture filesystem effects, INCR directly stores the `upperdir` generated by OverlayFS during dependency tracking. INCR memoizes only output streams, exit status, and replayable local filesystem effects (§3). All other externally visible effects are either used to disable reuse, blocked by isolation, or left outside the model.

Safe reuse: Correct incremental execution requires detecting when a command's dependencies remain unchanged and applying prior results correctly. During each execution, INCR compares each command's current dependencies against its dependency file. If any differ, INCR re-executes the command and records its new dependencies and effects; otherwise, INCR skips execution and applies its memoized results.

For output streams, INCR directly streams memoized `stdout` and `stderr` to their corresponding file descriptors. For filesystem effects, INCR scans the memoized OverlayFS `upperdir` that contains a component's post-execution set of filesystem effects. Inside it, OverlayFS represents created or modified files as regular files, deleted files as *whiteouts* (character devices with major and minor numbers `0,0`), created directories as regular directories, and overwritten or deleted directories as directories that have the `user.overlay.opaque` extended attribute set. To reuse these effects, INCR iterates over the `upperdir`, matches each filetype to the corresponding effect, and applies each change to the current environment.

INCR, with the `-N` flag, employs several best-effort heuristics to detect if a component (1) relies on the system time; it executes clock system calls, (2) performs network interactions; it executes network system calls, or (3) may be nondeterministic; it executes entropy-supplying system calls. In these cases, it will conservatively disable reuse for such components. Furthermore, INCR accepts optional annotation and configuration (§7) that allow developers to mark commands as non-incrementalizable.

6 Runtime Optimizations

INCR's tracing (§4) and memoization (§5) mechanisms may introduce significant runtime and storage overheads. This section describes several optimizations that make INCR practical for real-world workloads.

Eager stream-processing: The shell's streaming execution model allows commands in a pipeline to start processing as soon as their upstream commands begin emitting output. This complicates incrementalization. Consider `awk '{print $1}' $f | grep 'x'`. If the file `$f` points to changes but its first column remains the same, then `awk`'s output is unchanged, meaning that `grep 'x'` can reuse its memoized results. However, blocking on each pipeline stage to decide reuse disables the shell's streaming semantics and incurs high overhead for long pipelines.

To address this challenge, INCR employs *eager stream processing*, a mechanism that allows reuse decisions to be made on the fly, while streaming outputs. When executing a pipeline, INCR's probes begin executing each command as soon as input is available and without waiting to check if re-execution can be skipped. Each probe buffers its `stdin` stream in memory while computing a rolling hash and forwarding it to the probe's corresponding command. Then, once the probe finishes hashing `stdin`, it checks if the command's inputs have changed. Importantly, probes typically finish hashing `stdin` *long before* their commands finish processing it, especially for compute-intensive commands, enabling them to determine if memoized results can be reused early in each re-execution run. If the command's dependencies and `stdin` have not changed, then INCR sends a `KILL` signal to the command and outputs its memoized results starting from where it left off. Otherwise, INCR continues running the command and tracking its effects as usual. This process continues in a chain for all the stages in a pipeline.

However, aborting a command that has filesystem side effects early may produce an inconsistent system state if it is in the middle of a modification. INCR's effect isolation mechanism (§4) addresses this: each command's effects are entirely contained within its OverlayFS `upperdir`. Therefore, INCR simply discards a command's `upperdir` when aborting its execution and applies its memoized effects instead.

Introspection: Effect isolation (§4) is necessary to contain and memoize side-effectful commands. However, creating, copying, and committing OverlayFS directories generates potentially expensive overheads. To reduce such overheads, INCR employs *introspection* to detect, using knowledge from prior runs, whether commands need effect isolation. Specifically, INCR uses the tracing information to identify commands that do not perform filesystem modifications. INCR optimistically assumes that, given the same arguments, these commands remain effect-free in subsequent runs, similar to assumptions made by prior systems [42,71]. It then runs these commands without isolation.

However, if such a command modifies the filesystem in a subsequent run—as detected by INCR's tracing mechanism—INCR *still* guarantees correctness. INCR completes the command's execution as normal, correctly applying its effects to the filesystem. It then revokes the command's effect-free designation and invalidates its cache entry to avoid reusing potentially stale effects in future runs. In the next run, INCR re-executes the command with effect isolation enabled.

Certain commands may be practically effect-free but still create temporary files during execution that are cleaned up before they exit. For example, `sort` creates temporary files if its input is too large to fit into memory. INCR assumes that files created and removed within the same command execution are temporary, and does not record them as dependencies. This approach allows INCR to consider such commands effect-free and to skip effect isolation in subsequent runs.

Storage compaction: Memoizing dependencies and effects for commands that produce large outputs or across shell programs that have several opportunities for incrementalization can incur significant storage overheads. To mitigate this issue, INCR employs *storage compaction*, compressing memoized data with a configurable compression level. INCR uses the Zstandard compression algorithm, which provides acceptable performance and compression ratio [17].

To avoid invalidating memoized data when the compression level changes, INCR records the compression level used for each memoized output. Therefore, INCR can decompress and reuse data generated under any previous configuration.

7 Optional Annotations and Configurations

INCR can also leverage command annotations made available by other systems and optional developer configurations to lower its overheads and increase or decrease its incrementalization fidelity.

Existing crowdsourced annotations: INCR leverages crowdsourced command annotations made available by other systems [39, 42, 63, 71, 84] to further increase the granularity of incrementalization. These annotations target parallelization and distribution opportunities, but the information they expose can benefit INCR's analysis and accelerated re-execution. Each annotation maps a command invocation to a set of properties. For example, a combined annotation from POSH [71] and PaSh [42] for `cat` is:

```
cat: [], stateless, splittable_args
```

This annotation indicates that `cat` is stateless and splittable across its arguments when invoked without any flags. The following are the properties that INCR can exploit.

INCR exploits *statelessness*, a classification from both POSH [71] and PaSh [84] for commands that operate on each input line independently without maintaining any internal state across lines. For example, invocations of `grep` without `-c` are classified as stateless over their `stdin` stream. This allows INCR to re-execute only the affected parts of a stateless command's input stream. It splits the inputs of stateless commands into smaller chunks and memoizes each chunk separately and in parallel. Data streams are split using content-defined chunking [89], which produces chunks that are stable across input perturbations. If a modification to a stateless command's input affects only a few chunks (*e.g.*, when a log file is extended with new events), then memoized results of unaffected chunks can be reused.

INCR exploits *purity*, a classification for commands that do not modify the filesystem outside of a defined set of inputs and outputs. This classification comes from PaSh's parallelizability annotations [84]. For example, an annotation for `grep -f p.txt` classifies it as pure with read dependencies from `stdin` and `p.txt`, and a write dependency to `stdout`. INCR skips effect isolation and tracing (§4) on pure commands. For many common commands such as `cat`, `grep`, and `tr`, this reduces INCR's overhead when introspection (§6) has not yet detected that the command is pure.

INCR exploits *argument independence*, a classification from POSH [71] for commands that can be executed independently for each argument. For example, an annotation for `grep -H 'p' f1 f2` classifies it as argument-independent across its arguments. Specifically, if `f2` changes, then only `grep -H 'p' f2` needs to be re-executed. INCR performs argument-level incrementalization on these commands by syntactically transforming each invocation: INCR splits the single large invocation into multiple invocations inside a subshell, each with a single argument. For example, it transforms the previous `grep` invocation into `(grep -H 'p' f1 ; grep -H 'p' f2)`. INCR then places separate probes on each invocation and memoizes and reuses their results independently.

Optional developer configuration: Developers can also optionally configure INCR for specific script fragments to further improve performance, exploiting knowledge of a script's behavior and use patterns. To support such configurations in a backward-compatible fashion, INCR exposes a special annotation that it detects during parsing. These annotations instruct INCR either to disable incrementalization for a command or to group multiple commands together to memoize them as a single unit. Such annotations are expressed as assignments to the placeholder environment variable `INCR` before commands. For example, configuring INCR to skip `cat` and `grep` within a pipeline looks as follows:

```
INCR="s" cat f | INCR="s" grep . | tr a-z A-Z
```

Configuring INCR to group commands together by marking the first and last commands in the group looks as follows:

```
cat f | INCR="g" grep . | INCR="ug" tr a-z A-Z
```

INCR removes the `INCR` environment variable before executing the annotated commands.

Disabling incrementalization reduces runtime overheads for program fragments that perform minimal computation or

Table 2: **Benchmark summary.** Summary of all benchmarks used to evaluate INCR and their characteristics. Benchmarks are categorized based on the delta type: addition (+), deletion (−), modification (~), or a combination thereof and the reason for the change: behavior (B), wrong command (C), wrong flag (F), exploration (E), summarization (S), optimization (O), LLM assistance (L), replacement (R), input update (I), debugging (D), aggregation (A), or visualization (V).

	Benchmark	Description	Input	# deltas	LoC	Deltas	Source
1	**dpt**	Segments and classifies images.	2.4 GB	9	84	O 2F I A F V 2C	[48, 81]
2	**bio**	Extracts genome sequences.	3.5 GB	6	104	I B I D 2E	[11, 70]
3	**dict**	Calculates top-n most frequent words.	30 MB	1	2	S	[5]
4	**ngram**	Extends indexing stage to 1–3 grams.	106 MB	2	58	2B	[16]
5	**uppercase**	Analyzes word distribution.	200 MB	1	18	B	[16]
6	**unixgame**	Solves a Unix game question.	1.0 GB	5	6	2E E 2E	[8, 82]
7	**nginx**	Detects broken links.	974 MB	21	243	7E 5A R 5D S F O	[71]
8	**weather**	Calculates temperature statistics.	887 MB	2	138	2E	[87]
9	**covid**	Calculates public transit statistics.	381 MB	4	48	E E E E	[80]
10	**spell**	Finds spelling errors.	3.1 GB	6	48	3D E 2B	[5]
11	**poet**	Extracts used and rhyming words.	1 GB	3	47	3E	[16]
12	**image**	Renames images with a VLM.	38 MB	6	45	2D 2D L O	[48, 81]
13	**music**	Prepares music files for sharing.	16 MB	6	52	3L D O O	[71, 72, 78]
14	**beginner**	Inspects system logs.	974 MB	13	28	5F 4E A O E S	[71, 76]

have complex side effects. For example, configuring INCR to skip `cat` and `grep` commands in the example above avoids effect memoization for trivial commands that emit large outputs, thereby eliminating both runtime and storage overheads.

Grouping commands reduces overheads for program fragments that are unlikely to benefit from fine-grained, individual incrementalization. Additionally, grouping a fragment that is considered final and not expected to change allows INCR to focus only on fragments that will benefit from incrementalization. For example, configuring INCR to group the pipeline above incurs effect isolation and tracing overheads only once for the entire sequence rather than once per command. This can significantly improve performance for pipelines composed of many inexpensive commands.

8 Evaluation

This section applies INCR to 14 incremental development scenarios (totaling 85 deltas) to characterize its re-execution benefits (§8.1), its runtime overheads (§8.2), its behavioral equivalence (§8.3), the effectiveness of its optimizations (§8.4), and the impact of optional annotations (§8.5).

Benchmarks and modifications: To evaluate INCR, we use benchmarks from the Koala suite of real-world shell workloads [49] and modifications thereof. These benchmarks span data processing, machine learning, and system administration, with input sizes ranging from a few to several gigabytes, and consisting of a total of 85 deltas, summarized in Tab. 2.

Their modifications include fixing wrong commands or arguments, developing new functionality, exploring characteristics of data, and introducing modifications from LLM suggestions—collected from: (1) discussions with the original developers of these workloads, with modifications mirroring the iterations that led to the final script (seconds to minutes between iterations across **dpt**, **covid**, **weather**, **ngram**, **uppercase**, and **beginner**); (2) the Git commit history of these benchmarks (minutes to hours between iterations across **bio**, **unixgame**, and **nginx**); and (3) manually constructed edits to reflect realistic development trajectories (seconds to minutes between iterations across **dict**, **spell**, **poet**, **image**, and **music**). All modifications arise from a diverse set of goals (summarized in Tab. 2), resulting in three types of program deltas: in-place edits to existing commands (~), *e.g.*, changing command arguments; additions of new commands or stages (+); and removals of existing commands or stages from the script (−).

The Koala benchmarks used in INCR are only the ones for which we could identify and collect such program modifications. INCR contains only the digital pyramid text pipeline from **inference** (**dpt**), genome-sequencing from **bio** (**bio**), frequency, n-gram, transliteration, and poem generation from **nlp** (**dict**, **ngram**, **uppercase**, and **poet**), **unixfun**'s chess puzzle (**unixgame**), log-analysis program of **analytics** (**nginx**), core temperature computation from **weather**, excluding the Tufte weather plot (**weather**), all except the last, monolithic script of **covid** (**covid**), spell-checking of **oneliners** (**spell**), VLM-assisted image annotation from **inference** (**image**), and conversion, compression, and encryption programs from **file-mod** (**music**). Finally, **beginner** is an entirely new benchmark not available in Koala, representative of non-expert developers who perform multiple exploratory modifications in their development process.

Scenarios, in detail: The **dpt** benchmark (discussed in §2) segments and classifies hieroglyph images from a single

expedition. Its changes include optimizing by removing a redundant image-resizing stage (O), correcting awk's printing format (2F), filtering out irregular files in the **for** loop condition (I), aggregating the classification results (A F), and finally visualizing classification results with three iterations (V 2C). Inputs total 2.4GB, including model weights and ultra-resolution images.

The **bio** benchmark processes genomic data to extract chromosome-specific subsets using a six-stage pipeline. Changes include iterating over all BAM files instead of a hard-coded testing file (I), extracting per-chromosome reads (B), driving processing from an input file of population-sample pairs (I), ignoring malformed or incomplete entries in that list (D), and plotting summary statistics for per-sample coverage (2E). The script is applied on a corpus of genomic data comprising 15 samples and 3.5GB of aligned reads.

The **dict** benchmark counts the frequency of each word in a corpus using a four-stage pipeline. The change modifies the script to only output the top-n most frequent words, by adding a stage to `sort` words by frequency and a last `head` stage (S). The program operates over a large text corpus of 5.2M words, totaling 30MB of text from Project Gutenberg [35].

The **ngram** benchmark starts with a unigram computation pipeline of `tr`, `sort`, and `uniq`, extended to compute bigrams (B) and trigrams (B). It processes a 16-million-word, 106MB snapshot of Project Gutenberg [35].

The **uppercase** benchmark extracts all unique capitalized words from a large text corpus using multiple stages of `grep`, `tr`, and `sort`. The first delta modifies the script to count the occurrences of unique capitalized words by adding `sort -u` to sort the words by their frequency in descending order in the middle of the pipeline (B). Its input is a 33-million-word snapshot of Project Gutenberg, totaling 200MB [35].

The **unixgame** benchmark solves a series of questions from the Unix 50th anniversary game. It first counts the total number of rounds using `grep '.'` and `wc -l`. Changes insert `grep 'x'` to capture moves from one side (E), then a `cut` and `grep -v '[KQRBN]'` to count specific captures (E), then `cut`, `sort`, and `uniq -c` to count occurrences of each capture (E), normalize lowercase identifiers via `tr '[a-z]' 'P'` (E), and counting occurrence frequency with `sort -r`, `uniq -c`, `head`, and `awk` (E). Inputs are a chess dataset from Lichess [20] totaling 19M chess moves and 1.0 GB.

The **nginx** benchmark analyzes Nginx server log entries to identify broken links. A series of changes expands its scope, *e.g.*, extracting status codes, listing request paths that lead to `402` or `502` errors, identifying suspicious requests, counting unique clients, extracting referrers, sorting and ranking error-inducing URLs, and summarizing top 404-error paths (7E 5A R 5D S). Another set modifies ordering and summarizing behavior to use consistent reverse-numeric sorting (F), and deleting unnecessary outputs (O). It operates on a 5-million-record, 974MB web-server log [71].

The **weather** benchmark processes a large weather dataset to compute maximum temperatures for each day between 1995 and 2000. The changes modify the script to add two additional statistics by computing the minimum (E) and average temperature (E). Its input is an 887MB weather dataset of 3.6M temperature records from the National Oceanic and Atmospheric Administration (NOAA) [64].

The **covid** benchmark analyzes public transit data collected during COVID-19 to compute a series of statistics. The changes introduce more metrics such as total vehicles per day, days per vehicle (E), hours per vehicle (E), monitored hours per day (E), and hours per bus (E). Its input contains 5M bus schedule records, totaling 381MB [80].

The **spell** benchmark analyzes spelling mistakes in a large text corpus. It includes six changes: removing non-printable characters and turning the input into a word stream (D), lowercasing that stream (D), removing punctuation (D), sorting words in alphabetical order (E), reporting words not found in a dictionary (B), finally comparing only unique words against a dictionary to identify misspelled words (B). The input is a collection of 9001 books, totaling 527M words and 3.1GB of text [35].

The **poet** benchmark counts the frequency of each word found in a given directory containing text files. Changes include replacing the single-file input with a concatenated corpus of all poetry files to enable global text statistics (E), adding a second output that reports unique words in alphabetical order (E), and finally introducing a third output that orders words by rhyme by reversing strings prior to sorting and then restoring their original orientation (E). The input is a corpus of 3001 books, totaling 22.4M lines and 1GB of text from Project Gutenberg [35].

The **image** benchmark renames images based on their content using a vision-language model—`GPT-4o mini`. Changes include replacing spaces in LLM-generated titles with underscores to form basic filenames (D), lowercasing all characters for consistency (D), stripping non-alphanumeric, non-underscore, and non-dash characters to guarantee filesystem-safe names (D), separating the cleaned stem into a reusable `base` variable for clearer filename construction (L), consolidating the sanitization steps into a single `sed` invocation (O), and finally removing the mode suffix so outputs use only the cleaned base title (D). Its input is a set of 11 images from a browsing session (totaling 38MB) [48].

The **music** benchmark captures a vibe-coding development loop, where a user iteratively refines a multimedia pipeline through loosely guided interactions with an LLM [29]. Starting from a simple `mp3` to `wav` conversion with `ffmpeg`, changes include `tar`-ing each newly produced `.wav` file alongside conversion so every MP3 immediately gets its own archive (L), refactoring into a single post-loop that aggregates all WAVs into a combined tarball (D), encrypting it with `openssl` (L), introducing a configurable encryption-key variable instead of a hardcoded one (O), compressing individual WAV files to `.gz` before archiving (L),

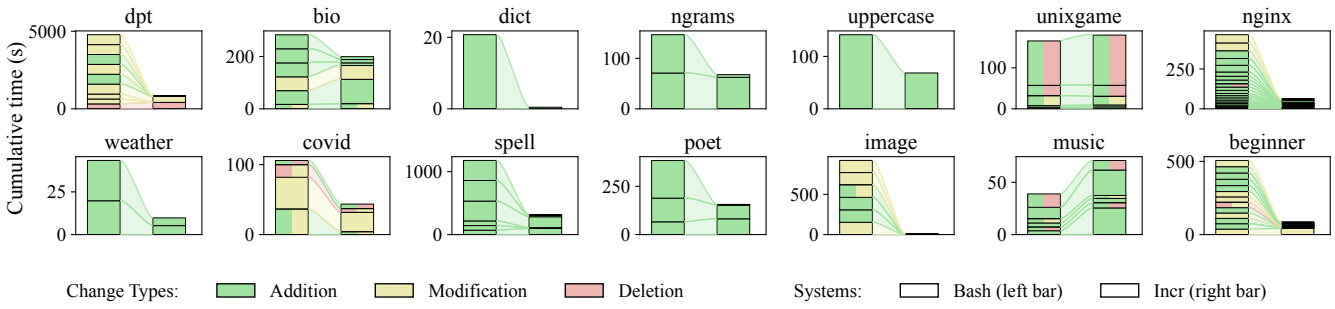

Fig. 4: **INCR's speedup on incremental changes**. Each vertical bar, *i.e.*, group of blocks, represents the execution time of a benchmark change during incremental development. Each block within a bar represents the time taken by the corresponding re-execution of the benchmark after a change. The curves connect the same block across the two systems.

and finally simplifying the layout by dropping per-file compression in favor of `gzip`-ing (`O`). Its input is a collection of 20 public-domain music files, totaling 16MB [49].

The **`beginner`** benchmark inspects system logs to identify failed login attempts. Starting from a numeric sort of the system log, changes include switching from numeric sorting to lexicographic sorting (`F`), counting duplicate lines (`E`), filtering for lines containing specific patterns—first case-sensitive (`E`) and later case-insensitive (`F`), counting matching lines (`A`), then consolidating filtering and counting (`O`), extracting the first two fields from the counted output (`E`), extracting different fields (`F`), grouping identical field pairs after sorting (`E`), numerically sorting the grouped results (`E`), reversing the numeric sort to rank largest first (`A`), selecting the top ten entries (`S`), and adjusting the `head` call to the explicit `head -n 10` form (`F`). Its input contains 5 million system logs, totaling 974MB [71].

Experimental setup: Experiments were conducted on a CloudLab m510 machine with an 8-core Intel Xeon D-1548 CPU at 2.0 GHz, 64 GB RAM, 256 GB NVMe storage, a 10 Gbps connection, running Ubuntu 22.04 on Linux 5.15.

8.1 Re-execution Performance

By how much does INCR accelerate re-execution?

Methodology: For each program modification, we measure the execution time of the script under INCR and Bash, and report the speedup as the ratio of Bash's runtime to INCR's runtime per incremental step. We run each re-execution 3 times and report the mean.

Results: Fig. 4 presents INCR's speedup—achieved without annotations—over Bash across all benchmarks and incremental re-executions. Out of 85 re-executions, INCR achieves a speedup in 69 cases and a slowdown in 16 cases: across the former set, it achieves an average speedup of 34.2×, with a maximum of 373.3× and a minimum of 1.003×; across the latter set, INCR incurs an average slowdown of 0.73×, with a minimum of 0.15× and a maximum of 0.95×.

Discussion: INCR's substantial re-execution speedups stem from its ability to track fine-grained dependencies and safely reuse previously computed results, thereby eliminating redundant computation. For example, INCR reuses LLM-generated image annotations in the **`image`** benchmark when incremental changes only modify the post-processing logic, reducing the execution time from 155.55 seconds to 1.62 seconds, achieving a speedup of 96.02×. INCR does not introduce a significant difference in accelerating different types of changes, primarily because INCR's fine-grained dependency tracking effectively identifies unaffected commands and reuses their results regardless of the type of modification.

INCR's overheads stem primarily from its use of system call tracing and isolation, which together enable the system to capture fine-grained dependencies and manage memoized results. These fixed costs become more pronounced and produce minor slowdowns in benchmarks dominated by many short-lived commands or in those with complex dependency behaviors. For example, in the **`unixgame`** benchmark—which consists of a sequence of short-running commands such as `tr ' ' '\n'`—the final iteration modifies only the third command, requiring full re-execution of the remaining eight commands. For these commands, fixed costs make up a larger fraction of the processing time, resulting in an increase in execution time from 107.8 seconds to 123.6 seconds. Moreover, in the first iteration of the **`music`** benchmark, tracing the `ffmpeg` and `tar` commands increases execution time from 3.7s to 12.4s, as they both perform thousands of system calls.

8.2 Time and Space Overheads

By how much do INCR's tracing, isolation, and memoization mechanisms slow down the initial execution of a script (before it benefits from incremental re-execution) and increase space usage during execution (by memoizing command effects)?

Methodology: To characterize INCR's overheads, we measure its execution time and peak space usage relative to Bash across all benchmarks with no script modifications. Time is re-

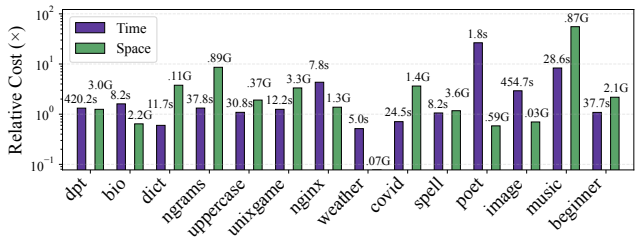

Fig. 5: **INCR's time and space overheads**. Each set of bars represents INCR's overhead per benchmark during the first run and the peak space usage over the benchmark's input size across all re-executions. The x-axis represents benchmarks. INCR's absolute execution time (s) and peak cache size (GB) are noted above each bar.

ported as the ratio between INCR's first execution and Bash's execution on the same script. This is the worst-case scenario for INCR: all tracing, isolation, and memoization overheads are incurred without any benefits from incremental execution. Space consumption is measured as INCR's cache size relative to the benchmark's original input size. In Fig. 5, the numbers above the bars denote the absolute first-run execution time for INCR (time bars) and the absolute cache size (space bars).

Results: Fig. 5 presents INCR's time and space overheads using these relative ratios. For benchmarks where INCR's execution exceeds five seconds, INCR exhibits a mean first-run time ratio of 2.01×, reaching 8.32× in the worst case on **`music`** and 0.52× in the best case on **`weather`**. INCR's cache occupies on average 6.05× of the original input size, ranging from 0.02× (0.04GB) for **`image`** in the best case and up to 55.44× (0.87GB) for **`music`** in the worst case. The average drops to 2.15× without the **`music`** outlier, which contains a tight **`for`** loop that inflates the cache as each iteration corresponds to multiple new cache entries. In absolute terms, INCR's cache size ranges from 0.04GB for **`image`** to 3.6GB for **`spell`**.

Discussion: INCR's time overheads stem from its tracing, isolation, and memoization mechanisms, while its space overheads stem naturally from storing memoized command outputs for later reuse. However, INCR can outperform Bash even on initial executions because its eager stream processing pulls from producers as soon as data is available, often avoiding blocking in ordinary shell pipelines. INCR's cold-start time overheads are often offset by the benefits of incremental execution in real-world development scenarios, where scripts are frequently modified and re-executed.

8.3 Behavioral Equivalence

Does INCR preserve behavioral equivalence to an unmodified shell interpreter during incremental re-execution?

Methodology: We characterize INCR's behavioral equivalence to the underlying shell interpreter in two ways. First, we apply it to all real-world scenarios in Tab. 2 and all unmodified Koala benchmarks (commit `e1610d9`), each executed twice. Using the same experimental setup as in §8.1, we confirm that the final outputs and exit code produced by both INCR and Bash match across all re-executions (confirmed using Koala's `verify.sh`).

Second, we apply INCR to the standard Bash test suite. Version `5.2.37(1)-release` consists of 83 test categories, each corresponding to a specific feature of Bash, totaling 534 test files and 22,064 LoC. The suite's ground-truth files contain 10,282 lines covering features from variable expansion, job control, invocation of external utilities (*e.g.*, `grep`, `cat`, and `awk`), covering the full POSIX shell standard and all of Bash's extensions. Because vanilla Bash itself differs from the bundled expected outputs on 362 lines, we use Bash as the ground truth and compare INCR's outputs against it. The test suite is unusually demanding: it is sensitive to whitespace, quoting, error text, and ordering, and many tests hinge on historically accumulated interpreter corner cases. For example, the suite checks how temporary environment assignments interact with variable expansion, how process substitutions affect `$!` and `wait`, and how shell options affect error handling.

Nineteen parser-error cases are considered out of scope because `libbash`'s unparsing diverges from Bash in line numbers and non-UTF-8 escape printing.

Results: Applied to the Bash test suite, INCR only differs by 3 ground-truth lines out of 10,282 (99.9% equivalence, Tab. 3). Differences come from (1; 2 diffs) recursive `alias` definitions, which INCR cannot identify during probe placement, thus placing a probe to the aliased command whose expansion (unlike normal shell expansion) INCR cannot observe; (2; 1 diff) an `execscript` test that unsets `PATH`, causing INCR to fail to locate its own dependencies. We re-ran all tests without clearing INCR's cache, obtaining identical results, to confirm reuse does not affect equivalence.

Discussion: INCR's broad compatibility required support for

Table 3: **INCR's behavioral equivalence.** The table shows several Bash test groups, example categories, the number of tests per category, and INCR's results.

Group	Example categories	INCR
Globbing	`extglob`, `globstar`	868/868 (100%)
Data structs.	`array`, `array2`, `assoc`	1261/1261 (100%)
Quoting	`quote`, `quotearray`	877/877 (100%)
Expansion	`comsub`, `alias`	1701/1703 (99.9%)
Utils	`getopts`, `strip`	80/80 (100%)
Env.	`attr`, `history`, `read`	1610/1610 (100%)
Constructs	`parser`, `func`, `case`	1547/1547 (100%)
IPC	`jobs`, `execscript`	1355/1356 (99.9%)
POSIX	`posixexp`, `posixpipe`	536/536 (100%)
Options	`set-e`, `set-x`, `shopt`	444/444 (100%)
Total		10,279/10,282 (99.9%)

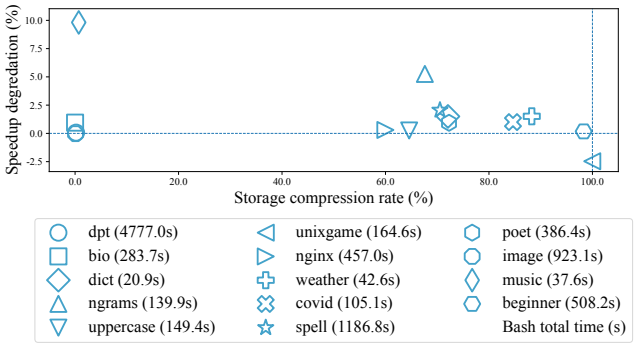

Fig. 6: **INCR's storage compaction impact on performance and storage**. Each point represents the storage reduction *vs.* speedup degradation with compaction.

all of Bash's invocation modes, types of expansion (*e.g.*, process substitution), correct escaping through the shell, probe placement that excludes non-trackable built-ins, backgrounding operators and effects such as permission changes, moves, named pipe creation, and symbolic links. INCR's remaining divergences, in `alias` and `execscript`, arise when scripts manipulate the shell environment in ways that prevent INCR from resolving script contents or locating its own runtime dependencies. Several approaches could be used to address these limitations, including deferring probe placement and packaging INCR as a standalone binary.

8.4 Effects of Runtime Optimizations

What are the benefits of various optimizations, including eager stream processing, introspection, and storage compaction?

Eager stream-processing: This optimization is always enabled (§8.1); when disabled, INCR waits for each command to finish before deciding whether the subsequent command needs to be executed.

We apply INCR to a synthetic program that executes a single 16-stage pipeline twice without any incremental change; all stages are streaming commands, *e.g.*, `grep` filtering lines and `sed` performing text substitutions. On the script's first execution, INCR takes 3m 22s with eager stream processing, reducing the execution time by 65.8% from 9m 50s without eager stream processing. On the script's second execution, INCR takes 10s to fetch the memoized results both with and without this optimization. Eager stream processing adds imperceptible overhead on reuse.

Introspection: This optimization is always enabled (§8.1); when disabled, INCR always re-executes commands within an isolation sandbox during incremental runs whether or not they have write dependencies.

We apply INCR to a synthetic script that includes a pipeline consisting of 20 commands that communicate only through their standard streams. Each incremental change modifies the input data processed by the pipeline, triggering re-execution of all commands. Without introspection, INCR takes 35s on all iterations. With introspection, INCR still takes 35s on the first iteration because it has not yet detected that the commands are pure, but only 31s (speedup: 13%) on subsequent iterations.

Storage compaction: This optimization is disabled by default (§8.1); when enabled, INCR compresses memoized dependencies and effects on disk, achieving significant space savings with slightly increased runtime overheads.

Fig. 6 shows that compaction reduces space usage across all benchmarks by an average of 55.7%, with a maximum of 100.0%, while trading off a 1.9% average speedup degradation and up to 9.8% runtime degradation. This optimization is especially beneficial for scripts that include longer pipelines, as each intermediate result is a separate cache entry.

8.5 Effects of Optional Annotations

How do optional crowdsourced annotations (§7) help INCR further accelerate incrementalization?

Methodology: We apply INCR with annotations to all benchmarks in Tab. 2. Additionally, we design two synthetic shell programs. The first program uses a five-stage pipeline of stateless command invocations—`cat`, `sed`, `awk`, `sed`, and `grep`. Changes append new lines to the input file. The second program invokes two argument-independent commands—`clang` and `sha256sum`—to compile and hash C files. Changes modify one of these C files.

Results: With annotations, INCR introduces an additional average speedup of 1.46× across all benchmarks, and up to 24.40× in the **`music`** benchmark. INCR lowers time overheads from an average of 101.05% to 43.55% and from a maximum of 732.45% to 278.15%. In the first synthetic program, INCR takes 29s on the first run (2.51×), and only 6s on the next two runs (12.17×), compared to 1m 13s on each run without annotations. In the second synthetic program, INCR takes 22.0s (4.9×) after changes, compared to 1m 48.8s without annotations.

Discussion: Annotations allow INCR to make informed decisions based on command semantics. For example, in the **`music`** benchmark, annotations indicating that the `ffmpeg` and `tar` commands are pure allow INCR to skip expensive tracing of these commands. Moreover, INCR applies chunked incrementalization for stateless commands in the first synthetic program, and decomposes each command's argument list into per-file invocations in the second synthetic program.

9 Related Work

Incremental computation: Incrementalization systems [1, 34, 37, 53] typically track fine-grained dependencies within one language, requiring language support or source modifications to expose dependency boundaries. INCR instead discovers dependencies at the *system level*, bringing incremental

behavior to environments that span multiple languages and opaque components.

Data processing systems [14,62,69,91] support incremental computation through dataflow or domain-specific computation models. Several production systems also provide elements of domain-specific incrementalization, such as Deno's aggressive caching of remote dependencies [22], LangChain's caching of language-model calls [51].

In contrast, INCR targets general-purpose shell environments with opaque components written in a variety of languages and arbitrary data-processing semantics.

Build systems: Build systems [26, 46, 56, 59] efficiently rebuild software after source code changes, often using developer-specified dependency graphs. Prior research reduces this burden by automatically inferring dependencies through execution tracing, thereby enabling incremental builds without explicit declarations [19, 38, 57, 75]. INCR fundamentally differs from these systems by targeting general computations that span data dependencies, transient effects, and mutable state that go beyond build artifacts.

Exploratory programming: Interactive environments such as notebooks [44] shorten the development feedback loop by exposing cell-based re-execution, but require manual control of dependencies [92]. Systems such as Jupyter [47, 55, 86] allow users to re-execute cells independently, but dependency boundaries are coarse-grained and users must decide which cells to rerun. INCR instead infers dependencies automatically across command boundaries, preserving the exploratory style of shell scripting without requiring users to manually decompose scripts into reusable cells.

Reactivity and view maintenance: Reactivity and view maintenance automatically maintain results as input data changes [2, 9, 25, 33, 52, 90, 91], often within specific domains such as relational databases [12] or MapReduce-style data processing [21]. INCR does not target reactivity.

Provenance tracking and reproducibility: Provenance systems [4, 13, 61, 68, 74] capture dependencies among entities to support auditing and forensics. INCR's goals and methods for extracting dependencies in shell programs fundamentally differ, but the provenance graphs produced by these systems are complementary to INCR's dependency tracking and could enable incremental execution across network boundaries.

Systems such as CDE [32], ReproZip [15], Nix [23], Guix [18], and Docker [58] package or specify execution dependencies to improve portability, reproducibility, and deployment reliability. Their goal is to recreate executions across environments. INCR instead accelerates repeated executions in scenarios where the environment is largely fixed but the program changes.

Other systems [6, 40, 65] record program execution for faithful replay on often unmodified applications. They target deterministic replay for debugging and reproducibility, whereas INCR targets accelerated incremental execution.

Research on the Shell: Recent systems such as POSH [71], PaSh [42], and Fractal [39] automatically parallelize or distribute shell programs. These systems target large-scale computations, rely on developer annotations to identify parallelizable and distributable fragments, and reduce latency of a single full execution. In contrast, INCR targets early-stage exploratory development, automatically infers dependencies and memoizes command effects at runtime, and reduces repeated work performed across re-executions. It can optionally leverage insights from these systems to increase incrementalization fidelity (§7).

Furthermore, a variety of systems improve the shell along many dimensions, including syscall refinement [27], fusion [36], elision [7], dataflow extension [78], synthesis [73], serverless execution [54], and mobile usage [88]. INCR is complementary to these works.

10 Conclusion

Fundamentally, INCR shows that bolt-on incrementalization atop unmodified shells is not only possible, but also broadly applicable—to accelerate development, debugging, optimization, and other settings where re-execution is prevalent. Its design includes lightweight effect tracking, safe memoization and reuse, optimizations that address key performance bottlenecks, and configurations that enable further incrementalization opportunities. Applied to real-world workflows, INCR delivers substantial re-execution speedups without program or environment modifications and retains behavioral equivalence to normal execution.

Availability

INCR, alongside all of its evaluation programs and data, is available as MIT-licensed open-source software:

A Software Artifact

Abstract

The software artifact that accompanies this paper includes INCR, its documentation, the behavioral-equivalence test suite, and the scripts used to reproduce the evaluation in §8. It supports three goals: inspecting the implementation and its accompanying materials, exercising the system through its test suite, and reproducing the paper's main evaluation results, including the benchmark-suite performance summary and the behavioral equivalence checks against Bash.

Scope

The artifact covers the paper's main contributions. In particular, it includes: (1) the INCR implementation and runtime mechanisms described throughout the technical sections (§4–§7); (2) the benchmark suite and supporting workloads used in §8; and (3) the automation used to reproduce the key evaluation results in §8, including re-execution performance and behavioral equivalence.

Contents

The artifact contains the following components:

- the INCR implementation itself, including the runtime, effect tracking, memoization, and annotation machinery;
- documentation, including a top-level README and artifact instructions;
- a behavioral-equivalence harness based on the standard Bash test suite;
- the benchmark drivers and supporting utilities for the evaluation workloads; and
- scripts for running the evaluation and generating the key result artifacts.

Hosting

The artifact is publicly available both as a GitHub repository and as a Zenodo archival snapshot. The GitHub version is hosted at https://github.com/atlas-brown/incr, and the archival version is hosted at https://zenodo.org/records/19488802.

A Compilation-based Under-Constrained Execution Engine

Mingjun Yin Zhaorui Li Ju Chen Haochen Zeng Chengyu Song
University of California, Riverside

Abstract

Software bugs continue to pose significant challenges to the security and correctness of computer systems. Finding and eliminating bugs for large-scale software systems, such as the Linux kernel, remains a difficult task. Static analyses can cover the whole codebase, but often produce too many false positives. Whole program dynamic testing is precise but has limited code coverage, and could require special environments. Due to the modular design of large software systems, a promising alternative is to instantiate an execution environment for individual components in isolation, and then apply precise dynamic analyses to these components. Unfortunately, existing execution engines that support such under-constrained execution are all interpreter-based, thus suffering from poor scalability. In this paper, we introduce UCSan, a compilation-based under-constrained execution engine that can compile an arbitrary set of C/C++ functions into a self-contained executable without manual modifications. To demonstrate the scalability and versatility of UCSan, we showcase combining UCSan with a compilation-based concolic execution engine to conduct under-constrained symbolic execution. Our evaluation shows that the resulting analysis engine is up to 15.06x faster on Linux kernel analysis tasks than the KLEE-based engine. This enhanced scalability not only improves the bug detection effectiveness but also enables its application across a broader range of software systems.

1 Introduction

Software bugs remain the major threat to the correctness and security of computer systems. This problem is especially severe for operating system kernels, which typically serve as the trusted computing base (TCB) for the entire system. Once a security vulnerability in the kernel is exploited, it usually can lead to the compromise of the whole system. Therefore, it is critical to identify and fix bugs before they are exploited by attackers.

Dynamic testing techniques, such as gray-box fuzzing [13, 26, 37], are state-of-the-art bug-finding techniques that have been widely adopted in the industry and have discovered a substantial number of bugs: the OSS-Fuzz [16] project has found more than 10,000 security vulnerabilities and 36,000 bugs in 1,000 open source projects; and the continuous kernel fuzzer syzbot [38] has helped fix over 6,500 bugs in the Linux kernel. Although fuzzers have been very successful in finding bugs, they also have notable limitations. One fundamental limitation, which applies not only to fuzzing, but also to all other dynamic analysis techniques, is the need for good *testing harnesses*—if a bug is not reachable from the harness, it cannot be found by fuzzers, no matter how much effort is put into the fuzzing.

Besides the testing harness challenge, another fundamental challenge for dynamic testing is the environmental setup. For example, to test an OS kernel, a fuzzer typically needs to set up a virtual machine; to test a file system, the fuzzer needs to prepare a disk image; and to test a device driver, the fuzzer either needs direct access to the real hardware, or a proper device emulator, which is often unavailable and non-trivial to implement. As a result, not all components in a complex software system can be effectively tested (e.g., an Android image for real phones).

Another widely used technique to find bugs is static analysis. While static analyses are not limited by testing harnesses and can analyze arbitrary sets of code (e.g. the whole kernel), they need to trade off precision for scalability. For large and complex projects like OS kernels, static analyzers tend to generate too many false alarms [2, 10, 12, 21, 22, 25, 46]. For example, the use-before-initialization analyzer [46] used in our evaluation generates 147,643 warnings, but only 52 were confirmed or patched.

Conceptually, it would be ideal if we could extract an arbitrary subset of code from the target software, make it self-contained, and then apply dynamic testing techniques to it. In this way, we can avoid the need for a testing harness and complex environmental setup, while still being able to leverage the precision of dynamic analyses. This approach faces two key challenges. The first challenge is how to initialize the memory properly. A program typically accesses three types

of memory objects: global, stack, and heap. Global and stack objects are relatively easy to handle, as existing compiler toolchains already know how to allocate and initialize them. However, heap objects are usually allocated and initialized dynamically at runtime. When we skip the typical initialization process (e.g., booting the kernel) and start the execution from an arbitrary (internal) function, we need a way to allocate and initialize heap objects expected by the code; otherwise, the execution will likely crash due to invalid memory accesses.

The second challenge is how to handle external dependencies. When we extract an arbitrary set of code from a complex software system, it is likely that the code will invoke functions outside the analysis scope, and we usually want to handle them differently. In most cases, we do not want to actually execute these external functions, otherwise we should have included them in the analysis scope in the first place. In other cases, we may want to provide a simplified model or a replacement. For instance, when running kernel code in the user space, we may want to replace invocations of `kmalloc` with `malloc`.

Unarguably, one can address these challenges manually. For example, researchers have manually extracted the TCP stack from the Linux and FreeBSD kernels for model checking [8]. Similarly, the Linux kernel library (LKL) project [1] aims to allow running Linux kernel code in user space, and has been used to build a fuzzing framework for file systems [43]. However, manual approaches are typically labor-intensive, error-prone, hard to scale (e.g., extract another module), and costly to maintain (e.g., keep updating with the upstream codebase).

Under-constrained execution, as pioneered by UC-KLEE [30], provides an automated approach to the above challenges. Under the hood, UC-KLEE employs a technique called *lazy initialization* to address the memory initialization challenge—when a pointer is dereferenced for the first time, if it points to an uninitialized memory object, the engine will allocate and initialize the object on-the-fly. This way, the engine can avoid the need to fully initialize the memory layout beforehand. To address the external dependency challenge, UC-KLEE provides a set of interfaces to allow users to specify how to handle external function invocations.

Besides UC-KLEE, some recently developed engines can also support under-constrained execution, such as Angr [34]. Unfortunately, these engines are all interpreter-based. As a result, they suffer from severe scalability issues. Yun et al. [44] reported that KLEE is around 3,000 times slower than native execution, and Angr is more than 321,000 times slower. Such performance is insufficient for analyzing slightly larger components like file systems, TCP stack, and device drivers.

Inspired by the recent advances in compilation-based concolic execution engines [9, 28], we propose UCSAN (Under-Constrained Sanitizer), a compilation-based under-constrained execution engine implemented as an LLVM Pass along with a runtime library.

UCSAN has two primary design goals. First, we decouple under-constrained execution from symbolic execution, enabling UCSAN to be combined with a variety of dynamic analysis techniques, including concolic execution, fuzzing, and model checking. Second, as a compilation-based approach, UCSAN is designed to be general-purpose, easy to integrate, and performant.

UCSAN addresses the aforementioned two challenges through compile-time transformations and runtime support. Specifically, we implemented a prototype of UCSAN based on the sanitizer framework of LLVM. It contains an instrumentation pass that (1) instruments all memory accesses to perform runtime address translation to support lazy initialization (i.e., accessing memory through uninitialized pointers), (2) instruments external function invocations based on configuration, and (3) removes all out-of-scope code. UCSAN also contains a runtime library that uses the shadow memory from the sanitizer framework to track aliased pointers, such that it knows: (1) which pointers have been initialized (i.e., have corresponding memory objects), (2) which pointers point to the same memory object, and (3) how to translate an under-constrained pointer to the proper offset within its corresponding memory object.

We then evaluated the performance and compatibility of UCSAN. First, we compared UCSAN with KLEE and Angr on the `nbench` benchmark [27], the results show that UCSAN is orders of magnitude faster. For compatibility, we compiled three versions of Linux kernel (4.14, 5.10, and 6.16) with UCSAN under different configurations. The results show that UCSAN can successfully compile over 80% of the kernel modules.

To demonstrate how UCSAN can benefit bug finding, we additionally developed **Thoroupy**, a Python-based analysis companion that orchestrates exploration and generates input seeds for UCSAN. Together they form a complete concolic execution engine we call UCSAN†. While UCSAN is independently usable, for evaluation purposes, we evaluate it in the UCSAN† setup in this paper and use the two names interchangeably. We conducted a few case studies with UCSAN†. First, we compared UCSAN† with a KLEE-based engine [47] on the task of filtering warnings generated by static analysis of UBITect [46]. UCSAN† can process 63,957 (95.46%) warnings under the same 2 minute timeout, which is 42,155 more than the KLEE-based engine. Such improvement allows UCSAN† to confirm at least 15 more patched vulnerabilities. Second, we applied UCSAN† to reproduce over a hundred known vulnerabilities in user-space open-source projects and the Linux kernel. The results show that UCSAN† can successfully reproduce a significant portion of them, without any manual effort to build test harnesses.

In summary, this paper contributes to the field in the following ways:

- **Novel design**: We present the design of a novel, compilation-based under-constrained execution solution

UCSAN, which is general, easy to use, performant, and can be combined with different dynamic analysis techniques.
- **Bug finding**: To demonstrate how the improved scalability can benefit dynamic analysis, we built an under-constrained concolic execution engine UCSAN† based on UCSAN, and evaluated it on multiple real-world case studies. The evaluation results show that UCSAN† can scale to large kernel modules and find real bugs.
- **Open-source**: UCSAN and UCSAN† are publicly accessible under the Apache 2.0 license.[1]

2 Under-constrained (Concrete) Execution

In this section, we provide an overview of compilation-based under-constrained execution engine, including workflow and key challenges.

2.1 Workflow

Figure 1 illustrates the workflow of a compilation-based under-constrained execution engine. It takes as inputs (1) the target Program Under Test (PUT) in the form of LLVM Intermediate Representation (IR), and (2) a YAML configuration file specifying the analysis scope (i.e. which functions and IR files to include), the entry function (i.e. where to start execution), and handling strategies for out-of-scope functions. The output is a self-contained executable that can run as a normal user-space program. UCSAN imposes no restriction on how the LLVM IR is produced, that is, any toolchain that emits LLVM IR can serve as the front end. For instance, enabling link-time optimization (LTO) in the Linux kernel build system is an easy way to obtain IR for the kernel.

The configuration file (e.g., Figure 2) is the key to remove the dependency on test harnesses, as one can specify any function (e.g., `cal`) as the entry point, and an arbitrary set of functions (e.g., `foo, bar`) as the analysis scope. UCSAN also supports mapping a function in the PUT to a replacement function (e.g., `kmalloc` to `malloc`). The configuration file can be generated manually. Alternatively, it can also be generated automatically using static analysis [30, 41, 46, 47], or using large language models (LLMs). In the evaluation, we used configurations generated by a static security checker UBITect [46], and a simple call graph analysis. For bug reproduction experiments, some configurations were generated manually, some were generated by LLMs.

Using the analysis scope specified in the configuration file, UCSAN first iterates over all included IR files and invokes `opt` from the LLVM toolchain to perform its instrumentation and output instrumented IR files. During this step, UCSAN will also remove out-of-scope functions, and replace their invocations with proper stubs, or a replacement function as specified in the configuration file (e.g. `kmalloc`). Optionally, the instrumented files can then be pipelined into additional dynamic analysis passes. For instance, in the evaluation, we pipelined UCSAN with SymSan [9] to perform under-constrained concolic execution, namely, UCSAN†. These dynamic analysis passes are optional, without them, the output binary can still run normally. Finally, UCSAN compiles the instrumented IR into object files and links them with all necessary runtime libraries (PUT's, UCSAN's, and any from the dynamic analysis passes) to produce a self-contained user-space executable.

The instrumented binary can then be used for dynamic analysis, but there are a few technical challenges to address. First, most internal functions consume memory objects instead of files or network I/O. In other words, dynamic testing should be done by providing different memory objects as inputs. To achieve this, UCSAN defines an input format to serialize memory objects into a file, and later deserialize them back to memory objects during execution. The second challenge is how to support lazy initialization, that is, when we start the execution from an arbitrary (internal) function, heap memory objects that would be accessed are neither allocated nor initialized yet. Similarly, all pointers used to access these memory objects are uninitialized as well. Therefore, we need a way to (1) allocate and initialize memory objects on-demand when they are accessed for the first time, and (2) bind uninitialized pointers to the proper memory objects. Related challenges include but are not limited to, **(C1)** how to handle aliased pointers, **(C2)** how to estimate the size of a memory object, **(C3)** how to adjust the size of a memory object dynamically in case the estimation is wrong, and **(C4)** how to deserialize memory objects from the input file to ensure deterministic execution. In this work, we address all these challenges with a new technique called *Just-In-Time Initialization* (§3.2).

As mentioned earlier, one primary design goal of UCSAN is to decouple under-constrained execution from specific dynamic analysis techniques, so that it can be combined with different dynamic analysis techniques. Therefore, we consider generating new test inputs (i.e., memory objects) as an orthogonal problem. For demonstration purposes, we showcase how to combine UCSAN with a compilation-based concolic execution engine SymSan [9] to perform under-constrained concolic execution UCSAN†. In a nutshell, SymSan performs compile-time instrumentation to generate symbolic traces as dynamic analysis outputs. It then parses the traces into symbolic path constraints, and uses an SMT solver to solve the constraints and generate new test inputs (e.g., memory objects that can negate a branch). The generated inputs can then be executed to explore new paths.

2.2 An Illustrative Example

In this subsection, we use an elevated linked list example as in [30] to explain the key steps in under-constrained (concrete) execution.

[1] Available at https://github.com/R-Fuzz/UCSan

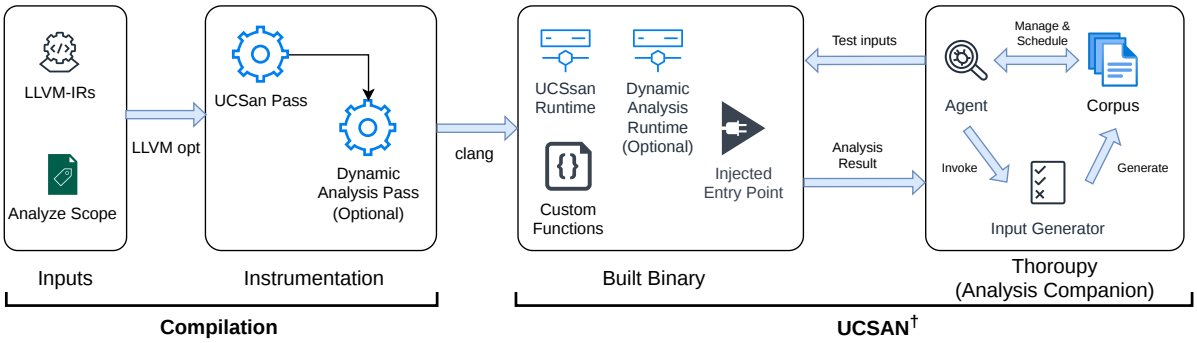

Figure 1: Workflow of a compilation-based under-constrained execution engine, and how it can be combined with different dynamic analysis techniques.

```
entry: cal
scope: [foo, bar]
custom:
  kmalloc:
    ref_name: malloc
    arg_maps: # map first arg and ignore rest
      - idx: 0
        ucsan_idx: 0
```

Figure 2: An example configuration file.

Consider the code snippet in Figure 3, which defines a simple linked list and a function `cal` that computes the sum of all node values. Traditional dynamic testing tools [6, 9, 11, 19, 28, 37, 45] cannot analyze `cal` directly. Instead, they require a testing harness. The testing harness is in charge of reading test inputs (e.g., from a file), instantiating a linked list, and invoking the target function. By generating different test inputs, we hope the execution can trigger the assertion failure at line 20.

In a nutshell, what UCSAN does is to automate the process via compiler techniques. Given `cal` as the entry function, UCSAN will automatically generate a harness (`main`) to invoke it. UCSAN will also instrument the code to instantiate a linked list on demand during the execution, and make sure all accesses through aliased pointers will visit the same memory object (addresses). If a test input is provided, UCSAN will also perform deserialization to populate the linked list accordingly. Next, we explain the key steps in detail.

2.2.1 Code Transformation

UCSAN directly executes `cal` from line 8, and initializes the environment on demand (§3.1). This is done by compile-time code transformations, which are annotated with + and - in Figure 3. Note that the actual transformation is done on the LLVM IR level, here we illustrate it in source code level for better readability. These transformations include three main parts:

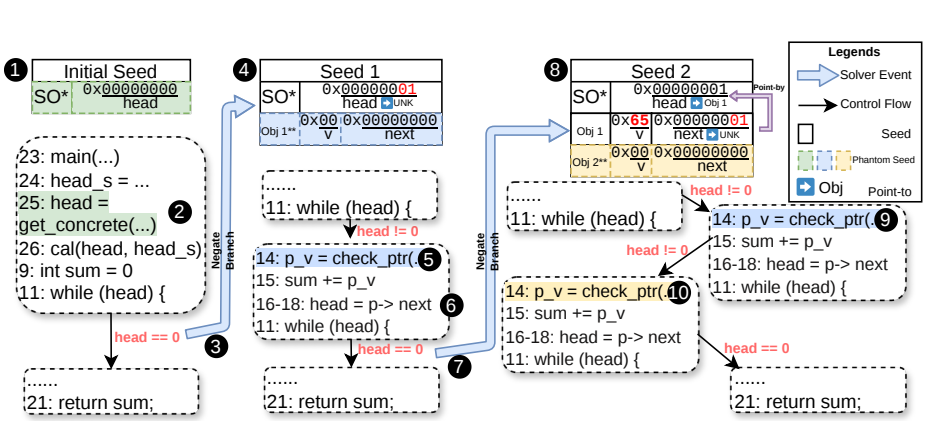
• *Entry point (*`main` *function) generation*. UCSAN will automatically insert a `main` function (lines 23 - 27) to create a self-contained binary (§3.1). The `main` function performs three universal tasks independent of the analyzed function(s): (1) UCSAN tracks aliased pointers using a shadow pointer

```
1    typedef struct {
2      struct list_entry* next;
3    } list_t;
4    typedef struct {
5      unsigned int v;
6      list_t list;
7    } node_t;
   - int cal(list_t* head){
8  + int cal(list_t* head, shadow_t head_s){
9      int sum = 0;
10     node_t* curr = NULL;
11     while (head) {
12 +     check_ptr(head, head_s);
13      curr = container_of(head, node_t, list);
14 +    int *p_v = check_ptr(&curr->v, head_s);
15 +    sum += *p_v;
   -    sum += curr->v;
16 +    list_t** p_next=check_ptr(&head->next,head_s);
17 +    head = *p_next;
18 +    head_s = get_shadow(p_next);
   -    head = head->next;
19   }
20   if (sum > 100) assert(false); /*bug here*/
21   return sum;
22 }
23 + int main(int argc, char** argv) {
24 +   shadow_t head_s = get_shadow_ptr();
25 +   list_t *head = get_concrete(head_s, sizeof(list_t)
       );
26 +   cal(head, head_s);
27 + }
```

Figure 3: Motivating example: linked list sum

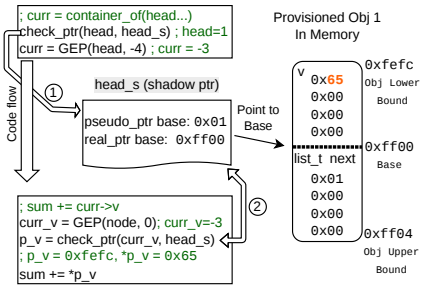
(i.e., all aliased pointers share the same shadow pointer). So the first task is to create a shadow pointer for each pointer argument. In this example, since the argument `head` of `cal` is a pointer, UCSAN creates a shadow pointer `head_s` at line 24. (2) If a test input is provided, UCSAN will deserialize it to populate `head` (line 25). Note that here UCSAN only populates a single list node pointer `head`, the actual node objects will be allocated and populated on-demand when they are accessed. (3) Call target entry function `cal` (line 26).

• *Pointer translation*. As mentioned before, one of the main challenges of under-constrained execution is to allocate memory objects on-demand, and initialize pointers properly, especially when there are aliased pointers. UCSAN solves this through shadow pointers. Conceptually, shadow pointers play a similar role as segmentation registers in virtual address translation: (1) all uninitialized/unbounded pointers will have a shadow pointer associated with them; and (2) all aliased point-



* SO is an abbreviation for Super Object, which stores global objects and initial argument(s) to the entry function. ** SO in Seed 0, Obj 1 in Seed 1, and Obj 2 in Seed 2 are dynamically introduced via JIT-initialization as a phantom seed.

Figure 4: Key steps in exploring different paths in the linklist example.



① The first `check_ptr` invocation creates its shadow pointer, records the pseudo-pointer base, and allocates Obj 1 from Seed 2.
② The second `check_ptr` leverages this data to return the translated real pointer: `curr_v - pseudo_ptr_base + real_ptr_base`.

Figure 5: Shadow pointer handling and real-pointer translation when dealing with Obj 1 in Seed 2

ers will share the same shadow pointer. In this example, the shadow pointer of `head` is `head_s`. And the three aliased pointers `curr`, `curr->v`, and `head->next` also share the same shadow pointer `head_s`. Before *every* memory access, UCSAN will insert a call to the callback function `check_ptr` to translate a potential uninitialized pointer to a valid pointer (line 14 and 16); and replace the use site with the actual pointer (line 15 and 17). Note that because we may need to reallocate the underlying object to adjust the object size on-the-fly (e.g., due to `container_of`), all translated pointers (`p_v` and `p_next`) are treated as "volatile", so `check_ptr` is called twice in this example, even though the pointers (`curr->v`, and `head->next`) are aliasing. For the same reason, we do not store translated pointer back to memory. We explain more about this design choice in §3.2. Finally, whenever a new pointer is loaded from the memory (e.g., line 17), UCSAN will also load the corresponding shadow pointer (line 18).

• *External function handling*. To ensure that the target program is compilable, we need to make sure that all calls to external functions (i.e., functions outside the analysis scope that are not specified in the YAML configuration) can be handled automatically. Note that the example does not contain external functions for brevity. UCSAN offers three options. First, a custom wrapper can be provided to summarize the effects (e.g., `memcpy`). The user can implement the wrapper function in an arbitrary way to simulate the actual behavior of the external function. UCSAN also allows mapping a function in the PUT to a known wrapper function (e.g., `kmalloc` to `malloc`). Second, UCSAN can assume that the function is *pure* and no changes would be made to the current memory state, which is similar to UC-KLEE [30]. Third, UCSAN can assume that the function can perform arbitrary changes to memory objects passed to the function as pointer arguments, and return arbitrary values. For instance, a call of `read(fd,buf)` may fill `buf` with arbitrary values. In this case, UCSAN will reallocate all memory objects passed to the function (i.e. put a new object corresponding to `buf_s`), as under-constrained memory objects.

2.2.2 Path Exploration

Figure 4 demonstrates key steps of UCSAN† in exploring three different paths in the example (Figure 3) by combining UCSAN with a dynamic testing technique. The goal is to cover all paths that can trigger the assertion failure at line 20. In the figure, we use *Seed 0 - 2* to represent three different test inputs and their corresponding execution paths.
• *Seed 0*. ❶ UCSAN executes the compiled binary with an initial seed. This initial seed is empty, i.e., it contains nothing at all. ❷ When the execution reaches line 25 and `get_concrete` is called, UCSAN looks up the seed for an object matching `head`. Because no such entry exists, UCSAN treats the object as a *phantom*: it allocates a new memory object based on the type information of `head` (i.e., a pointer) and provisions it with all zeros. In general, whenever the seed does not contain an entry for a requested object, UCSAN pretends the object exists and initializes it with zeros—we call this a *phantom seed*. We use colored backgrounds to annotate phantom objects in the figure. `get_concrete` then returns `nullptr(0x00)` to initialize the `head` pointer. This new object resides in a memory segment we call *super object* (SO). We use this segment to store global objects and initial arguments for the entry function. When the execution reaches line 11, since `head` is initialized as a `nullptr`, the concrete execution goes to the *false* branch, reaches line 20, does not trigger the assertion failure, returns to `main`, and terminates.

To explore a different path, UCSAN needs a new seed. To clarify again, this step (input generation) is done by the integrated dynamic testing technique, namely UCSAN†. If

we are performing under-constrained symbolic execution, we can solve the negated path constraint `head != null` (❸), by assigning `head` to `0x1`; and generate a new seed. Note that here the engine does not have to assign `head` to a valid address, just a non-null value (i.e., it should point to something, but exactly where, can be determined later). Since the values of `head` and other pointers in the original source code do not directly address real objects, and only their shadow pointers hold references to the actual backing memory, we refer to them as *pseudo-pointers*.

• *Seed 1*. ❹ UCSAN now has the newly generated *Seed 1*. When the execution reaches line 11, because the seed is not empty, UCSAN uses the shadow pointer `head_s` to locate the corresponding content in the seed, and populates values for the allocated memory object accordingly (i.e., `head = 0x1`). Because `head` now satisfies the predicate `head != null`, the concrete execution can enter the loop body and try to read from the `curr->v` pointer. ❺ When `check_ptr` is called, UCSAN lazily allocates a new (phantom) memory object `obj1`. In this example, we highlight three key challenges in lazy initialization in concrete execution. First, how to know the size of `obj1`? If we simply use the type information of `head` in the declaration of `cal`, then the size would be insufficient, as the type of it is just an infrastructure for linked list. To solve this problem, UCSAN instruments pointer arithmetic operations (e.g., `container_of`) and type casting operations to accurately track the allocation size of the underlying object. Note we omit the size tracking instrumentation in the example for brevity. In this case, the size of `obj1` is estimated based on the type information of `curr` (i.e., `sizeof(node_t)`), instead of the type of `head` (i.e., `sizeof(list_t)`). The concrete content of `obj1` is initialized as all zeros.

The second challenge is how to calculate the correct offset within the underlying object. UCSAN solves this problem using the segment register: shadow pointer `head_s`. In particular, when materializing `obj1`, UCSAN updates `head_s` to record the concrete value of the under-constrained pointer, the logical base of the segment. In this example, the pointer `curr->v`'s value is `-3`, due to `container_of` (`1-4=-3`). This allows UCSAN to handle arbitrary pointer arithmetic and type casting operations, as well as growing the segment on-the-fly.

The third challenge is how to locate the content in the seed to initialize `obj1`. UCSAN solves this problem by recording *object relationships*. Specifically, UCSAN records in the shadow pointer `head_s` that `obj1` is *pointed-by* the pointer at offset `0` from `S0`; so next iteration, it can find the content from the seed to initialize `obj1`. After materializing `obj1`, `check_ptr` returns `obj1.v` (offset `0` from `obj1`) to initialize `p_v`. Again, `p_v` is ephemeral: it is only used for the memory read, then discarded immediately after the read and never used again. We call such pointers *real-pointers*.

❻ A pseudo-pointer is loaded from the lazily allocated object `obj1.next`, and its corresponding shadow pointer is created. Note that in this step, `head->next` has a concrete value of `0x1`, but UCSAN can correctly translate it to `obj1.list.next` (offset `0x4`), because `head_s` has recorded that the base pointer is `-3`. ❼ The concrete execution reaches the loop head again. Because `obj1.list.next` is initialized as a `nullptr`, the loop exits.

In this execution, `sum` still has a concrete value of `0`, so the assertion failure is not triggered. However, it is now a symbolic value (`0+obj1.v`). By solving the negated path constraint `((0+obj1.v)>100)==true`, we can generate a new seed that triggers the assertion failure.

To explore a different path, the dynamic analyzer generates a new seed. This can be done by assigning `obj1.list.next` to `0x1`, i.e., *Seed 2*. Notably, `obj1.list.next` does not have to be a valid pointer, and can have the same value as `head` (i.e., same logical address of different segments do not conflict). For simplicity, we also assign `obj1.v` to `0x65` (decimal 101) to trigger the assertion failure.

• *Seed 2*. ❽ UCSAN schedules Seed 2. This seed includes two serialized objects: SO and `obj1`. The `head` field in SO is initialized to `0x1`, and the `obj1.list.next` field is also set to `0x1`. As with Seed 1, the execution enters the loop body. ❾ When `check_ptr` is called, UCSAN lazily allocates `obj1`. However, this time, it loads the content from the seed, based on the recorded pointed-by annotation from ❺. As a result, the `obj1.list.next` field is now initialized to `0x1`. This causes the execution to re-enter the loop body. ❿ When `check_ptr` is called again, UCSAN allocates a new (phantom) memory object, `obj2`, initializes its content to zero, and records the point-to relationship (i.e. pointer defined at offset `4` from `obj1` points to `obj2`). Since `obj2.list.next` is initialized to `null`, the loop terminates. When the execution reaches line 20, the concrete value of `sum` is `101`, so the assertion failure is triggered, and all paths are covered.

3 UCSAN

In this section, we present technical details of UCSAN. UCSAN is built on the sanitizer framework from LLVM, reusing the shadow memory design of DataFlowSanitizer (DFSan) [35], to track shadow pointers and function calls (arguments and return values).

3.1 Compile-time Instrumentation

This instrumentation performs three main tasks, as briefly illustrated in §2.2: (1) `main` function generation, (2) pointer translation, (3) handling external functions.

Preprocessing. UCSAN operates on LLVM IR, so any build system that produces IR can serve as its front end.

Harness Generation. As discussed in §2, UCSAN inserts a `main` function to produce a self-contained binary. It first discards the original `main` (if present), then, if the entry function (e.g., `cal` in Figure 2, 3) is defined in the current module, in-

troduces a new `main` there. As shown in Figure 3, this `main` is a wrapper that populates arguments (lines 24–25, deserializing from the super object if available, otherwise all zeros) and calls the entry.

Pointer Translation. UCSAN refers to all PUT-managed pointers as *Pseudo-Pointers* (pseudo-pointers), which are translated into valid pointers (*Real-Pointers*, real-pointers) only upon dereference. We call this process *Just-In-Time Initialization* (JITI), which is conceptually similar to segmentation-based logical-to-linear address translation in x86 processors, but implemented in software. Unlike classical lazy initialization [30], which allocates objects only when they are about to be accessed, JITI may provision objects eagerly (e.g., during address computation), hence the distinct name. A key invariant of JITI is that real-pointers must never escape into the PUT's own data flow: they are handed only to memory-access instructions (e.g., `Load`) and discarded immediately afterward. The PUT itself carries only pseudo-pointers or constant pointers (e.g., globals in the data/bss segment). UCSAN handles constant pointers specially by having their pseudo-pointer and real-pointer values coincide, so that they can coexist with pseudo-pointers transparently.

To enforce this invariant, UCSAN instruments all LLVM IR instructions and intrinsics that involve pointer operations, including `Load`, `Store`, `AtomicRMW`, `memset`, `memcpy`, `memmove`, `GEP`, and `BitCast`. Before each such instruction, UCSAN inserts a call to the runtime function `check_ptr`. For dereferencing instructions (e.g., `Load`, `Store`, `memcpy`, line 15 in Figure 3), the original pointer operand is replaced with the real-pointer returned by `check_ptr`, ensuring the access targets a valid, allocated memory object. For address-computing instructions (e.g., `GEP`, `BitCast`, line 13 in Figure 3), UCSAN notes the expected object size and updates the pointer arithmetic metadata accordingly. The runtime logic of `check_ptr` is detailed in §3.2.

Shadow Pointers. To perform pointer translation, UCSAN uses *shadow pointers* to track three pieces of information: (1) the logical base address used to materialize the underlying memory object, (2) which memory object a pseudo-pointer points to (**point-to**), and (3) where a pseudo-pointer originates (**point-by**). Shadow pointers propagate alongside the data flow of pseudo-pointers. To implement this, UCSAN builds upon DFSan's shadow memory design. This design associates each byte of application memory with a shadow value. It also provides local shadow variables for fast access, and defines a calling convention to pass shadow values through function arguments and return values. UCSAN also instruments casts between integer and pointer types. A shadow pointer is introduced whenever a pseudo-pointer is created. For instance, loading a pointer from a JITI-ed object produces a fresh shadow pointer.

External Function Handling. To satisfy the linker, UCSAN replaces out-of-scope external functions with dummy stubs using one of three options: (1) *Custom Wrapper* to summarize specific effects (e.g., `memcpy` must copy shadow memory) or to map to a known function (e.g., `kmalloc` mapped to `malloc` as in Figure 2). A custom wrapper can be easily introduced by providing a function that matches the stub's signature; (2) *Assume Pure* (the default) to assume no side effects; and (3) *Assume Arbitrary Changes* to conservatively reallocate all pointer arguments. For the latter two options, return values are treated as newly allocated objects (i.e., their values are drawn from the super object).

Inline Assembly. Inline assembly is prevalent in performance-critical applications and system software (e.g., OpenSSL and OS kernels). In our current prototype, we apply heuristics to handle common inline assembly patterns. More complex assembly blocks can be modeled using the aforementioned custom wrapper functions. Manually modeling every inline assembly instruction is highly case-specific and labor-intensive. It is therefore out of scope for this prototype. However, the ability to resolve inline assembly via wrappers remains a significant advantage over engines like KLEE. Furthermore, we observed that LLMs can automatically generate these wrappers, which significantly reduces the manual effort and improves scalability.

3.2 Just-In-Time Initialization

Starting the analysis from an arbitrary function poses a notable challenge: pointers accessed by the target function may not be initialized. In under-constrained symbolic execution [30], this is handled by *lazy initialization*, where a symbolic object is created when an uninitialized pointer is dereferenced. However, in UCSAN, we deal with concrete executions, so we must provide valid virtual addresses to the CPU, otherwise the program will crash with a segmentation fault. To address this challenge, we propose *Just-In-Time Initialization* (JITI). JITI consists of two key components: a new pointer representation called *Pseudo-Pointer* and a runtime mechanism to handle pointer translation and object allocation.

Pseudo-Pointer. To bridge the gap between uninitialized pointers and concrete execution, we introduce a new concept called *Pseudo-Pointer* (pseudo-pointer). Conceptually, UCSAN's pointer translation mechanism can be viewed as a software-based segmentation mechanism, where each memory object is considered as a segment, each pseudo-pointer is a 64-bit value containing the (pseudo) logical address to the segment, and the shadow pointer of a pseudo-pointer is its segment register. Under this scheme, a pseudo-pointer serves two purposes: (1) it stores the (logical) offset (introduced by pointer arithmetic) within the memory object, and (2) it provides the value required to satisfy path constraints in the concrete execution (e.g., `p != NULL`). The shadow pointer (segment register) of a pseudo-pointer tracks (1) the (logical) base of the segment, (2) the actual virtual address of the underlying memory object, and (3) the point-by relationship (i.e., where

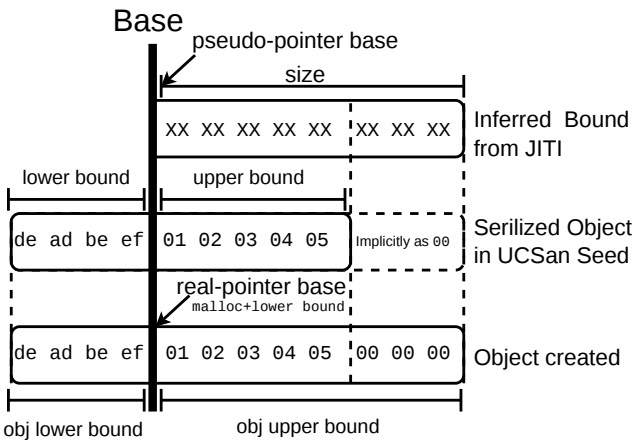


Figure 6: Allocation for one specific object during JITI.

the pointer is loaded from). Therefore, a pseudo-pointer is not a valid virtual address and cannot be dereferenced directly. Instead, it must be translated into a valid *Real Pointer* (real-pointer) before access. This translation is performed by the JITI runtime.

JITI Runtime. The core of JITI is implemented in the runtime function `check_ptr`, which is invoked before every pointer operation (as instrumented in §3.1). `check_ptr` performs the following steps:

1. Pointer Validation. First, `check_ptr` checks if the input pointer is a pseudo-pointer. It does this by inspecting the associated shadow pointer. If the pointer is a valid real-pointer (e.g., pointing to stack, global, or heap memory returned by `malloc`), `check_ptr` simply returns it. If it is a pseudo-pointer with a valid shadow pointer, `check_ptr` continues processing to the next step below.

2. Lazy Allocation. Using the shadow pointer, UCSAN looks into a metadata/segment table to check if the corresponding memory object has been allocated (i.e., does the shadow pointer have a valid object ID). If the pseudo-pointer points to an object that has not been allocated yet, UCSAN allocates a new memory object (Figure 6). The size of the allocation is inferred from the pointer type (e.g., pointer arithmetic and type casting) or the operation (e.g., `memcpy` size). UCSAN maintains an object table (indexed by Object ID) to track allocated objects, including their size, bounds, and base addresses. In certain cases, the inferred size could be larger than the current allocation (e.g., `container_of`). When this happens, UCSAN automatically reallocates the object to accommodate the larger size. As mentioned earlier, because the translation results are always ephemeral (i.e., only used for the immediate memory access and never used again), and because all pointer dereferences must go through `check_ptr`, reallocation can be done transparently without affecting correctness (i.e., no stale real-pointer will be used).

3. Initialization. After allocation, UCSAN initializes the memory content. UCSAN first retrieves the point-by metadata using the shadow pointer and checks if the test input provides specific values for this object (see §3.3). If so, UCSAN populates the memory with these values (Figure 6); otherwise, it initializes the memory with zeros. Then, UCSAN initializes the shadow memory of the memory object with shadow values to track the origin of the data, in the form of `(object_id, offset)`.

4. Pointer Translation. If the pseudo-pointer is used in pointer arithmetic (LLVM's `GEP`) or type casting (LLVM's `BitCast`), UCSAN will return pseudo-pointer value without translation. In this way, `GEP` can update the (logical) offset of the pseudo-pointer normally. When the pseudo-pointer will be dereferenced (e.g., in `Load`, `Store`), `check_ptr` translates pseudo-pointer to the actual real-pointer. This is done as follows. When the shadow pointer is first created, it records the actual value of the pseudo-pointer as the (logical) `base_offset` (which could be arbitrary value, like `-3` in Figure 4). During execution, pointer arithmetic may update the actual value of a pseudo-pointer. To compute the final real-pointer, `check_ptr` retrieves the `object_base` from the object table, based on the object ID from the shadow pointer, and adds the difference between the `current_offset` in pseudo-pointer and the recorded `base_offset` to it. Figure 5 illustrates how an object is created from the seed via JITI for the first time and how a real-pointer is retrieved via shadow pointer afterwards.

3.3 Seed Composition

In traditional symbolic execution, a different execution context is created via forking. For UCSAN, path exploration is driven by concrete inputs. Therefore, we must address the challenge of how to serialize memory objects under the current execution context into a test input; and conversely, how to deserialize a (new) test input into memory objects during JITI. The key correctness guarantee is to ensure the relationships between memory objects.

Object Provisioning. UCSAN consumes the test input during JITI. When JITI materializes a new object, it needs to decide how to initialize it. We call this process *object provisioning*. If the object corresponds to an entry in the test input, UCSAN populates it with the provided concrete values; otherwise, it initializes the object with zeros. To correctly map runtime objects to input entries, UCSAN uses two identification mechanisms: *explicit IDs* for global/argument objects and *dereference chains* for dynamically allocated objects.

1. Structured Seed Format. The test input is organized as a list of (serialized) memory objects in binary format. Each object entry contains: (1) object ID, (2) point-by metadata, (3) object size, and (4) object content.

2. Super Object and Explicit IDs. The *Super Object* (SO) (ID=0) serves as a container for all "root" under-constrained values, similar to the starting points of a mark-and-sweep garbage collector. These include: (1) initial arguments to the entry function. (2) global variables accessed by the code. (3)

return values from external functions. These values are identified by the order in which they are initialized via JITI. During execution, UCSAN maintains a counter for the number of JITI-ed values from the Super Object. When a new value is needed (e.g., an argument is accessed for the first time), UCSAN retrieves the next available value from the SO in the test input.

3. Chained Objects and Dereference Chains. For objects that are accessed via pointers (e.g., linked list nodes), we cannot rely on simple IDs because the allocation order may vary across executions. Instead, we identify these objects based on how they are reached, i.e., their *dereference chain*. This is inspired by the mark-and-sweep algorithm in garbage collection: every accessible object must be reachable from a root (anchor) via a sequence of pointer dereferences. In UCSAN, we track the *point-by* relationship: each object records where its base pointer comes from (i.e., its origin). The origin is a tuple `<source_obj_id, offset>`. By chaining these origins backward, we can uniquely identify any object starting from a root in the SO. For example, in a linked list, the second node (`obj2`) is identified as "pointed to by the `next` field (offset 4) of the first node (`obj1`)." `obj1` in turn is "pointed to by the `head` argument (ID 0) in the SO."

3.4 Memory Safety Checkers

LLVM ships with AddressSanitizer (ASAN) [33], which detects memory safety violations such as out-of-bounds accesses and use-after-free by instrumenting every memory operation and maintaining a shadow memory to track allocation metadata. Because UCSAN also uses shadow memory to associate metadata with pointers and memory, as well as instrumenting every memory-accessing instruction to call `check_ptr` first, we can reuse this infrastructure to perform the same safety checks at negligible additional cost. Specifically, we implemented three checkers to check for typical memory safety violations: out-of-bounds (OOB) access, use-after-free (UAF), and use-before-initialization (UBI). These checkers give UCSAN built-in ASAN-equivalent checking without requiring a separate sanitizer pass.

Out-of-Bounds (OOB). OOB checkers detect out-of-bounds access to *explicitly allocated* stack and heap objects. Specifically, UCSAN instruments the stack allocation site (LLVM `Alloca` instruction) and heap allocators (through custom functions) to record the base address and the size of the allocated object (i.e., the lower and upper bounds). It then stores the bounds information in the metadata table, and uses a shadow pointer to associate the bounds information with the returned pointer. UCSAN uses a field in the metadata table entry to distinguish explicitly allocated pointers from pseudo-pointers. Before every subsequent memory access, during the `check_ptr` call, UCSAN retrieves the bounds information using the shadow pointer, and checks if the access is within the recorded bounds. If the access is out of bounds, it raises an OOB error. Note that our checker operates at the allocation level and does not perform type-safety checks; intra-structure out-of-bounds accesses (e.g., overflowing one field into an adjacent field within the same struct) are not detected.

Use-After-Free (UAF). UAF checker detects accesses to memory objects that have been freed. It reuses the same metadata table entry for OOB checking, but uses a different flag. In particular, UCSAN instruments function exits (for stack objects) and explicit deallocation calls such as `free` and `kfree` (via custom functions). In these runtime functions, UCSAN uses the shadow pointer to retrieve the metadata, and marks the object as freed. Before any subsequent dereference of an aliased dangling pointer, during the `check_ptr` call, UCSAN will check the freed flag in the metadata and raise a UAF error if it is set.

Use-Before-Initialization (UBI). To detect UBI, UCSAN marks the shadow memory of every *explicitly allocated* object with a special uninitialized tag (`UNINIT=-1`). Note that objects allocated through JITI will not be marked, as we consider their content as under-constrained. Since any write to the object will also update the corresponding shadow memory, an initialization operation will clear the uninitialized tag. The UBI checker reports an error upon two types of uses: (1) an uninitialized pointer (from an explicitly allocated object) is dereferenced; and (2) uninitialized data is used as the condition for a branch.

Impact of Analysis Scope on Bug Detection. As a form of dynamic analysis, these memory safety checkers will only report errors that are actually triggered during an execution (i.e., no false positives with regard to the analysis scope). Therefore, for UCSAN to confirm a bug, the execution must traverse a concrete path that connects at least three program points: the entry function, the relevant allocation or deallocation site, and the offending use. This means that the user-specified analysis scope *must* include at least the allocation (or deallocation) and the use site; otherwise, UCSAN lacks sufficient context to report errors. However, as a form of under-constrained analysis, if the analysis scope misses important constraints (e.g., constraints on array indices, initialization of buffers), then the reported errors may still be false positives, as the execution from the real program entries (e.g., `main` or syscall entries) may not be able to reach the offending use.

This is the inherent trade-off in under-constrained analysis: on one extreme, we can analyze the whole program (i.e., reverting to traditional whole program concolic execution [6, 9, 28]), which provides the most accurate context but suffers from path explosion; on the other extreme, we can analyze only a small subset of functions, which is more efficient but may suffer from false positives due to missing constraints. In practice, there are several heuristics to strike a balance between these two extremes, which were utilized in our evaluation. First, we can use a static analysis (static bug checkers) to find potential bugs. Such static bug checkers typically (e.g.,

Sys [5] and UBITect [46]) will report the relevant control- and data-flow paths, which can then be used to define the analysis scope for UCSAN. Second, users can iteratively adjust the analysis scope based on the reported errors and their domain knowledge of the program. Third, with recent advances in large language models (LLMs), we can also leverage LLMs to automatically suggest the analysis scope.

4 Under-Constrained Concolic Execution

To demonstrate UCSAN's ability to support dynamic testing techniques, we build an under-constrained concolic execution engine UCSAN† by combining UCSAN with SymSan [9], a compilation-based concolic execution engine, and a Python-based companion server to orchestrate the path exploration.

Instrumentation. The overall process is relatively straightforward: we first apply UCSAN instrumentation pass to remove out-of-scope functions, and instrument `check_ptr` for pointer translation; then we apply SymSan's instrumentation pass to add concolic execution support; finally, we link both UCSAN's and SymSan's runtime libraries to generate the final executable. The only caveat is that since both UCSAN and SymSan use shadow memory, we need to make sure they use different memory regions to avoid conflicts. In addition, we added bridge functions to allow UCSAN to invoke SymSan to symbolize memory objects.

Path Exploration. We implement a companion server to orchestrate concolic execution by managing path constraints, querying solvers, and scheduling exploration. It is implemented as a hybrid Python/C++ program: a Python-based controller for extensible exploration strategies, and a performance-critical C++-based path constraint solver (from SymSan) for parsing symbolic traces collected from the instrumented executable into Z3 expressions, and querying Z3 to solve the constraints. The path exploration strategy used in our prototype is Breadth-First Search (BFS) (79 LoC). It is worth mentioning that it is straightforward to extend it to other strategies through the Python controller. For instance, we have also implemented a hierarchical scheduler [39] in 166 LoC, and a directed scheduler in 394 LoC.

Solving Pointer Constraints. Thanks to the introduction of pseudo-pointers, solving pointer constraints becomes more straightforward. We treat them as 64-bit bit-vectors, and find values that can satisfy path constraints. Similar to UC-KLEE [30], one limitation is that our prototype does not support the creation of cyclical data structures yet. Since this is a non-trivial problem, we consider it out of the scope of this paper.

5 Evaluation

In this section, we evaluate our prototype implementation of UCSAN, in order to answer the following research questions:

- **RQ1** **Performance Overhead**. As a compilation-based approach, does UCSAN incur lower runtime performance overhead than existing interpretation-based engines?
- **RQ2** **Compatibility**. Does UCSAN have good compatibility in analyzing real-world programs?
- **RQ3** **Impacts on Dynamic Analysis**. Can the improved efficiency of UCSAN improve the effectiveness of bug finding tools?

5.1 Experimental Setup

All experiments are carried out on a server with two Intel(R) Xeon(R) Platinum 8168 CPUs and 755GB memory. The server runs Ubuntu 20.04.3 LTS with the Linux kernel 6.5.0-25-generic. UCSAN is built with Clang 12.0 and LLVM 12.0. Since the original UC-KLEE [30] repo was no longer publicly available at the time of writing, we used the KLEE-based engine from the IncreLux [47] project (commit `80dea92`), which is a follow-up project of UBITect [46]. We refer to this engine as KLEE-IL. Both UCSAN† and KLEE-IL are configured to use Z3 4.8.15 for constraint solving.

5.2 RQ1: Performance Overhead

The key advantage of a compilation-based execution engine is its scalability (i.e., the ability to effectively handle large, complex, or growing software systems while maintaining acceptable performance, precision, and resource usage) over interpretation-based engines. In this subsection, we conduct several experiments to compare UCSAN's performance with two interpretation-based engines: KLEE-IL and Angr [34].

Linked List. First, we use the linked list example from Figure 3 as a micro-benchmark. We set the list size to 20 nodes, so the loop will iterate 20 times. Then we measured the end-to-end execution time, without path exploration. On this micro-benchmark, UCSAN's execution time is 9 seconds, while KLEE-IL took 20 seconds, and Angr took 79 seconds.

Table 1: nbench Performance (Iterations/sec)

Test	Native	UCSAN	UCSAN†	KLEE
NUMERIC SORT	1056.5	80.763	67.478	0.21653
STRING SORT	648.27	41.993	31.017	0.01282
BITFIELD	4.8555e+08	3.342e+07	2.0802e+07	65179
FP EMULATION	112.54	7.3962	5.3332	0.02442
FOURIER	1.7279e+05	95159	87193	103.29
ASSIGNMENT	32.035	1.8866	1.2791	0.0073587
IDEA	11522	349.53	204.61	0.93574
HUFFMAN	2430.7	167.96	123.43	0.51373
NEURAL NET	34.438	1.7772	1.3971	Crash
LU DECOMPOSITION	1264.6	62.549	45.997	0.16605

nbench. We further evaluated UCSAN, UCSAN† (UCSAN with SymSan), and KLEE-IL using the `nbench` benchmark suite [27]. Angr was excluded from this experiment due to severe performance limitations: it failed to complete a single

iteration after 18 hours and ultimately crashed from memory exhaustion. As shown in Table 1 (higher values indicate better performance), UCSAN outperforms KLEE-IL by several orders of magnitude across all tests. Furthermore, since nbench does not involve constraint solving, the additional overhead observed in UCSAN† stems primarily from the symbolic tracing of SymSan.

5.3 RQ2: Compatibility

In this experiment, we evaluate the compatibility of UCSAN, by compiling Linux kernel functions with it. We chose the Linux kernel as the target for this experiment because it is a widely-used open-source project with various coding styles and practices. It also has its own complex build system and dependencies.

We analyze functions from three versions of Linux. The first set is from 4.14.0, and the analysis scope is generated by the static use-before-initialization (UBI) analyzer UBITect [46]. UBITect generated 103,351 warnings from the Linux kernel 4.14.0, where each warning defines an entry function and an analysis scope (i.e., the set of functions that are involved in a UBI bug), which may span across multiple source files. We write a script to parse the list of warnings, extract the analysis scope, and generate the configuration files for UCSAN. The use of KLEE-IL follows the same procedure as described in the UBITect paper [46, 47]. The objective is to check if UCSAN offers similar compatibility as KLEE.

Table 3 reports the number of warnings UCSAN and KLEE-IL can analyze, where both engines failed to analyze all warnings. We analyzed the failed cases and found that most of them are due to the lack of support for inline assembly. Specifically, UCSAN resolves unnecessary external dependencies outside the analysis scope by replacing calls to those functions with dummy functions. However, due to the lack of support for inline assembly, when external functions are referenced in inline assembly, UCSAN will fail to build binaries for those cases and cannot analyze them. Notably, KLEE-IL also suffers from this issue. From the results, we conclude that UCSAN has good compatibility to analyze C functions compared to KLEE-IL.

In addition to 4.14.0, we also analyzed the version 5.10.240 (the longterm version used by Android) and 6.16.0 (the latest stable version at the time of evaluation). For these two versions, we used statically initialized function pointers as entry functions, and applied a simple call graph analysis to include all functions from the same module as the analysis scope. The ideal goal is to be able to compile all analysis scopes (i.e., 100%). The current prototype of UCSAN is able to compile 14,503 (96.2%) and 139,509 (88.9%) analysis scopes; most of the failed cases are also due to unhandled inline assembly.

Table 2: Overall TTF Statistics *T.O.: Timeout is 2 mins.*

	Min	25th%	Median	75th%	Mean
UCSAN†	0.51s	3.98s	4.62s	6.21s	14.37s
KLEE-IL	0.64s	92.13s	T.O.	T.O.	105.71s

5.4 RQ3: Impacts on Dynamic Analysis

We hypothesized that with the improved efficiency of UCSAN, dynamic analysis tools built on top of it, like UCSAN†, could scale to larger analysis scopes, and/or explore more execution paths. As a result, they would be able to find more bugs than previous engines. In this subsection, we conduct three experiments to validate this hypothesis.

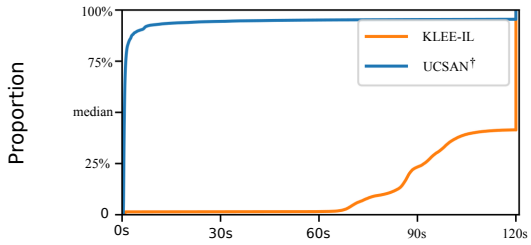
5.4.1 Processing UBI Warnings

Due to its ability to faithfully reason about memory states and path feasibility, under-constrained symbolic execution has been used to filter false positives from static analysis [5,42,46]. However, the scalability issue of existing under-constrained symbolic execution engines has limited their practicality in this context. In this experiment, we evaluate how the improved efficiency of UCSAN would impact its ability to process the results of the static analysis and identify the true positives.

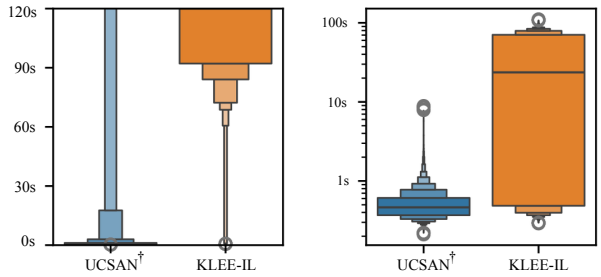
The experiment setup followed the same procedure as described in §5.3. For each warning generated by UBITect, we aim to find a feasible path from the allocation site of a variable to its use site, without going through initialization (thus use-before-initialization). For comparison purposes, we take the Time-To-Finish (TTF) as the primary evaluation metric. For fairness, the TTF includes both compilation time (for UCSAN) / linking time (for KLEE-IL), and analysis time. The compilation time for UCSAN includes the time to instrument the LLVM-IR and assemble the instrumented code to binary; while the linking time for KLEE-IL includes the time to link multiple LLVM IR modules into a single module. For this evaluation, we used 24 parallel instances for both UCSAN† and KLEE-IL, where each instance handles a different analysis task (entry function). Both UCSAN† and KLEE-IL are configured with 2-minute and 2GB limits for time and memory, the same configuration used in the UBITect/IncreLux paper [46, 47].

Figure 7 and Table 2 show that UCSAN† is 6.36x faster than KLEE-IL on average TTF. According to Table 3, when the 2 minute timeout is reached, UCSAN† was able to finish 95% of the warnings, while KLEE-IL only finished 41%. Moreover, all the cases that KLEE-IL finished processing were also completed by UCSAN†. Overall, we observe that UCSAN† processed at 0.32s/warning on average, while KLEE-IL processed at 5.14s/warning (i.e., UCSAN† is 15.06x faster than KLEE-IL on this metric).

We further investigated the 111 more confirmed results from UCSAN†. Given the large numbers, we decided to check



(a) CDF of Time-To-Finish for UCSAN† and KLEE-IL.



(b) Distribution of TTF (compile and solving time)

(c) Distribution of Compilation / Linking Time.

Figure 7: Performance for UCSAN† and KLEE-IL.

Table 3: Analyzed warnings from UBITect.

	Analyzable	Finished	Timeout	Total Time
UCSAN	66999	95.46%	4.54%	5.88h
KLEE-IL	52802	41.29%	58.71%	75.36h

the git history to see if any of these warnings have been patched in later kernel versions. The results show that at least 15 additional UBI bugs, which were reported by UBITect's static analysis but not confirmed by KLEE-IL, have since been patched in later kernel versions. This suggests that these bugs were indeed real and eventually caught by other means, yet they remained unconfirmed at the time of the original study due to the limitations of KLEE-IL. Had the authors of UBITect had access to UCSAN†, these bugs could have been confirmed and reported much earlier, potentially reducing the window of exposure for the affected kernel versions.

5.4.2 Analyzing Vulnerabilities

In this experiment, we evaluate the capability of UCSAN† for bug-finding purposes without the requirement of hand-crafted test harnesses. For reproducibility, we apply UCSAN† to rediscover known vulnerabilities. This experiment includes three datasets.

First, we manually collect 30 known vulnerabilities from the National Vulnerability Database (NVD). These vulnerabilities include both user-mode open-source software (OSS) and the Linux kernel (Table 5 in the Appendix). The selection criteria are as follows: (1) the vulnerability is a memory safety bug (e.g., buffer overflow, use-after-free, etc.) that can be detected by UCSAN's built-in checkers; (2) the vulnerability has a known root cause (i.e., the vulnerable function and the corresponding patch are known); (3) the vulnerability is not trivial to trigger (e.g., it cannot be triggered by simply calling the vulnerable function with random inputs); (4) the vulnerability is well-known or well-studied (e.g., CopyFail [36]).

Table 4: Bugs from SyzSpec analyzed with UCSAN†

Crashed Function	Bug Type	UCSAN†	False Positive
fast_imageblit	out-of-bounds	Y	
addrconf_verify_rtnl	use-after-free	Y	
dup_fd	use-after-free		F
nsim_fib6_rt_nh_del	use-after-free	Y

gsm_cleanup_mux	task hung		
kvfree_rcu_bulk	task hung	Y	
rss_counter	logic bug	Y	
depot_fetch_stack	logic bug	Y	
free_pgtables	logic bug	Y	
input_mt_init_slots	logic bug	Y	

For the 30 vulnerabilities we initially selected, we manually extracted the analysis scope and entry function based on the related bug-inducing/fixing commit from the NVD database. The results listed in Table 5 indicate that UCSAN† can indeed rediscover most of the known vulnerabilities (marked as **Y**) without any test harnesses. In cases marked as **P**, UCSAN† can identify the vulnerability without requiring test harnesses, but needs to disable UCSAN's dynamic re-allocation capability. As discussed in §3.2, UCSAN estimates buffer sizes based on information collected from the operations involved. It assumes that mistakes in buffer size estimation will occur, and

will automatically re-allocate the buffer if the estimated size is insufficient. While dynamic re-allocation allows UCSAN to avoid execution errors, it could negatively impact UCSAN's buffer overflow sanitizer *when the buffer size is not known* (e.g., when the buffer is allocated outside the analysis scope). For these cases, because the analysis scopes are manually defined in an iterative manner, we did not observe any false positives.

Second, following the suggestion from the reviewers, we included 94 CVEs from the AFGen [24] paper, where we can find corresponding entries in the NVD database (Table 5 in the Appendix, from `ffjpeg` to `tcpreplay`). AFGen is a fuzzing-based approach that shares the same goal as UCSAN—testing internal functions of OSS. The main difference is that AFGen uses bi-directional program slicing to generate test harnesses (with proper object initialization) for fuzzing, while UCSAN only needs to know the scope and the entry function.

Due to the size of the datasets, we tasked a coding agent (OpenAI Codex with GPT-5.5) to generate the configuration files. Specifically, for each vulnerability, we provide the NVD database entry to the coding agent, and task it to finish three tasks: (1) identify the vulnerable version of the target OSS; (2) locate a proper entry function for the analysis, and (3) define the analysis scope. The analysis scope should contain the root cause chain of the vulnerability (e.g., from `malloc` to the out-of-bound access), but exclude irrelevant functions like `printf`. Then the agent should use UCSAN† to reproduce the vulnerability, and report whether UCSAN† reported any false positives during the analysis. The result shows UCSAN† successfully re-discovered 69 CVEs, and failed to re-discover 25 CVEs. Most of the failed cases are due to a common limitation of symbolic execution—the path explosion problem: if triggering the vulnerability requires looping too many times, or for each loop iteration or recursive call, we need to take different paths, then UCSAN† cannot finish the analysis within the 10 minutes time limit. We also checked if UCSAN† reported false positives during the analysis. The results show that UCSAN† reported false positives in 7 cases, all of which are caused by missing constraints from external functions (i.e., functions outside the analysis scope).

The third dataset is from SyzSpec [18], a recent work that uses KLEE-based under-constrained symbolic execution to extract syscall descriptions for syzkaller [37]. However, due to the performance limitations of KLEE, SyzSpec only aims to extract syscall descriptions, instead of directly finding vulnerabilities. In contrast, we apply UCSAN† to directly analyze kernel modules for bug reproduction.

Similar to the previous experiment, we use a coding agent to generate the configuration files. Moreover, since several bug types (e.g., deadlock, corrupted lock) cannot be detected by UCSAN's built-in checkers, we also tasked the coding agent to write custom checkers for those cases. The results are shown in Table 4. Among the 38 bugs reported in the SyzSpec paper, UCSAN† can successfully re-discover 26 bugs without the need for a fuzzer or syscall descriptions. Among the 12 not confirmed cases, 10 are likely due to incomplete analysis scope. Specifically, the SyzSpec paper [18] only provides the faulty function name (i.e., where a bug has manifested) and the type of the fault. However, it does not provide the detailed root cause information nor a corresponding patch. Its code repository also does not contain any reproducible test cases. As a result, the coding agent can only guess a root cause and the corresponding analysis scope. One involves a loop that exceeds UCSAN's default iteration threshold. The remaining one case is due to concurrency, which is not supported by the current prototype of UCSAN. Due to the analysis scope issues, we also observed 8 false positives among the failed cases.

6 Limitations

The current prototype of UCSAN has several limitations, which we plan to address in future work.

External functions. UCSAN tries to automatically handle external function calls outside the analysis scope in a configurable fashion. However, there may be some external functions that require special modeling, such as string related functions (`strlen`, `strchr`). Currently, UCSAN does not support these functions and may generate incorrect inputs due to missing the dependencies between the input and the return value (i.e., under-constrained). For instance, several of the CVEs from the AFGen [24] paper cannot be reproduced due to missing modeling of file I/O functions (`fstat` `vfprintf`).

Cyclic Data Structures. UCSAN does not support cyclic data structures in the current implementation. We plan to support cyclic data structures in the future, by incorporating more sophisticated shape analysis [31, 40].

Scope Annotations. The current implementation of UCSAN requires the user to provide scope annotations to specify the target functions. As shown in the bug reproduction experiments, an improperly inferred scope may lead to incomplete analysis and result in false positives or false negatives. This challenge can be partially mitigated by pairing UCSAN with a static analysis tool like UBITect [46]. With recent advances in large language models (LLMs), one can also leverage LLM-based coding agents to infer the analysis scope.

Loop and Recursion. The current prototype of UCSAN only supports coarse-grained control of loop iterations and recursive calls (i.e., a global threshold). As a result, if triggering a bug requires increasing the threshold, we can only increase the threshold globally, which may lead to state explosion and prevent UCSAN† from finishing the analysis within the time limit. We plan to support more fine-grained control of loop iterations and recursive calls in the future.

Concurrency. The current prototype of UCSAN only supports a single "thread" and does not support concurrent execution. This limits its applicability to modeling and reproducing

concurrent bugs (e.g., data races). Since concurrency is a complex topic, we consider it out of the scope of this paper and plan to support it in future work.

Multiple Entry Points. The current prototype of UCSAN only supports a single entry point specified by the user. As a result, it cannot effectively analyze stateful code like `tcp_v4_do_rcv` in the Linux kernel, which requires multiple invocations to fully cover the execution state space. Similarly, it also does not support unit testing like chaining of a series of functions. We plan to add such support in the future.

7 Related Work

Symbolic and Concolic Execution. Symbolic execution, a technique that treats program inputs as symbolic variables to explore multiple paths, has been studied extensively for decades [4, 7]. Concolic testing, which combines symbolic execution with concrete inputs, has been implemented in tools like DART [14] and CUTE [32]. Path explosion is a major performance issue for symbolic and concolic execution. SAGE [15] proposed using generational search to mitigate the path explosion issue and increase the number of generated test cases in one execution. Dowser [17] proposed using static analysis to guide concolic execution to places where it is more likely to have buffer overflow vulnerabilities. Under-constrained symbolic execution [30] is an alternative approach to reducing path explosion. This method eliminates the need for harnesses because it begins execution from an arbitrary function. Recent works like Janus [43] and SCENT [8] have demonstrated the effectiveness of analyzing kernel components in isolation to find deep bugs in file systems and kernel protocols. However, these approaches rely on manual effort to extract code or build models. Janus, for instance, manually ports file systems to user space using LibOS to enable fuzzing. In contrast, UCSAN automates the under-constrained execution process by directly compiling and analyzing the target functions, thus removing the manual effort required by previous works.

Recently, a series of works have been proposed to improve the performance of symbolic execution, by leveraging instrumentation, instead of interpretation, including QSYM [44], SymCC [28], SymQEMU [29], and SymSan [9]. UCSAN also adopts this approach to speed up symbolic execution. It extends the SymSan project.

Test Harness Generation. Automated harness generation techniques like Fudge [3], FuzzGen [20], and APICraft [48] synthesize drivers by analyzing code usage or dependencies. LLM-based approaches [23] also show promise but struggle with complex dependencies like kernel functions. UCSAN avoids these issues by leveraging the original build system and directly analyzing target functions without synthesized harnesses.

8 Conclusion

In this paper, we present UCSAN, a compilation-based under-constrained execution engine. Our evaluation shows that UCSAN is more scalable than interpretation-based engines like KLEE and Angr. We further demonstrate how UCSAN can support dynamic analysis by combining it with a compilation-based concolic execution engine to build an under-constrained symbolic execution tool. The resulting tool can effectively analyze both Linux kernel and user-mode programs, and detect bugs that are difficult to uncover using other techniques.

9 Appendix

9.1 Instrumented IR for the motivating example

- Line 10: This is the first time `head` is checked for dereference. Though the subsequent instruction is a `GEP` instruction, which does not dereference the pointer, we still initialize the object pointed to by `head` and return the real-pointer to the `GEP` instruction. Notably, the size of the object is determined by the size of the pointer type which is `sizeof(struct node)`.
- Line 12: `ptr_v` is a pseudo-pointer, which is derived from `head` through pointer arithmetic. Note that `ptr_v` shares the same taint information with `head` as they point to the same object. Thus, no object is introduced in this step. Since the subsequent instruction is a `load` instruction, we return the real-pointer pointing to the desired offset and put it as the operand of the `load`.
- Line 24: Similarly to Line 10, JITI is not engaged in this step, as the object has been initialized.
- Line 26: Similarly to Line 12, JITI is not engaged in this step. Note that the returned real-pointer will be different from the previous one, as the desired offset points to the `next` field.
- Line 10′: Once the first loop iteration is finished and hits this line again, the taint information of `head` will be the next node pointed by the initial one, which points to an uninitialized object. Thus, JITI will be engaged again.

The original **`main`** function in the input code will be dropped and replaced by a crafted **`main`** function as shown in Line 31 in IR. In this function, we insert a call to `__set_label_for_args` to retrieve the value for the argument from the *super object* and set up taint for the argument. Then we invoke the target function `cal` with the argument. Note that the target function is specified by the user via analysis scope annotations.

9.2 Analyzing Additional Kernel Modules

To further demonstrate UCSAN†'s scalability, we analyzed a few kernel modules, with a 1-hour time budget for each module.

- `binder_ioctl`: The main entry function in the Binder IPC module from the Android kernel. Due to its complexity, there have been multiple security vulnerabilities discovered in this module. So we used UCSAN† to analyze this module from the latest Android 5.10 LTS kernel. The analysis scope includes 202 functions and 2,027 basic blocks. UCSAN† is able to cover 1,390 basic blocks (68.6%). The exploration triggered several error exits and 7 null-pointer dereferences. Upon manually replaying the traces and inspecting the logs, all of them were false positives due to missing context.
- `tcp_v4_do_rcv`: The main entry function for processing incoming TCP packets in the Linux kernel. We chose this function as it was analyzed in a prior work [8] where the authors manually extracted related code for model checking. We analyzed the function from the 6.16.0 kernel. The analysis scope includes 1,028 functions across 26 files, and 8,930 basic blocks. UCSAN† is able to cover 1,437 basic blocks (16.1%). After inspection, we found that this function is stateful and re-entrant. However, our current prototype only invokes the entry function once, which limits the code coverage. Neither error exits nor checker-reported errors are triggered in this analysis.
- `acpi_ex_opcode_2A_1T_1R` and `acpi_ex_opcode_1A_0T_1R`: The entry functions of the ACPI AML Interpreter module in the Linux kernel. We analyzed these two functions from the 6.16.0 kernel. The analysis scope of `acpi_ex_opcode_2A_1T_1R` includes 324 functions across 74 files, and 2,415 basic blocks. UCSAN† is able to cover 1,192 basic blocks (49.36%). The analysis scope of `acpi_ex_opcode_1A_0T_1R` includes 315 functions across 73 files, and 2,446 basic blocks. UCSAN† is able to cover 1,382 basic blocks (56.50%). For each of these two entry functions, the checker reported one null-pointer dereference, and one OOB access; both are false positives caused by calling `kmalloc` with size 0.

9.3 CVE Reproduction Case Studies

This section presents the detailed results of UCSAN†'s bug reproduction experiments. We evaluate UCSAN† on three datasets of known vulnerabilities: (1) 30 manually curated CVEs from the NVD, covering both user-mode OSS and the Linux kernel; (2) 94 CVEs from the AFGen [24] benchmark, spanning 11 open-source projects; and (3) 38 kernel bugs from SyzSpec [18].

Table 5 lists the full results for datasets (1) and (2). For each CVE, we report the project, CVE identifier, bug type, and whether UCSAN† successfully reproduced it (**Y**), failed (**N**), or succeeded only with dynamic re-allocation disabled (**P**).

Table 4 lists the SyzSpec kernel bugs. Since these bugs span diverse types (e.g., deadlock, corrupted lock) beyond memory safety, we also tasked a coding agent to generate custom checkers. UCSAN† reproduced 26 out of 38 bugs. Among the 12 unconfirmed cases, 10 are due to structural differences between the kernel version under test (v6.10) and the version described in the SyzSpec specification, and one exceeds the default loop iteration threshold.

```
define i32 @cal(%struct.node* %arg) {
  %sum = alloca i32, align 4
  %head = alloca %struct.node*, align 8
  store %struct.node* %arg, %struct.node** %head
  br label %while_loop
while_loop:

Aletheia: Automated Detection of Data Integrity Violations in Microservices

Mafalda Sofia Ferreira, João Ferreira Loff, João Garcia, Rodrigo Rodrigues
INESC-ID, Instituto Superior Técnico, Universidade de Lisboa

Abstract

The decomposition of applications into microservices results in data being stored across heterogeneous systems, with data schemas partitioned and managed by separate services. As the size and complexity of microservice deployments grow, the consistency of data associations at the application level can be overlooked, and it becomes challenging to manually identify data integrity violations.

In this paper, we present a systematic approach for identifying semantic violations in microservice ecosystems, namely operations and service interactions that break data integrity. We formalize these violations by leveraging the Entity-Relationship model and relational algebra to characterize problematic operation patterns across distributed services. We then introduce Aletheia, a static analysis tool that operationalizes this framework, using the static single assignment (SSA) representation to track data flow and a novel abstract call graph to detect integrity violations. We evaluate Aletheia on 7 open-source applications, detecting 46 previously unreported integrity violations, and use production-scale synthetic applications to demonstrate scalability to large call graphs with up to 500 microservices.

1 Introduction

The microservice architecture is a paradigm in which applications are decomposed into small components that can be independently developed, deployed, and scaled [1–4]. Contrary to a monolithic architecture where application logic is centralized into a single unit, the loose coupling of microservices enables the separation of responsibilities among different teams [5]. This design not only allows teams to work independently on smaller, self-contained codebases, but also to adopt the programming languages and storage systems that best align with their business requirements [5, 6].

Consequently, data management in microservice architectures is also decentralized, namely by allowing each service to choose its storage backend [2], which can range from scalable and weakly consistent NoSQL data stores [7–9] to relational databases with one-copy serializability semantics [10]. While this flexibility aligns with and preserves the benefits of microservices, it also introduces challenges in maintaining data consistency and integrity across the distributed system.

More concretely, when a large-scale service is decomposed into a set of microservices, the logical relationships within the data that form the state of the service should naturally persist even when the actual data is partitioned and therefore physically isolated across these services. As such, it becomes crucial to find systematic ways to model and reason about these logical connections. In this context, the Entity-Relationship (ER) model provides a time-tested, principled formalism for modeling these cross-service relationships, since the ER model already abstracts *logical* relationships from their *physical* implementation.

However, while the logical relationships remain conceptually identical to those captured by the ER model, the microservice decomposition renders database-level enforcement mechanisms (such as foreign key relationships) no longer applicable across service boundaries. Hence, these data dependencies and associations are typically handled by application code. Yet, due to the complexity of microservices, it can be almost impossible for developers to have a comprehensive understanding of the entire system [11, 12]. As a consequence, the preservation of data relationships can be overlooked or dismissed, compromising data integrity [13]. In practice, such inconsistencies have been reported even in large-scale production systems [14].

In this paper, we tackle this problem through a principled approach based on two pillars. First, we develop a formal framework for detecting data integrity violations in microservices by extending concepts from the ER model with relational algebra specifications tailored to cross-service data dependencies. Our framework characterizes how a microservice decomposition can violate three canonical types of data integrity constraints: referential integrity (ensuring that references between entities remain valid), entity integrity (ensuring that primary keys uniquely identify records across partitioned data), and uniqueness constraints (ensuring that unique values remain consistent despite concurrent operations). In particular, for each constraint type, we identify operation patterns — including cascading deletes and concurrent operations — that violate integrity when data relationships span service boundaries, and we formalize these patterns using relational algebra for their systematic detection.

Second, building on these formal specifications, we introduce *Aletheia*[1], a system for automated detection of integrity

[1] Aletheia is available at `https://github.com/aletheia-microservices`.

violations in microservice codebases. Aletheia leverages static analysis to identify the operation patterns formalized in our ER-based framework, translating the corresponding relational algebra specifications into concrete detection rules without relying on user input. Aletheia's detection relies on two key techniques. First, the system analyzes the code of each microservice in its static single assignment (SSA) intermediate representation (IR) [15]. In particular, by building upon taint propagation [16] over an SSA-based IR [17] and annotating variables with information about database operations, Aletheia can infer how values flow throughout any execution into various database operations. Second, we introduce a new *abstract call graph* that represents possible call graphs containing microservice invocations and database operations, along with filtered taint information from the SSA analysis. This graph enables the automatic extraction of the application data schema and integrity constraints, which are then validated against our formal specifications.

We implemented Aletheia as a framework in Go and used it to analyze several microservice benchmarks and applications [18–23] written in Blueprint [24]. These applications span diverse domains (including e-commerce, social networks, media processing, and reservation systems) and employ storage backends ranging from relational databases to document stores, key-value stores, and message brokers.

Our evaluation shows that Aletheia effectively identifies data integrity violations in real-world microservice applications. The system achieves a precision of 81% and a recall of 69% across applications of varying sizes and storage architectures. Notably, Aletheia detected 50 distinct integrity violations, of which 46 had not been previously reported in the literature, including issues in widely used benchmarks such as DeathStarBench and TrainTicket [18, 19]. These findings demonstrate that data integrity violations are pervasive even in well-studied codebases. Furthermore, Aletheia scales to large deployments, processing synthetic codebases containing up to 500 microservices and 2,887 distinct call graphs in under 20 minutes, making it practical for integration into development workflows. These codebases are designed to closely resemble real-world production systems [12, 25].

In summary, this paper makes the following contributions:

- We highlight the problem of data integrity violations in microservice architectures and propose a principled detection framework, built on a formal extension of relational algebra and the ER model.
- We introduce Aletheia, a system that automatically analyzes microservices and detects interactions that may result in such data integrity violations.
- We demonstrate that our system can effectively analyze applications at scale and identify previously unknown integrity anomalies in existing microservice codebases.

The remainder of this paper is organized as follows. §2 discusses data integrity challenges introduced by microservice architectures. §3 describes our principled approach for identifying violations of data integrity constraints in microservices. §4 presents the architecture and implementation of Aletheia. In §5, we present our experimental evaluation, which analyzes real-world microservice applications and assesses the scalability of the framework. Finally, we discuss the limitations of Aletheia in §6, survey the related work in §7, and conclude the paper in §8.

2 Data Integrity in Microservices

In this section, we motivate the main data integrity challenges introduced by microservices and overview our approach.

2.1 Challenges

Microservices introduce two key challenges to data integrity: heterogeneous storage and partitioned schemas.

Heterogeneous storage systems. Microservice applications typically employ heterogeneous storage systems, each with its own consistency model and transactional semantics. While some databases provide ACID transactions with strong consistency, others adopt BASE (Basically Available, Soft State, Eventually Consistent) principles [8], prioritizing availability through eventual consistency [7]. This diversity creates several problems. First, the guarantees provided by individual databases cannot be maintained when systems are combined. Even when each datastore individually offers some level of guarantees, applications cannot enforce a unified consistency model across all datastores. Providing stronger guarantees (e.g., causal consistency or read-your-writes) across heterogeneous systems requires instrumenting code with specialized libraries [20, 26, 27]. Second, transactional semantics do not extend beyond individual databases. Developers must either forego transactions entirely or adopt weaker patterns such as sagas [28], which implement sequences of local transactions at each service but provide no isolation guarantees across datastores. Third, using even a few weakly consistent datastores introduces complexity. For example, in multi-master databases with eventual consistency [29] (found in both NoSQL [30, 31] and SQL [32, 33] systems), concurrent writes may target different replicas and create divergent state. While conflict resolution mechanisms such as CRDTs [34] or last-writer-wins (LWW) policies [30, 35, 36] ensure convergence, they complicate application semantics, particularly when a single request triggers multiple conflicts resolved differently by each service.

Enforcing data integrity across partitioned schemas. As data is split across databases according to the logic of each service, schemas become fragmented and adapted to different database models [1], complicating in several ways the database-level enforcement of constraints that would exist in monolithic applications. First, certain constraints cannot be enforced across separate databases — for instance, foreign keys that establish referential integrity cannot be declared when schemas are distributed across multiple datas-

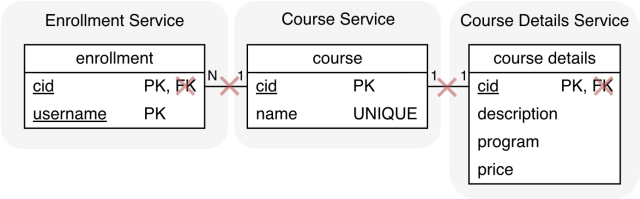

Figure 1: ER diagram with a possible decomposition of a monolithic application into microservices. The cross symbol in red represents the effects of the decomposition on the integrity constraints.

tores [13]. Second, some databases lack support for certain constraint types entirely, as is common for numerical constraints in NoSQL storage [30, 31]. Third, even for constraints that individual databases can enforce, a single request may span operations across partitioned data, requiring developers to understand how different enforcement mechanisms (e.g., distinct conflict resolution policies) interact and influence the overall side effects of an operation.

In practice, these limitations have forced developers to take on the responsibility for maintaining data integrity at the application level [13], yet the inherent complexity of microservices [11, 12, 37] hinders ensuring correctness. To concretely illustrate these challenges, we introduce an example that demonstrates their effects on data integrity constraints.

2.2 Motivating example

Consider an application for online course enrollment with the relational schema depicted in Fig. 1. This shows a monolithic version containing the *course*, *course details*, and *enrollment* entities along with their integrity constraints, and overlays a possible microservice decomposition. This example contains all three canonical types of data integrity constraints.

Referential integrity. The referential integrity constraint ensures that records can only be referenced if they exist in the referred table [38, 39]. In relational databases, referential integrity is preserved by ensuring that, whenever a record delete (or update) operation is issued, the operation is either blocked, returning an error, or the effects of the operation are propagated to all the records referencing the deleted record, thereby also being deleted (or updated).

In the example monolithic system, the database enforces referential integrity through foreign keys (e.g., the `cid` column linking enrollment and course tables). However, after decomposition into microservices, these foreign keys can no longer be defined, and the cross-table relationships they enforced disappear (denoted with a red cross in Fig. 1).

In general terms, microservices cannot rely on referential integrity across databases, shifting this responsibility to the application layer — and ultimately to the developer [13].

Entity integrity. The entity integrity constraint ensures that records in a table are uniquely identified through primary keys, which must be unique and not null [38, 39].

In the exemplified monolith, entity integrity is enforced by the database through the `cid` primary key in both *course* and *course details* tables, and through the composite primary key `cid` and `username` in the *enrollment* table.

After decomposition, all entities share a copy of the same primary key across different databases. Then, while databases still enforce entity integrity, the services must collectively ensure system-wide integrity: if a primary key value can identify one record for a given entity (e.g., *course*) in one database, then the same primary key value must also identify all the remaining partitioned records (e.g., *course details*) for entities in other databases.

Uniqueness constraint. The uniqueness constraint (also enforced by primary keys) ensures that a specific value is never repeated [38, 39]. In our example from Fig. 1, the uniqueness constraint is enforced by the database for the `name` column in the *course* entity.

After decomposition, the *course* entity that contains both uniqueness constraints is bound to a single service (*course* service), whose database includes mechanisms to ensure that values never repeat. However, the *course details* database (whose data may depend on the *course* database) may not be aware of the implications of such mechanisms, and jeopardize the overall data integrity. For example, the *course* database may discard the insertion of a new record if another course with the same name already exists, while the respective details are successfully inserted in the *course details* database, leaving the system with a partially created course.

These examples show how distributing data across microservices increases the risk of violating the canonical constraints that are trivial to enforce in monolithic systems.

2.3 Automating Data Integrity Analysis

Ideally, developers would have access to automated tools that can easily identify situations that endanger integrity constraints, despite the inherent complexity of microservices. However, given the limited research and the low visibility of this problem, developers are either not aware of such risks or are forced to manually debug their systems, thereby increasing the chances of compromising data integrity.

To address this, we introduce Aletheia, whose goal is to identify the parts of the code that may invalidate foreign key, primary key, and uniqueness constraints. However, to determine the code patterns that flag these potential problems, we require a precise understanding of the semantics of microservices, how their state is accessed and shared across different services, and which integrity-related invariants must hold when data is accessed. To this end, we formally model these concepts and define the conditions that can lead to violating the above-mentioned integrity constraints, which enables us to precisely derive a set of problematic sequences of actions. Building on this foundation, Aletheia (detailed in §4) then conducts a static analysis of an entire set of microservices. This starts with an intra-procedural analysis to detect how values flow throughout the execution to infer which variables are used in datastore operations and included in remote ser-

vice calls. Then, for scalability to larger codebases, we move into an inter-microservice data flow analysis based on a new abstract call graph, which is formed by retaining minimal information from the previous intra-procedural step according to our formal model. Ultimately, Aletheia operates exclusively on the abstract call graph, traversing it to infer cross-service foreign key relationships, and then searching for patterns in which database operations on data shared across services suggest that an integrity violation may occur.

3 A Model for Data Integrity in Microservices

In this section we lay out our approach to reasoning about how operations in microservices may break data integrity. We build on relational algebra to specify conditions to break the various integrity constraints, and then reason about the combinations of operations that may trigger those conditions.

3.1 System Model and Notation

We consider microservice applications where data is partitioned across several databases, and operations are issued individually to each database by the corresponding service.

The state S of a database consists of a set of data objects in a domain $\mathcal{D}$. The initial state of a database A is S_{A_0}, and a subsequent state, S_{A_i}, is obtained after applying a sequence of i operations. We restrict the set of database operations $\mathcal{O}$ to writes, reads, and deletes on tabular data, and denote them as $w,\ r,\ d \in \mathcal{O}$. We define a request as a group of operations $\mathcal{O}$ that are collectively triggered by a client application call.

For any two databases, A and B, that are part of a microservice application with current states S_{A_i} and S_{B_j}, the global application state can be denoted as $S_{\{A_i,B_j\}} = S_{A_i} \cup S_{B_i}$, which contains all data objects from both databases. We use T_A and T_B to denote relational tables from databases A and B.

When a database is replicated under weak consistency (which will be necessary to present data inconsistencies related to uniqueness constraints) its state may diverge when operations execute concurrently on different replicas. Here, we make the usual assumption that a convergent state is subsequently obtained by applying a merge procedure [40].

We consider data integrity to hold when a given integrity constraint, defined as a condition over the global application state, is satisfied by the current state. Table 1 presents the notation for defining the most commonly used integrity constraints in relational databases, namely foreign key, primary key, and uniqueness constraints. We do not include other constraint types such as check or not null, since they are either application-specific or enforced locally by a single database whose integrity does not depend on the state of other databases. Note that while we define constraints using relational database terms such as tables, columns, or records, this does not lose generality. In particular, these concepts can be adapted to other data models used in document-based (collections, fields, documents) or key-value stores (tables, attributes), as we will subsequently show by analyzing realistic microservice ecosystems with a diverse set of storage backends. Table 1 also shows the notation to represent operations.

Constraints	$\text{FK}\left(b_j^{T_B}, a_i^{T_A}\right)$	column b_j in table T_B is a foreign key referencing column a_i in table T_A.
	$\text{PK}_{T_A}(a_i)$	column a_i is the primary key of table T_A
	$\text{UNIQ}_{T_A}(a_i)$	column a_i is declared as unique in table T_A
Operations	$w_{T_A}(a_i = x, \ldots)$	write a record to table T_A specifying the values for one or more of its columns (in this example, column a_i with value x).
	$(a_j = y, \ldots) \leftarrow r_{T_A}(a_i = x)$	read from table T_A filtering only the records where column a_i has value x.
	$d_{T_A}(a_i = x)$	delete from table T_A the records where column a_i has value x.
	$[o_1 \wedge o_2]_{req}$	request req, including at least operations o_1 and o_2

Table 1: Notation to represent database constraints and operations.

3.2 Referential Integrity Violations

To understand the operation patterns that endanger referential integrity constraints, we first recall the respective definition: referential integrity states that an association can only be established between two records if the referenced record exists. In a microservice application, this link is established through *implicit inter-microservice associations* [13] between partitioned database records in different microservices, creating a *foreign key* relationship.

The definition of a foreign key is formalized as follows, where databases A and B hold tables T_A and T_B, respectively:

$$FK(b_j^{T_B}, a_i^{T_A}) \triangleq \forall b_j \in T_B \ (b_j \neq null \Rightarrow \exists a_i \in T_A : b_j = a_i)$$

Furthermore, we want to formalize a way to derive the existence of foreign key relationships, even when a schema annotated with those relationships does not exist, which is the case in microservice code. To this end, we infer that a foreign key $FK(b_j^{T_B}, a_i^{T_A})$ is established between tables T_A and T_B whenever a value x that is written to or read from table A is subsequently written in a column of table B (even if column a_i is not uniquely constrained in T_A). The intuition is that the value x is first associated with a record in table A, and its subsequent use for creating a record in table B establishes a referential dependency from T_B to T_A, since the newly written record in T_B depends on the existence of the other record in T_A. This corresponds to the following operation pattern:

$$\left((a_i = x, \ldots) \leftarrow r_{T_A}(\ldots) \vee w_{T_A}(a_i = x, \ldots)\right) \ \wedge \ w_{T_B}(\ldots, b_j = x)$$

Following the notation in Table 1, the left conjunct represents one of two possible operations that must occur in table A: a read to table T_A that returns a record where column a_i has value x, or a write to table T_A to add a new record where column a_i has value x. Then, the right conjunct states that the same value x is subsequently persisted in table T_B of another database. This establishes $FK(b_j^{T_B}, a_i^{T_A})$, where column b_j in table T_B is a foreign key referencing column a_i in table T_A.

As mentioned, this generalizes to other types of datastores such as document-based or key-value stores, namely by generalizing the previous reads and writes as any operations where the shared value x is assigned to an attribute or an underlying

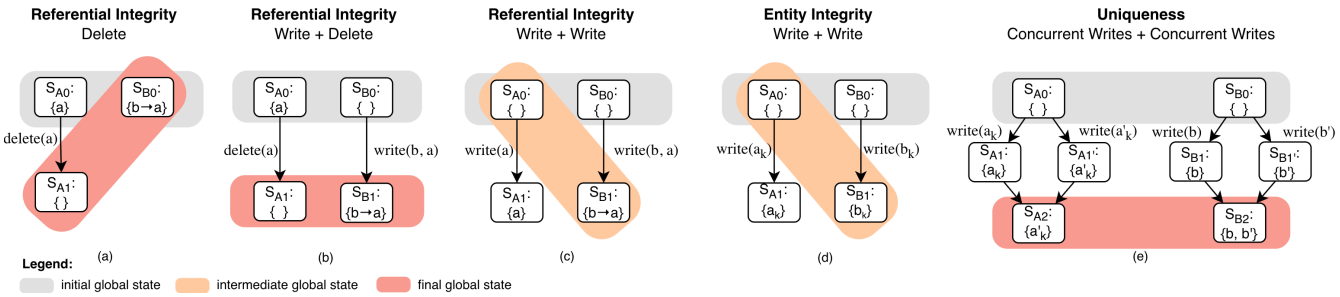

Figure 2: Examples of operations on two databases that may break integrity constraints. Orange and red states are inconsistent intermediate and final states, respectively. In (e), both databases are weakly replicated, and a final state is obtained by merging divergent replicas [40].

field of the object that is passed as an argument in writes, creating a referential dependency.

Once we determined which foreign key relationships exist, we can identify, across all combinations of operation types, which are the ones that may violate the foreign key association condition defined by $FK(b_j^{T_B}, a_i^{T_A})$ when applied concurrently to the state of a pair of microservices. In our particular case, since our generic model only includes three types of operations, we are able to exhaustively enumerate all possibilities, thus gaining confidence in the completeness of the set of problematic scenarios we identified, which are shown in Fig. 2 (a)–(c). Each depicted scenario comprises two databases, managed by different microservices, and the bottom part of the figure shows how two concurrent operations (or a single operation in scenario (a)) cause the system to transition to a final database state. For simplicity, we use $b \to a$ in the figure to represent a record a that has a non-null column referencing another column of record b, establishing a foreign key.

Absence of cascading deletes (RI-1). Fig. 2(a) illustrates how delete operations may break the validity of data associations. The initial global state corresponds to $S_{\{A_0,B_0\}} = \{a, b \to a\}$, where a exists in database A, and b in database B contains a reference to a. The delete operation on database A to delete record a causes the database to transition from $S_{A_0} = \{a\}$ to $S_{A_1} = \{\}$, where record a no longer exists. In contrast, no operations are issued to database B, thus its final state is the same as the initial state $S_{\{B_0\}} = \{b \to a\}$. At the end, the final global state $S_{\{A_1,B_0\}} = \{b \to a\}$ contains a record b with a reference to a, but record a does not exist in database A, breaking referential integrity.

In a monolithic database, this could be seamlessly addressed through schema annotations such as ON DELETE CASCADE[2], which atomically propagates the effects of a delete operation to all records that reference the record being deleted. However, these mechanisms are not present in microservices due to their decomposition, and the absence of equivalent safeguards has been shown to be prevalent [13].

[2]We do not consider patterns involving updates to columns referenced by foreign keys. While ON UPDATE CASCADE can be used to preserve referential integrity in monolithic databases, updating referenced foreign keys is a convoluted approach, dependent on application semantics, and no real examples were observed in microservice codebases.

This leads us to an operation pattern describing this scenario that is formalized as follows.

$$\exists a_i \in T_A,\ b_j \in T_B, x \in \mathcal{D}, d \in \mathcal{O} : \mathrm{FK}\left(b_j^{T_B}, a_i^{T_A}\right) \wedge \\ [d_{T_A}(a_i = x)]_{req} \wedge \nexists d' \in \mathcal{O} : d'_{T_B}(b_j = x) \in req \quad \textbf{RI-1}$$

The first line sets the existence of a foreign key, establishing an association across tables T_B and T_A of different databases. Then, there must exist a request where a delete operation on table T_A is not followed by any subsequent delete operation on the associated column b_j of table T_B, with value x.

Concurrent operations (RI-2). The second set of operations pertains to concurrent delete and write operations across different databases, as illustrated in Fig. 2(b). The initial global state of the application is $S_{\{A_0,B_0\}} = \{a\}$, and a pair of concurrent operations is applied to each database: the deletion of record a is applied to the initial state $S_{A_0} = \{a\}$ of database A, resulting in $S_{A_1} = \{\}$, and the insertion of a reference from record b to a is applied to the initial state $S_{B_0} = \{\}$ of database B, resulting in $S_{B_1} = \{b \to a\}$. However, when we aggregate the final states of each database partition into a global state, we obtain $S_{\{A_1,B_1\}} = \{b \to a\}$, where record b references a, but a does not exist. Therefore, the foreign key is not valid, and referential integrity does not hold. (The same issue appears in non-partitioned, weakly consistent replicated databases, a context for which Bailis et al. [40] showed that delete operations are not $\mathcal{I}$-confluent under foreign key invariants, meaning that concurrent deletes and writes of references are unsafe, and thus require coordination to preserve the invariant.)

The code pattern that flags this potential problem corresponds to the existence of two requests that perform these conflicting operations, as expressed by the following:

$$\exists a_i \in T_A,\ b_j \in T_B,\ x \in \mathcal{D}, r, w, d \in \mathcal{O}, n \neq m : \\ \mathrm{FK}\left(b_j^{T_B},\ a_i^{T_A}\right) \wedge \quad \textbf{RI-2} \\ [r_{T_A}(a_i = x)\ \wedge\ w_{T_B}(\ldots,\ b_j = x)]_{\mathrm{req_n}} \wedge [d_{T_A}(\ldots)]_{\mathrm{req_m}}$$

Here, request req_n performs a write operation on table T_B to create a new association in column b_j referencing an existing record with value x. This value is obtained from a preceding read operation on table T_A, confirming that the precondition for referential integrity is satisfied. Then, a concurrent request, req_m, executes a delete operation on table T_A, resulting in

the removal of a record that violates the referential integrity constraint established by the first request.

Uncoordinated replication (RI-3). Concurrent write operations may also affect referential integrity, namely when this constraint is enforced among objects partitioned across different storage systems.

To illustrate this, consider the scenario in Fig. 2(c), with an initially empty global state $S_{\{A_0,B_0\}} = \{\}$. To establish an association between objects, a request must contain two writes: one that inserts record a in database A, and another that inserts a reference from record b to a in database B. Together, these lead to the final global state of $S_{\{A_1,B_1\}} = \{a,\ b \to a\}$. However, before reaching that state, there may exist a visible intermediate global state $S_{\{A_0,B_1\}} = \{b \to a\}$ where b references a, but a does not yet exist, breaking referential integrity.

This violation stems from the lack of coordination among datastores when replication is asynchronous. In such cases, objects written in the same request may not become visible together. As a result, foreign key references can temporarily point to missing records, breaking referential integrity.

(RI-3) below formalizes the operations that can lead to this class of intermediate states with integrity violations.

$$\exists a_i \in T_A,\ b_j \in T_B,\ x \in \mathcal{D}, r, r', w, w' \in \mathcal{O}, n \neq m:$$
$$\mathrm{FK}\left(b_j^{T_B},\ a_i^{T_A}\right) \wedge \left[w_{T_A}(a_i = x,\ \ldots) \wedge\ w'_{T_B}(\ldots, b_j = x)\right]_{\mathrm{req_n}}$$
$$\wedge \nexists w'' \in \mathcal{O} : w''_{T_A}(a_i = x) \in req_m$$
$$\wedge \left[(\ldots,\ b_j = x) \leftarrow r_{T_B}(\ldots)\ \wedge\ r'_{T_A}(a_i = x)\right)$$
$$\vee\ \left(r_{T_A}(a_i = x) \wedge\ r'_{T_B}(b_j = x)\right]_{\mathrm{req_m}}$$
RI-3

First, there must exist a foreign key in database B referencing an entity in database A. The pattern then starts with a set of two writes in the same request (line 2): w_{T_A} that inserts the object to be referenced, and w'_{T_B} that creates an association with the former. The other request (lines 3-5) begins by excluding the write of the referenced object (line 3). Otherwise, under common read-your-writes semantics, the write would become visible to the subsequent reads, and the reference to the written record would remain valid, preserving integrity. Lines 4-5 describe the two alternative ways in which the same key x may read from table T_B (where it is a foreign key) and from table T_A, potentially exposing a missing reference. The first pair of reads (line 4) retrieves record b with $r_{T_B}(\ldots)$ using an arbitrary key to extract the foreign key value x in the record's column b_j, and then uses that foreign key to read record a with $r'_{T_A}(a_i = x)$. The second pair (line 5) reads record a containing the field x (through $r_{T_A}(a_i = x)$), and then reads a record b holding the value x as a foreign key with $r'_{T_B}(b_j = x)$.

3.3 Entity Integrity Violations

Entity integrity — which states that unique and non-null keys must identify records in a table — is enforced by databases through the use of primary keys. However, in microservices, entities may be partitioned among different services and share the same common primary key, allowing each database to uniquely identify its portion of the partitioned record. In this scenario, these various databases cannot guarantee consistency between themselves, and this lack of coordination can affect the overall application correctness.

Uncoordinated replication (EI-1). The effects of uncoordinated replication are akin to those in the context of referential integrity where, because writes are not coordinated across datastores, the validity of primary keys may be compromised.

Fig. 2(d) illustrates this through a scenario where an entity is decomposed into smaller entities in databases A and B, each managed independently by different services.

Both databases A and B are replicated with eventual consistency with initially empty states $S_{A_0} = \{\}$, $S_{B_0} = \{\}$. Then, two writes are executed. $write(a_k)$ is applied to database A to insert record a with a primary key k, and $write(b_k)$ is applied to database B to write record b using the same primary key k. Before reaching the final global state, there may exist an intermediate global state $S_{\{A_0,B_1\}} = \{b_k\}$ where record b exists, but record a does not. At this moment, the primary key k can be used to identify record b but not record a, and the primary key becomes invalid across the application.

The following pattern captures the microservice operations that may expose this problematic intermediate state.

$$\exists a_i \in T_A,\ b_j \in T_B,\ x \in \mathcal{D}, r, r', w, w' \in \mathcal{O}, n \neq m:$$
$$\mathrm{PK}_{T_A}(a_i)\ \wedge\ \mathrm{PK}_{T_B}(b_j) \wedge\ \left[w_{T_A}(a_i = x) \wedge\ w'_{T_B}(b_j = x)\right]_{\mathrm{req_n}}$$
$$\wedge \nexists w'', w''' \in \mathcal{O} : w''_{T_A}(a_i = x) \in req_m \wedge\ w'''_{T_B}(b_j = x) \in req_m$$
$$\wedge\ \left[r_{T_A}(a_i = x)\ \wedge\ r'_{T_B}(b_j = x)\right]_{\mathrm{req_m}}$$
EI-1

There are two primary key constraints: one on field a_i in table T_A of database A, and another on field b_j in table T_B of database B. The pattern then starts with a set of two writes within the same request (line 2): $w_{T_A}(a_i = x)$ and $w'_{T_B}(b_j = x)$, splitting a single record across T_A and T_B using the same primary key (line 2).

Then, the problematic request (lines 3-4) begins by excluding a write of the two records in the same request as the reads (line 3); otherwise, similarly to pattern RI-3, these newly written values would be visible under read-your-writes. With this exclusion in place, two read operations $r_{T_A}(a_i = x)$ and $r'_{T_B}(b_j = x)$ reading the same primary key value x may expose an inconsistent state of the application, containing only one of the two prior writes (line 4).

3.4 Uniqueness Violations

Similarly to primary keys in entity integrity constraints, databases can individually enforce uniqueness constraints, which can be defined at the column or table level.

However, when entities are decomposed across partitioned systems, the per-database mechanisms to enforce uniqueness may fail to preserve the overall data integrity of applications.

Conflicting writes (Un-1). This entails the occurrence of concurrent writes that conflict in a partitioned database. Consider Fig. 2(e) where databases A and B are both replicated with weak consistency, but only database A has a uniqueness constraint in column k. Then, two clients, c_1 and c_2, access the application from different regions and each issues a request to the application ($write(a_k)$ and $write(b)$ from c_1, and $write(a'_k)$ and $write(b')$ from c_2). We use a_k and a'_k to denote write operations that insert records a and a' using the same key in column k. In this specific execution, the request from client c_1 leads to states $S_{A_1} = \{a_k\}$ and $S_{B_1} = \{b\}$, whereas the request from client c_2 leads to states $S_{A'_1} = \{a'_k\}$ and $S_{B'_1} = \{b'\}$.

Since the same column k was written concurrently to different replicas, a weakly consistent database must be able to merge these writes through a mechanism such as LWW [35, 36] or CRDTs [34]. With the correct mechanisms, this convergence will be automatic and preserve uniqueness constraints, e.g., applying LWW in database A can discard the effects of $write(a_k)$ and preserve the uniqueness of the key in column k in a final state $S_{A_2} = \{a'_k\}$. However, despite data integrity being preserved in A, the application data is now inconsistent across databases A and B. This is because the final global state $S_{\{A_2,\, B_2,\}} = \{a'_k, b, b'\}$ includes the effects of both initial operations on B, but only one operation on A, meaning that the effects of one of the requests are only partially reflected.

To detect such inconsistencies, the following pattern captures requests that include two writes and at least one of them is on a constrained column.

$$\exists a_i, a_u \in T_A,\ b_j \in T_B,\ k,\ v \in \mathcal{D}, w, w', w'' \in \mathcal{O}:$$
$$UNIQ_{T_A}(a_u)\ \wedge \Big[\big(w_{T_A}(a_u = k)\ \vee\ w'_{T_A}(a_i = k,\ a_u = v)\big)$$
$$\wedge\ w''_{T_B}(b_j = k)\Big]_{req} \qquad \textbf{Un-1}$$

Here, there is one write w_{T_A} or w'_{T_A} to a database A that has some uniqueness constraint (line 2, split into inserting value k either (1) in a uniquely constrained column a_u or (2) in any column a_i and another value v in a uniquely constrained column a_u) and another write w''_{T_B} to database B that uses one of the values written in the former operation (line 3), regardless of whether the value is part of the uniqueness constraint. The idea is that, whenever there is a data dependency between the two writes (in this case, through the shared value k) and one of the databases holds a uniqueness constraint, then the overall data integrity can break, as the effects of the constrained operation may be lost upon applying the convergence mechanism, contrary to the other operation.

4 Aletheia

The formal framework from the previous section characterizes code patterns that lead to data integrity violations in microservices. However, manually inspecting codebases to identify these patterns becomes increasingly difficult as applications grow in size and complexity. To address this challenge, we introduce *Aletheia*, a static analysis tool that operationalizes our formal framework to automatically detect integrity violations.

Aletheia has four high-level steps. It begins with an *intra-procedural* analysis based on SSA graphs (§4.1), followed by an *inter-microservice* analysis that constructs an *abstract call graph* (§4.2). This is then used to extract a schema for objects stored across the application's databases (§4.3). Finally, Aletheia identifies the code sections that violate integrity constraints (§4.4). We now detail each of these steps.

4.1 Intra-Procedural Analysis

Statically identifying foreign keys through implicit microservice data associations as well as problematic code patterns requires reasoning about how values assigned to variables flow through the program, as we need to identify the provenance of the inputs to database operations. To this end, we first perform an intra-procedural analysis whose goal is to determine, within each method, how values assigned to variables flow into database operations and are used as input parameters in remote service invocations. The latter is necessary to subsequently broaden the scope of the analysis across services, ultimately reaching different databases.

In particular, we conduct a data flow analysis on graphs based on the SSA [15] intermediate representation of programs, where each variable has exactly one definition site, and new assignments result in new versions of these variables. This identifies the locations where variables are defined and subsequently used while also providing a standardized view of the program that abstracts away unnecessary details. In this step, we also extend the analysis across procedure invocations but within the same microservice, thus obtaining a per-service data flow representation.

Building SSA graphs. These graphs are constructed from the SSA intermediate representation of each method in the microservice code, with nodes corresponding to SSA instructions. We illustrate how the SSA graph allows for tracking data flow through an example of a *product service* (see Listing 1), which takes the *id* and *name* of a product as parameters to be written to its relational database, creates a new composite product variable from the parameter values, and returns the product. Fig. 3 depicts a simplified version of the corresponding SSA graph. In total, there are eight nodes that correspond to the instructions from the SSA representation. In this example, the *id* and *name* parameters are used as input to the database write operation, which is represented by a variable t_0. Variable t_1 is associated with the newly created *product* object with its fields *id* and *name*, respectively t_2 and t_3. The *product* constructor assigns to t_2 and t_3 the values of the parameters *id* and *name*, creating the nodes $*t_2 = id$ and $*t_3 = name$, which are connected to t_2 and t_3.

Tainting SSA graphs. After constructing the SSA graphs for each function, we have the information to determine which variables in the function flow into database operations and

```
1 func RegisterProduct (id, name) (Product, error) {
2     product_db.Exec("INSERT INTO products (id, name)
          VALUES(?, ?)", id, name)
3     product := Product{id: id, name: name}
4     return product, nil
5 }
```

Listing 1: Snippet of Go code for *register product* method of *product service* for an e-commerce application.

microservice invocations, either directly as arguments or indirectly through other assignments and operations. This is accomplished by employing a taint-propagation approach, whose first step is to identify nodes corresponding to these operations, and then proceed to discover all variables whose values flow into these operations. For this, we annotate variables used both as input parameters and return values of those operations. These annotations identify the call, along with the interface parameter (in the case of microservice invocations) or schema field (in the case of database operations) to which variables flow. Then, we propagate these annotations to all reachable nodes in the graph. Hence, whenever a variable contains such annotations, we can determine that its value flows into the corresponding operations.

Fig. 3 illustrates how this technique determines which database operations each function variable flows into. Through graph traversal, the system identifies variable t_0 as a database operation. Then, since *id* and *name* are passed as arguments, they are annotated, and taint information is propagated to the neighboring nodes, following the edge flow in the figure. Both taints on *id* and *name* eventually reach the local composite *product* defined by t_1, indicating that its underlying fields *id* (denoted by $_obj.id$) and *name* (denoted by $_obj.name$) had been written in the *product_db* database on the *product* table and *id* and *name* columns, respectively.

The previous process determines, for this particular function, which variables flow into the write operation (implemented as a SQL insert on *product_db*) whenever the respective service is invoked. Furthermore, if the service makes multiple internal function calls, we extend this analysis by propagating taint information across the SSA graphs of the various methods. To this end, we determine the final taints (and thus their triggering operations) of objects that reach microservice boundaries (i.e., other service invocations). In our example, these are the *id* and *name* parameters, as well as the product t_1 returned by the function, whose taints identify the write operation on *product_db* to which they flow. This enables a subsequent inter-service analysis of taint propagation, specifically how the parameters *id* and *name* supplied by the invoking service are transformed by the remote service invocation, which returns a value t_1 that incorporates taints generated during the current analysis.

Note that this approach not only supports raw SQL, which explicitly specifies record columns, but also NoSQL databases such as key-value or document stores, and queues: by propagating taint annotations through variables and their fields,

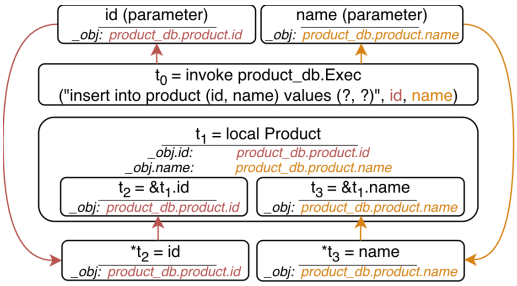

Figure 3: Example of a simplified SSA graph for a *product service*. Arrows represent the flow of taints originating in the write operation on t_0. Nodes affected by the taint contain the corresponding annotation below their SSA instruction. The standard execution flow arrows from the SSA graph are omitted.

we can identify, for a given object used as an argument in a call, the specific object fields that are referenced. The tainting also extends to data passed as binary objects (as employed by queues) as long as writers and readers use data types whose fields can be statically identified (e.g., maps with statically known keys) to construct and parse the binary objects.

4.2 Inter-Service Propagation

The second step broadens the analysis so we can detect when the patterns from §3 occur across multiple microservices. The main challenge is that we cannot simply continue the SSA taint analysis beyond individual services: this does not scale to large codebases, since it would require iterating over the joint SSA graphs of potentially thousands of microservices. Instead, the second step operates at a higher level of abstraction by building an *abstract call graph*, which provides a scalable representation of applications while keeping minimal taint information from the previous SSA graphs. The idea is that the *abstract call graph* only retains, per service, the information about interaction points, namely microservice calls and database operations, and the variables involved in them, including incoming parameters and returned values of these calls. This is the necessary and sufficient information to do a similar analysis to the first phase, namely to detect the patterns formalized in §3, even if they occur across microservices.

Building *abstract call graphs*. This graph comprises nodes representing microservice endpoints or datastore instances, and edges that denote invocations from one node to another. Edges between services represent remote invocations from one service to another. Edges connecting services and datastores represent either a service performing a datastore operation or a datastore triggering the execution of a service through, for example, an asynchronous event.

Furthermore, to track the taint flow through invocation or return arguments, we represent parameters and return values of either microservice or database operations as *abstract objects*. These objects contain the taint information obtained in the previous SSA analysis, which indicates the service or datastore calls into which variables flow. These objects are attached to nodes or edges, depending on whether they are

parameter/return variables associated with method declarations or used in call sites, respectively, as explained through the next example.

Fig. 4 illustrates a simplified *abstract call graph* for an e-commerce application containing three services: *APIService*, *ProductService*, and *InventoryService*. The logic of the *ProductService* and its *RegisterProduct* method closely follows the example introduced in §4.1 and the SSA graph in Fig. 3. The graph consists of five nodes, three for the interfaces exposed by each service (*APIService*, *ProductService*, and *InventoryService*), and two for the database instances (*product_db* and *inventory_db*). There are four *abstract objects*, namely the parameters and returned values involved in the example, annotated with taint information from the preceding intra-service analysis. These objects mediate the propagation of database and service invocation taints across nodes, allowing us to identify how data flows through services and operations.

The flow of interactions (solid arrows in Fig. 4) starts when the client uses the *APIService* interface to register a product, passing its *id*, *name*, and the *amount* to add to the inventory. Within this method, the *APIService* calls the *RegisterProduct* method in *ProductService*, which subsequently writes to its database *product_db* and returns a *product* object ao_2. Then, the *APIService* uses the *id* field in product ao_1 as the *id* argument (ao_3) to call the *AddInventory* method in *InventoryService*. The latter then uses the *id* parameter (ao_4) and *amount*, which we omit, as a value in the write operation to its database *inventory_db*.

Tainting *abstract call graphs*. The *abstract call graph* contains taint information extracted from SSA graphs, but this only captures the flow of objects within the boundaries of each microservice, which is insufficient for an analysis across microservices. Thus, after constructing the *abstract call graph*, the next step is to traverse the graph from each entry point in the application to propagate taints across the invocation chain. This will enable us to determine which objects, exchanged between services, hold taints from different databases, indicating a data dependency between services. This in turn will enable both detecting foreign keys and reasoning about common values used in different operations, as required by the formal model we previously defined.

To achieve this, for every node in the graph, we identify its outgoing edges and propagate the taints present in the objects associated with the call performed by the current node (either as parameters or return values) into the corresponding objects of the callee method declaration. Then, for each *abstract object* that acquires new taints, the algorithm propagates them to subsequent database and service calls the object flows into by merging annotations.

To illustrate this, we return to our example in Fig. 4. Here, we begin the tainting process by visiting the *APIService* on *RegisterProduct*, and then proceed to subsequent nodes according to the outgoing edges. The first database tainting propagation (red dashed arrows in Fig. 4) occurs when we finish visiting the *ProductService* and return the analysis to the *APIService*, propagating the taints from ao_2 to ao_1 through the object returned by the *RegisterProduct* method. This propagation results in a new annotation on ao_1 indicating a write in *products_db*, meaning that the value of ao_1, provided by the *APIService*, flows into the database of *ProductService*.

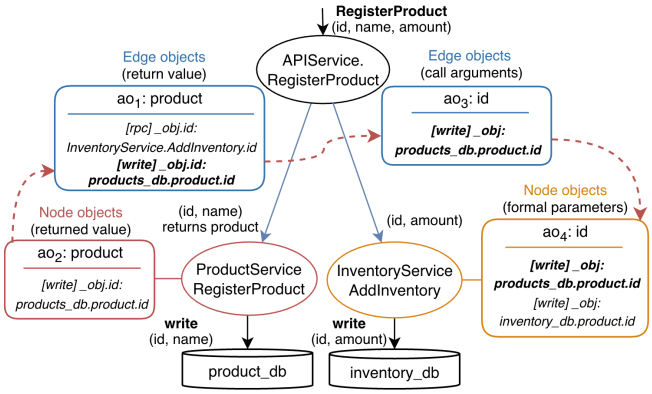

Figure 4: Example of a simplified *abstract call graph* for an e-commerce application. *Abstract objects* are prefixed with *ao*. Taint annotations in bold correspond to new annotations computed during the iteration of the *abstract call graph*. Solid arrows describe execution flow. Dashed arrows describe taint propagation.

Then, the graph traversal returns to the *APIService*. Since ao_1 contains an *rpc* annotation indicating that its *id* field is used as a parameter in the *AddInventory* call, then the new *write* taint on ao_1 is propagated to the corresponding object in that call (ao_3). Finally, when visiting the *InventoryService*, we see that object ao_4 is used as an *id* parameter of the method invoked by the *APIService*. Therefore, following the same logic as in *ProductService*, we propagate the taints from ao_3 to ao_4 by matching caller-callee objects, thus completing the taint chain from *product_db* to *inventory_db*.

This step of connecting the two databases through two taint annotations on object ao_4, is fundamental for our next analysis. For instance, in our example, we observe a group of operations matching pattern RI-3 (line 2) for referential integrity, where related records (*product* and *inventory*) are written in the same request, but may not be visible together during reads due to the lack of coordination. Then, when the detector module identifies another request executing reads on both the newly created records, completing the RI-3 pattern, it identifies a referential integrity violation.

4.3 Extracting the Application Data Schema

The two previous components allow Aletheia to determine how values are exchanged between services and included in different database accesses. This allows us to determine the schema information and search for the access patterns defined by our methodology.

Computing foreign keys. During the graph analysis, any taint propagation that causes an *abstract object* to contain multiple taints originating from different datastore operations results in a foreign key being added to the schema. However,

we still need to determine the direction of the foreign key association, since taints capture the order and type of operations, but do not indicate which field references the other. To determine which table holds the foreign key and which table contains the referenced records, we account for (i) the types of operations, which tell us whether we are obtaining a possible foreign key (through reads or writes whose values are propagated to other operations) or merely storing it (through writes), as well as (ii) the objects used as keys in these operations, whose taints specify the database fields being accessed and for which the foreign key will be constructed.

To this end, we denote each pair of operations as an ordered tuple (op_1, op_2), where $op_i \in \{read, write\}$ and *write* denotes any mutating operations.

Since foreign keys establish a data dependency between two tables, there is always one object whose value is included in operations to both tables, whose taints indicate the fields accessed in each table. Therefore, we use $field_1$ and $field_2$ to denote the fields accessed by that same object in op_1 and op_2, respectively. After having determined the fields being accessed for each operation, we can construct foreign key relationships according to the rules below for the pair (op_1, op_2). This is based on the intuition that if one of the operations is a read and the other is a write, then the write inserted a reference to the field that is read, independently of whether it appears before or after the write (① and ②). In case of two writes (③), since they occur when both the referenced and referencing objects are written in the same request, we assume that the second write inserts a reference to the former, which has just been created.

① if $(read, write)$, then $field_2$ references $field_1$
② if $(write, read)$, then $field_1$ references $field_2$
③ if $(write, write)$, then $field_2$ references $field_1$

For $(read, read)$ pairs, the direction depends on whether the propagated value is a key that was used as a parameter in a read operation ($read_{key}$) or a returned value ($read_{val}$). A field returned as $read_{val}$ and subsequently used as $read_{key}$ (④) is considered the referencing field, as it provides the key that was retrieved and then subsequently used as a foreign key to look up a value. When both operations use $read_{key}$ (⑤), we cannot infer the direction exclusively from the operation that reads a foreign key. Therefore, based on the order of operations, we assume that the first read retrieves the referenced field directly using a foreign key, while the second read looks up the record holding that foreign key.

④ if $(read_{val}, read_{key})$ then $field_1$ references $field_2$
⑤ if $(read_{key}, read_{key})$, then $field_2$ references $field_1$

4.4 Pattern Detection

The role of the detector module is to search for problematic code patterns that violate data integrity. This is enabled by the previous steps: constructing the data schema to extract data integrity constraints (see §4.3) and performing taint propagation in the *abstract call graph* to determine the flow of objects into service invocations and database operations (see §4.2).

With this information, the detector only needs to traverse the *abstract call graph*, locating the database operations, and checking for the presence of the problematic operation patterns defined in §3 (RI-1, RI-2, RI-3, EI-1, Un-1).

4.5 Implementation

Aletheia was implemented in Go using its Go SSA IR [41]. Thus, it can be extended to support other programming languages, since SSA representations can be obtained for multiple languages using analysis or compiler frameworks [42, 43].

Aletheia relies on three important mechanisms to analyze microservice codebases: identifying service methods that implement remote invocation endpoints, the locations where these invocations occur, and locating database accesses. However, microservices may employ a range of frameworks and communication protocols to interact with one another, and also use a variety of libraries and drivers tailored to each specific storage system. This diversity makes it difficult to encompass all frameworks and thus to locate these calls.

Given these difficulties, we analyze applications written with Blueprint [24], which identifies this information. In particular, Blueprint implements microservice invocations as regular function calls, and database operations through interfaces that abstract the underlying storage, thus allowing us to easily locate both of them. In the future, Aletheia could be extended to support other frameworks [44, 45] besides Blueprint, as long as they provide standardized abstractions for database and microservice calls that can be statically identified.

5 Evaluation

We evaluate our system to answer the following questions:
- Can Aletheia detect data integrity violations effectively?
- Which data integrity violations were found by Aletheia?
- How does application complexity impact analysis time?

5.1 Case Studies

We evaluated Aletheia using a dual approach that combines existing open-source microservice codebases (denoted as *realistic applications*), and production trace-based generated code (denoted as *synthetic applications*) to compensate for the lack of production-scale open-source microservice collections while evaluating the scalability of our approach.

Realistic applications. We conducted a broad search for open-source microservice applications across multiple programming languages. Aletheia was evaluated using the identified applications, namely seven microservice applications spanning four domains: e-commerce (Digota, SockShop, ESHopMicroservices), social networks (PostNotification, SocialNetwork), media storage (MediaMicroservices), and booking systems (TrainTicket) [18–23]. The SocialNetwork and MediaMicroservices applications (both part of DeathStarBench [18]) and TrainTicket [19] correspond to benchmarks

Name	#MS	#DS	#LoCs	#RPCs	#CGs	Mem.	RI-1	RI-2	RI-3	EI-1	Un-1	TP	FP	FN
Digota(1) [21]	4	4	1179	27	19	266 MB	2	2	0	0	0	4	0	0
EShopMicroservices(1) [22]	5	5	875	33	23	257 MB	2	6	0	0	0	8	0	2
Sockshop [23]	8	6	1676	49	19	291 MB	3	3	0	0	0	0	6	0
PostNotification(1) [20]	3	2	173	6	3	228 MB	0	0	1	0	0	1	0	0
SocialNetwork [18]	13	10	1374	31	6	341 MB	0	0	3	0	0	3	0	0
MediaMicroservices(1) [18]	14	19	1480	54	12	265 MB	0	0	3	1	1	5	0	0
TrainTicket [19]	31	21	4462	170	58	285 MB	14	17	4	0	0	29	6	20

Table 2: Static analysis results per application. For each application, we report: (1) characteristics such as microservices (#MS), datastores (#DS), lines of code (#LoC), RPC calls (#RPCs), and call graphs (#CG, equaling the number of frontend requests); (2) Aletheia's peak memory usage (Mem.); and (3) detection errors broken down by integrity violation pattern, and its true positives (TP), false positives (FP), and false negatives (FN). Applications marked with (1) were ported to Blueprint.

that approximate large microservice applications in real deployments. The overall set of applications (see overview in Table 2) involve typical microservice operations such as managing product catalogs and orders, creating posts and notifications, storing media content with reviews, and handling ticket reservations with associated services. Applications employ various storage systems, including document stores (MongoDB), message brokers (RabbitMQ), caches (Redis, Memcached), and relational databases (MySQL), with system sizes ranging from 3 to 31 microservices, 2 to 21 datastores, and up to 4462 lines of code. Communication spans 6 to 170 RPC calls in 3 to 58 call graphs.

In two cases, we extended applications with missing logic that seemed intuitively necessary, without which some problematic data partitioning could not be uncovered. In particular, we extended MediaMicroservices by adding endpoints (i) to insert complete movie records in a single request, instead of having the client separately calling four endpoints to write the associated data, and (ii) with a previously missing operation to read movie details, which is necessary to obtain an ID that was writable but not accessible to the client, and is required to read movie pages. In TrainTicket's implementation, ticket reservations trigger the creation of insurance, consignment, food order, and delivery records, but the system was missing an operation to access this state as part of a reservation query. Hence, we added an endpoint to query all records for a given reservation through existing read endpoints.

Synthetic applications. To demonstrate that Aletheia scales to production-like scenarios and to assess how the call graph structure influences performance, we generated synthetic applications based on graph characteristics (call depth, fan-out, and request volume) derived from Alibaba's production microservice traces [12] (see Table 3). Since there is no public access to the service logic, we generated microservice stubs with a configurable number of write and delete operations per method. Additionally, to assess the sensitivity of the results to varying graph parameters, we created five variants that modified one of the call graph characteristics at a time.

Experimental Setup. The experiments were conducted on 2x Intel Xeon Gold 5320 CPUs at 2.2GHz with 52 cores and 256GB of RAM, and all results represent an average of 5 runs.

5.2 How Effective is the Detection in Aletheia?

Table 2 presents the analysis results across all realistic applications. In our methodology, we computed an approximate false negative rate by manually and extensively searching for the patterns of operations defined in §3 to determine an approximation of the ground truth for the total number of problematic code patterns. In our analysis, we refer to the programming issues that may lead to data inconsistencies as bugs, while acknowledging that, in some cases, the application logic may tolerate the resulting semantic anomalies, or work around those issues through careful database configuration.

Aletheia achieved 81% precision and 69% recall, identifying 50 true positives, 12 false positives, and 22 false negatives. Notably, 46 of these true positives represent previously unreported bugs, with the exceptions being PostNotification and SocialNetwork, whose bugs were previously identified as *cross-service inconsistencies* through a runtime consistency enforcement shim [20].

We reported all bugs to the developers of the respective applications. All bugs were confirmed for TrainTicket, Digota, PostNotification, SocialNetwork, and MediaMicroservices by the respective authors. The developers of EShopMicroservices replied only to an initial report on RI-1, but confirmed the bugs and suggested solutions to address them. Furthermore, the authors of TrainTicket indicated these issues would be further investigated and addressed in future implementations due to their relevance in the application.

False positives. We examined the sources of false positives and how developers can interpret these warnings. The primary source of false positives is Aletheia's conservative approach, which flags patterns as potential violations even when application-specific business logic ensures safety: SockShop produces 3 RI-1 false positives from cart deletions that intentionally do not cascade to orders, and 3 RI-2 false positives from concurrent cart deletions and order creation, where the application coordinates safely. TrainTicket exhibits similar patterns where deleting contacts or price configurations does not propagate to reservations, which is correct by design but conservatively flagged, resulting in 3 RI-1 false positives.

A second source of false positives arises from over-approximation in taint tracking. Aletheia propagates taints to all reachable variables, so when variables tainted by differ-

ent database operations are combined in expressions (e.g., `x←a+b`), the result inherits all taints. This can lead to incorrectly inferred foreign key relationships. In TrainTicket, 3 of 35 warnings (1 for RI-1, 2 for RI-2) are such false positives.

To reduce the number of false positives, Aletheia allows developers to suppress cascade warnings for entities not intended for deletion and to be ignored by the detection module.

False negatives. False negatives occur when query patterns prevent foreign key detection. Some applications retrieve related objects by using values as query filters rather than as direct foreign key lookups. For instance, TrainTicket retrieves price configurations by filtering on train type name instead of using a foreign key to access the related object. This prevented Aletheia from identifying 3 foreign key relationships, resulting in 8 undetected bugs (3 for RI-1, 5 for RI-2).

Another source of false negatives arises from *cross-request implicit associations*, where relationships between entities exist outside of the microservice code, and are established through user-provided values that bridge arguments of different RPC requests. For instance, TrainTicket allows users to query station information in one request, then use the returned station name as input for order creation in a subsequent request. Since the order service never queries the station database using the value from the user, but the order creation populates related records (DELIVERY, FOOD-ORDER, ROUTE, TRIP) with this station name, the connection between STATION and these records exists only across separate requests rather than within application code, leaving foreign keys undetected. This limitation caused 12 false negatives in TrainTicket (5 for RI-1, 7 for RI-2). Similarly, a missing foreign key between COUPONS and PRODUCTS caused 2 false negatives in EShopMicroservices (1 for RI-1, 1 for RI-2).

The results in Table 2 show that larger codebases (measured by number of microservices, datastores, and LoC), contain more potential integrity violations. For example, TrainTicket, with 170 service invocations, contains almost eight times more violations than Digota, with 27 invocations. This is because more service invocations and cross-datastore interactions create additional data associations across services, increasing violation likelihood. Importantly, this trend validates Aletheia's relevance: as applications grow in complexity, the number of integrity violations rises substantially, making automated detection essential where manual debugging is challenging.

5.3 Which Data Integrity Violations were Found by Aletheia?

Next, we present a detailed description of the detected bugs.

Digota. Four referential integrity bugs were detected (2 for RI-1 and 2 for RI-2). For RI-1, deletions of PRODUCTS are not propagated to their SKUs (Stock Keeping Units), and deletions of SKUs are not propagated to ORDERS. Although similar patterns involving orders are false positives in other applications, invalid references from ORDERS to non-existent SKUs cause order returns to FAIL whenever the *order service* cannot retrieve the related SKUs, preventing refunds from completing. For RI-2, we found that a PRODUCT can be concurrently deleted while an SKU is created, and an SKU can be concurrently deleted while ORDERS referencing it are created.

EShopMicroservices. Eight referential integrity bugs were detected (2 for RI-1, and 6 for RI-2), which affect the correct processing of baskets. For RI-1, the two bugs occur when the deletion of PRODUCTS or COUPONS is not propagated to the BASKET that contains references to them. For RI-2, the six bugs occur when PRODUCTS or DISCOUNTS are deleted while a BASKET is concurrently created or updated.

PostNotification. One referential integrity bug was detected for RI-3 concerning a foreign key from a NOTIFICATION to its POST. The bug occurs when the *notify service* receives a new NOTIFICATION via a message broker and uses the POST ID to fetch the corresponding post in *storage service*. If replication is stale, users may receive notifications for non-existent posts.

SocialNetwork. Three referential integrity bugs were detected for RI-3 under asynchronous replication, and concern foreign key associations between timelines (USERTIMELINE and HOMETIMELINE) and POST. The bugs occur when POST IDS retrieved from timeline caches or the USERTIMELINE document store are later used to fetch POSTS from the *post-storage* database. Under stale replication, loading timelines may fail whenever one POST is unexpectedly missing from the *post-storage* database.

MediaMicroservices Five bugs were detected regarding referential integrity (3 for RI-3), entity integrity (1 for EI-1), and uniqueness (1 for Un-1) violations under asynchronous replication. For RI-3, reading a page may fail whenever foreign keys obtained from reading MOVIE-INFO and MOVIE-REVIEW are then subsequently used to retrieve the movie details (CAST, PLOT) and the review content (REVIEW-STORAGE), as any referenced record (all created together in the same request) may be missing. For EI-1, obtaining the movie ID and reading the page may fail as MOVIE-ID and MOVIE-INFO are not guaranteed to be visible simultaneously. For Un-1, concurrent movie registrations with the same title require conflict resolution in MOVIE-ID to preserve the uniqueness constraint, discarding one MOVIE-ID, thus leaving an orphaned record in MOVIE-INFO. Consequently, subsequent PAGE reads and REVIEW writes may observe partial results across MOVIE-ID and MOVIE-INFO.

TrainTicket. Twenty-nine referential integrity bugs were detected (10 for RI-1, 15 for RI-2, and 4 for RI-3). RI-1 bugs arise when deleting: (i) ORDERS without propagating effects to INSURANCE, CONSIGNMENT, DELIVERY, or FOOD-ORDER; (ii) STATIONS without propagating effects to ORDERS or CONSIGNMENTS; (iii) ROUTES without propagating effects to PRICE CONFIGURATIONS; (iv) TRIPS or USERS without propagating effects to ORDERS or CONSIGNMENTS. RI-2 bugs involve the previous entity pairs (except those in (i), as all records are created in the same request) and new pairs (ORDERS referencing CONTACTS and PRICE CONFIGURA-

#	Purpose	CD	FO	#DS	#CG	#MS	Mem
App1	Median	6	2	7	267	50	1.17 GB
App2	p90 #DS	6	2	55	267	50	1.70 GB
App3	p90 CD	12	2	7	267	500	9.94 GB
App4	p90 FO	6	16	7	267	500	10.08 GB
App5	p90 #CG	6	2	7	2887	50	11.32 GB

Table 3: Synthetic applications with varying call depth (CD), fan-out (FO), datastores (#DS, equaling the number of writes), and call graphs (#CG, equaling the number of frontend requests) according to Alibaba's report [12], as well as stateless microservice count (#MS).

TIONS), and occur when a record may be deleted while a new reference to it is created. RI-3 bugs occur when the ORDER ID is used to read the ORDER and query related INSURANCE, CONSIGNMENT, DELIVERY, and FOOD-ORDER records.

5.4 How Do Application Size and Complexity Impact Analysis Time?

We evaluate how application size and complexity affect the scalability of our approach. Fig. 5 shows the analysis times for both sets of applications, decomposed into *parsing*, *schema building*, and *detection* phases. *Parsing* includes code retrieval, SSA graph construction and tainting, and *abstract call graph* generation. *Schema building* taints the abstract graph while reasoning about data associations. *Detection* searches for the problematic patterns.

We start by analyzing applications in the realistic set, which complete in under 4 seconds. The analysis time increases mainly with the remote call count, whereas microservice and datastore counts have a smaller impact. For example, more than doubling the number of microservices from 13 (SocialNetwork) to 31 (TrainTicket) results in a smaller than 2× increase in analysis time (2.07 to 3.52 s). Breaking down into phases, *parsing* dominates total time, while *schema building* and *detection* are barely visible.

We now examine synthetic applications (Table 3) to understand how specific parameters influence the analysis time. Compared to realistic applications, the *schema building* and *detection* phases consume larger proportions of both time and memory. This reflects the substantially higher complexity of synthetic applications: up to 2887 call graphs vs. 58 maximum, with greater per-graph complexity from increased microservice and datastore accesses. The shift occurs because more operations generate larger volumes of taint information, increasing propagation overhead through invocation chains, and extending *schema building* and *detection* times.

Our detailed analysis of the synthetic set begins with App1, which represents the median Alibaba call graph parameters, and completes in 20 seconds. Comparing App2 with App1, increasing datastore operations from 7 to 55 per request results in a 3× increase in total time, demonstrating some sensitivity to database access frequency. Comparing the largest applications (App3 and App4) with App1 reveals the primary scalability driver. Despite using the same number of datastores, their 10× increase in microservices (from 50 to 500) produces a corresponding 10× increase in total invocations (from approximately 13k to 130k). This leads to analysis times reaching 801 and 908 seconds, respectively, confirming that total invocation count strongly predicts analysis time. App5 validates this finding by achieving high invocation counts through a different approach than App3/App4, namely maintaining a low microservice count (50) but increasing the number of call graphs (and thus frontend requests) from 267 to 2887, allowing it to reach similar total invocations as the larger applications. The resulting analysis time of 1152 seconds is comparable, confirming that invocation count drives analysis costs regardless of whether complexity arises from more services or more entry points.

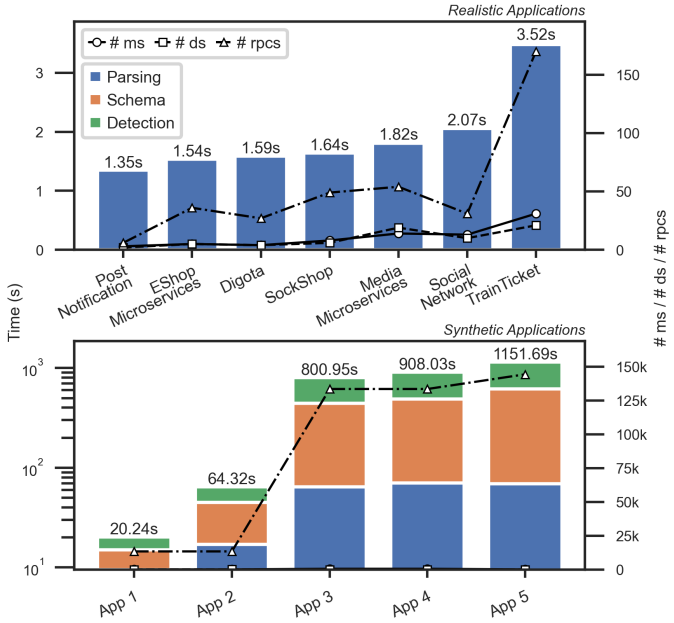

Figure 5: Analysis time per application, sorted by complexity (sum of the number of microservices and datastores). The reported analysis times are given for Total, Parsing, Schema Building, and Detection, where Total is the sum of the other three components.

Finally, comparing App3 and App4 reveals that the structural properties of the call graph have minimal performance impact: despite differing significantly in call depth (12 vs. 6) and fan-out (2 vs. 16), they show nearly identical *schema building* and *detection* costs.

6 Limitations

Parameterized dynamic queries. As a static analysis tool, Aletheia supports only statically defined queries and filters and cannot infer data relationships from dynamically constructed query operations. For instance, when SockShop dynamically adds tag name filters based on user input (`WHERE tag.name=?`), these relationships are not captured by our analysis. However, we did not find instances where this limitation affected the evaluation results for any application.

Cross-request implicit associations. When relationships between entities are established through user input that bridges separate RPC requests, Aletheia cannot infer them.

This caused a few false negatives in two services, as discussed in §5.2. In the future, we could address this by allowing developers to explicitly annotate association variables with foreign key metadata, enabling Aletheia to recognize these relationships while preserving its automated analysis.

Lazy enforcement of data integrity. Certain applications may handle data integrity lazily. For instance, when a user is deleted, dependent data may be retained and deleted later. This can be captured by Aletheia if the delete is executed upon an asynchronous event published as part of the triggering deletion. However, if deletions are propagated outside the request path (e.g., through a background process that periodically cleans *orphaned* records), developers would have to specify which cascade warnings to ignore during the analysis.

7 Related Work

Analyzing Microservices. Laigner et al. [13] conducted a study of data management practices in microservices, identifying fundamental challenges in ensuring application safety across services due to decentralized storage and application-layer logic. Their work provides a valuable high-level characterization of microservice consistency challenges through practical examples where applications can observe inconsistent states due to the lack of database support for transactional guarantees and event coordination. However, it lacks both a formal problem specification to systematically reason about integrity constraints, and automated detection mechanisms.

Romão et al. [46] recently introduced MAD, an anomaly detection tool that takes a monolithic service written in Java and a proposed decomposition, and uses an SMT solver to flag anomalies from non-serializable executions. While this shares the setting of detecting semantic inconsistencies in microservices, it has a different focus on anomalies in the migration into microservices, receiving as input the monolithic implementation of Java applications and a proposed decomposition, instead of a microservice codebase. Furthermore, the correctness criteria of serializable executions may be too restrictive, whereas Aletheia allows broader semantics and pinpoints only the problematic data integrity violations.

Peng et al. [37] introduced an architectural measurement approach through trace analysis, which allows users to identify architectural issues due to poor service decomposition, such as redundant services with similar functionality and invocation chains in which a single service is invoked multiple times. In contrast, we operate at the source code level to identify sections that violate data integrity constraints, which would remain undetected even when addressing architectural issues.

Hutcheson et al. [47] propose a methodology for the high-level understanding of microservice system architectures from service dependency graphs and context maps extracted through static analysis. This approach detects REST endpoints and calls without capturing how data values are exchanged, and, while it identifies overlapping service entities based on similarities, it does not capture the necessary data flow to infer foreign keys or data dependencies that affect integrity.

Addressing Inconstencies in Distributed Systems. FlightTracker [26] is a centralized solution that offers Read-Your-Writes (RYW) session guarantees with support for intra-session concurrency by storing the writes of users in the form of a *ticket* propagated throughout the request. Antipode [20] uses a distributed approach that enforces *cross-service causal consistency* (XCY) by tracking and propagating dependencies from writes in the form of lineages that capture the partial order of events. However, these are runtime consistency enforcement shims [48] for distributed systems. In contrast, our approach executes prior to runtime and identifies the specific causes of potential inconsistencies, enabling developers to decide whether the code should be modified to address them.

Modular Development Frameworks. Service Weaver [49] and Blueprint [24] are frameworks that allow users to write modular applications through regular function calls for inter-component communication, and later deploy them as microservices. Service Weaver [49] separates the logical boundaries (code) from the physical boundaries (deployment) by compiling and automatically deploying components. Blueprint [24] allows users to explore microservices across several dimensions, including application logic, middleware, and frameworks, enabling the reproduction of anomalies such as metastability failures [50], tail latency effects [51], and cross-system inconsistencies [14]. As such, both have a complementary goal of simplifying microservice development and can benefit from automatic detection of data inconsistencies.

8 Conclusion

Data decomposition in microservices creates challenges in maintaining integrity across physically separated but logically related data. This paper presents a formal framework to systematize integrity violations in microservices, identifying specific operation patterns that compromise constraints. We leveraged these foundations to build Aletheia, a static analysis tool for automated violation detection. We demonstrate that Aletheia detects previously unreported bugs in open-source microservice-based applications, while also showing good scalability in synthetic benchmarks. These results suggest that automated integrity verification can become a practical reality in microservice development toolchains.

ARCTIC: a practical lock-free adaptive radix tree

Newton Ni, Nicolas Garza, Jenny Stinehour, Michael Goppert, Michal Friedman*, Emmett Witchel
The University of Texas at Austin *ETH Zürich*

Abstract

Indexing data structures are vital to the modern systems ecosystem, but there are no indexes that offer high performance, lock freedom, *and* range scans. ARCTIC is a lock-free adaptive radix tree that achieves all three: ARCTIC outcompetes lock-based indexes, including a concurrent hash map, on many YCSB configurations, guarantees non-blocking operation through careful metadata layout and an (eponymous) freezing-based coordination protocol, and offers non-linearizable range and prefix scans. ARCTIC also contributes a novel safe memory reclamation scheme that uses operation keys to approximate reachable pointers. We integrate ARCTIC into RocksDB and Turso, improving throughput up to 40% and 12% on their write-heavy benchmarks relative to their default skiplist indexes.

1 Introduction

Indexing structures are a fundamental component of modern systems infrastructure: they underpin persistent key-value stores [10,26], distributed caches [9], and databases [18,41,59]. In these settings, index operations are frequently on the critical path of request processing and must scale across many cores and sockets. We focus on three properties that such indexes should provide. First, **performance**: indexes must offer high throughput and low tail latency on real hardware. Second, **lock-freedom**: indexes should provide strong progress guarantees and scale under high contention without relying on coarse-grained locks. Lock-freedom is important when systems have more threads than physical cores: a thread suspended inside a lock-based index's critical section stalls other threads waiting on that lock, while a lock-free index makes progress regardless of scheduling (§ 4.1). Third, **range scans**: many workloads require efficient range and prefix scans. For example, LSM trees [46] in key-value stores rely on range scans for fast compaction, and databases use range scans to accelerate range queries and index-only plans. We claim that no existing index satisfies all three of these properties, a conclusion supported by previous studies [27,42].

We group index structures into a few families: hash maps, skiplists, B+-trees, prefix trees, and hybrids. Hash maps achieve excellent performance and admit highly concurrent and even lock-free implementations [39], but they do not support efficient range scans. Skiplists [58] are ordered, but suffer from poor cache locality and high contention at higher levels of the list. B+-trees are the default choice for most databases, but lock-based B+-trees using optimistic lock coupling [36] perform far better than the state-of-the-art lock-free Bw-tree [54]. In the prefix-tree family, the lock-based adaptive radix tree (ART) [35,37] is a widely used ordered index, while the lock-free SMART [38] struggles with memory usage and reclamation (§5). We are not aware of any lock-free hybrid or trie-based data structure that consistently outperforms these lock-based alternatives while also supporting efficient range scans.

ARCTIC is an adaptive radix tree based on ART that provides all three properties. (1) ARCTIC out-performs ART on almost every YCSB [24] workload we evaluated (§4.1); at 80 threads, the throughput increase over ART (geomean across seven key distributions) ranges from 1.3× on YCSB-C to 7.7× on YCSB-A. (2) ARCTIC's new metadata layout and (eponymous) freezing-based [14, 15] coordination protocol enable it to achieve lock-freedom at minimal performance cost: ARCTIC introduces no additional pointer indirection relative to ART, and updates nodes in-place (as opposed to read-copy-update), reducing both cache and allocator pressure. (3) ARCTIC provides wait-free (but non-linearizable [31]) range and prefix scans, as well as wait-free reads.

ARCTIC also integrates a novel safe memory reclamation (SMR, §2.5) scheme, which we call hazard keys, that correlates logical operations with physical pointers. We start with hazard pointers (HP) [43], which guarantee bounded unreclaimed memory [48] by announcing the exact set of pointers an operation is accessing, but add overhead to every pointer dereference as a result. In §3.9, we show how we can instead approximate protected pointers "for free" by correlating an operation's key with the tree structure, enabling us to protect all pointers by announcing just the key, up front, once per operation. Our evaluation (§4.3) explores how hazard key reclamation efficiency is sensitive to request distribution, but less sensitive to thread stalls or oversubscription.

In return for performance, lock-freedom, and range scans, ARCTIC requires 128-bit atomic compare and swap (CAS) for correctness, and 128-bit atomic loads for reasonable performance. ARCTIC's memory overhead varies with the key distribution, but is generally higher relative to ART for integer keys (0.97×-1.5×), and lower for string keys (0.19×-0.61×).

In summary, this paper makes the following contributions.

- We present the design of ARCTIC, the first lock-free ordered index to surpass lock-based alternatives in performance, and sketch proofs of its correctness and lock-freedom.
- We contribute a novel SMR scheme—hazard keys—and evaluate its sensitivity to request distribution and thread count.
- We demonstrate the real-world potential of ARCTIC by replacing concurrent skiplists in RocksDB [16] and

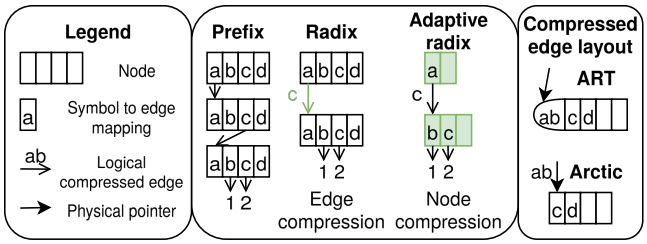

Figure 1: The midddle panel shows the evolution of prefix trees, with fixed nodes and height, to radix trees, which compress shared symbols into edges, to adaptive radix trees, which compress nodes into smaller partial mappings. All three trees represent the map $\{acb=1, acc=2\}$. The right panel shows two physical layouts of a logical compressed edge: ART stores the bytes in child node headers, while ARCTIC stores them alongside child pointers.

Turso [11], resulting in end-to-end speedups up to 40% and 12% on their write-heavy benchmarks.

- ARCTIC is open-source and available at https://github.com/nwtnni/arctic.

2 Background

This section provides technical background on lock-freedom, prefix trees, and safe memory reclamation.

2.1 Lock-freedom

An object is *lock-free* if, in every execution where operations are continually invoked, some operation always completes in a finite number of steps. A data structure is lock-free if, regardless of schedule, threads make progress in every execution. Even if some threads halt or crash, other threads will be able to continue executing their operations on the object, as no thread may block another. As a result, an operation on a lock-free object always keeps the memory in a consistent state.

Lock-free data structures are most commonly implemented using compare-and-swap (CAS) as a hardware synchronization primitive, which can atomically load, compare, and store up to 16B. The x86 has a 16B CAS instruction (`CMPXCHG16B`), as does ARM in the LSE extension (the `CASP` instruction).

2.2 Prefix and radix trees

A prefix tree is an associative data structure composed of nodes and edges that maps keys—sequences of symbols—to values. Each node is a total map from symbol to edge (typically a fixed size array). Each edge has one child, which can be a value or a node (which can be null). A simple example is shown in Figure 1. Prefix trees provide point operations in time complexity linear to the key size, and admit efficient range scans due to their lexicographically ordered structure. In practice, however, prefix trees suffer from (a) high time overhead when keys are long, due to following one pointer per symbol, and (b) high space overhead when keys are sparse, due to fixed size nodes.

Radix trees. Radix trees are a variant of prefix trees. Radix trees still use fixed size nodes, with the radix r determining the node size 2^r. The radix is commonly chosen as 8 so that symbols are bytes, which is efficient for hardware; we assume byte symbols in this paper. Radix trees reduce overhead through edge compression, i.e., labelling edges with shared bytes, which reduces the height of the tree and eliminates nodes with one child. Two physical representations of these edge bytes are shown in Figure 1: ART [35] stores them in child node headers, while ARCTIC stores them inline with child pointers.

Judy arrays [1] and the adaptive radix tree [35] (ART) additionally reduce space overhead through node compression, i.e., choosing different node representations depending on how many children the node has, which reduces the size of sparsely populated nodes. Both of these optimizations are displayed in Figure 1.

Important properties. We will briefly describe some properties that help us reason about correctness. First, every prefix tree element (node, edge, value) can be labeled inductively with a prefix:

Definition 1 (Prefix)**.** *The root edge has the empty prefix. If an edge has prefix p and bytes $[b_1, b_2, \ldots]$, then its child has prefix $p + [b_1, b_2, \ldots]$. If a node has prefix p and maps byte b to edge e, then edge e has prefix $p + [b]$.*

Prefix trees must satisfy two invariants: for a given prefix, there is at most one node in the tree, and for a given node in the tree, it has exactly one prefix. Second, we point out a major precondition of prefix trees:

Precondition 1. *No key is a prefix of any other key.*

This precondition avoids a vexing case where the same key maps to both a node and a value, and the restriction is easy to satisfy in practice. Fixed-size integers and C-style null-terminated strings both have this property; other dynamically-sized keys can append a sentinel byte. ARCTIC and all other prefix tree-based data structures we are aware of have this restriction.

2.3 Structural modification operations (SMOs)

SMOs are operations that modify the physical state of a data structure *without* modifying its logical state, and are typically necessary to maintain data structure invariants. For example, tree rotation maintains balance in a binary search tree, and resizing maintains load factor in a hash map. We will focus on SMOs because they are often the most challenging part of designing lock-free data structures, especially when they require writes to multiple memory locations. For example, a B+-tree node split requires writing both parent and child.

Naive prefix trees have very simple SMOs (bottom of Figure 2) that only write to the parent. Once we introduce edge compression and node compression, however, the number and complexity of SMOs also increase; they are necessary to manage edge bytes and node representations, respectively. We will reference these SMOs extensively, as our design is grounded in implementing SMOs atomically without extra indirection or locking (§3.3).

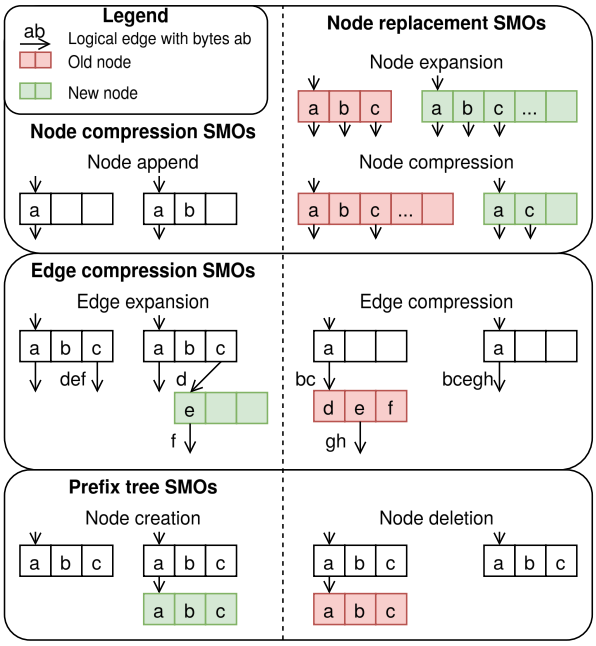

Figure 2: SMOs in prefix tree variants. Prefix trees (bottom) only have two SMOs: node creation and deletion. Edge compression (middle) requires two new SMOs to expand and compress edge bytes. Node compression (top) requires three new SMOs to append to node partial mappings and change the representation of a node. SMOs on the right side require unlinking (Figure 3); we refer to them collectively as node replacement SMOs.

2.4 Node life cycle

Figure 3 illustrates the life cycle of a ARCTIC node: the states a node can occupy and the transitions between them. Informally, we say a node is *reachable* if there exists some path to it from the root. Linking makes a node reachable, and unlinking makes it unreachable; in ARCTIC, these transitions are implemented atomically by CASing a pointer to the node. We will introduce *freeze* next, and *reclaim* in §2.5.

Freezing [14, 15] addresses a specific race between unlinking a node and concurrently accessing that same node. Depending on the data structure, it may still be correct to read an unreachable node, but it is generally incorrect to write to an unreachable node. For example, if thread A loads a pointer to node n, thread B unlinks n, and thread A writes to n, then thread A's write is not observable.

At a high level, freezing prevents unlink-write races by requiring unlinking threads to set a `frozen` bit on every CASable location in a node before unlinking; on the other side, a writing thread promises to CAS only when the frozen bit is clear. This provides a mechanism for writers to detect when the node they are writing *may* be unreachable—it could be frozen but still reachable. For reading threads, it is usually safe to restart when reading a location whose frozen bit is set, but this could be quite slow.

ARCTIC uses freezing as a primitive coordination mechanism, but there are many edge cases that must be specialized

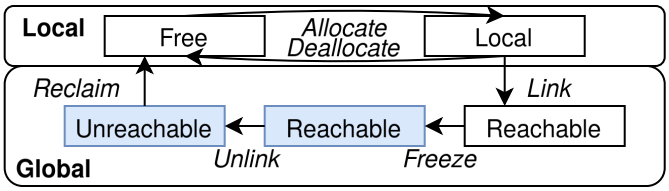

Figure 3: The life cycle of a node in ARCTIC. The top two states are local, meaning that there is at most one thread that can access the node. The bottom three states are global, meaning there may be any number of threads accessing the node. We use freezing to coordinate unlinking (§2.4); a frozen node may be reachable *or* unreachable. Our hazard key protocol (§3.9) determines when an unreachable node becomes safe to reclaim (§2.5).

for our data structure: for example, what does a writing thread do when it fails to CAS? When is it safe for a reader to read an unreachable node? Our design (§3) answers these questions and we sketch a correctness proof (§3.8).

2.5 Safe memory reclamation (SMR)

Any concurrent data structure that allows optimistic traversal (in other words, loading and dereferencing pointers without acquiring a lock) must be especially careful to avoid use-after-free errors. This is the safe memory reclamation (SMR) problem: determining when a pointer will never be dereferenced again, so it can be freed. In managed languages like Java or Go, SMR is handled by the language runtime's garbage collector. In languages with manual memory management like C, C++, or Rust, SMR falls to the programmer.

SMR algorithms make a fundamental trade-off between precision—how closely they can estimate the set of pointers that will no longer be dereferenced—and performance—how much runtime overhead they incur. Hazard pointers [43] keep track of the exact set of pointers being accessed, which bounds unreclaimed memory, but the cost is overhead for every pointer access. On the high performance end of the trade-off, epoch-based reclamation (EBR) [29] tracks quiescent periods between operations. EBR is popular for its consistently high performance, but even a single stalled thread can prevent all memory reclamation.

3 Design

To develop some high-level intuition for our design, and how it differs from ART, we walk through of a series of insertions (§3.1). Then we will go over:

- ARCTIC's metadata layout (§3.2)
- How to perform SMOs atomically (§3.3)
- How to traverse (§3.4) and insert (§3.5)
- How to reclaim memory (§3.9)
- Why ARCTIC is correct, linearizable, and lock-free (§3.8)
- How to optimize ARCTIC (§3.10)

3.1 Walkthrough

Figure 4 illustrates a series of insertion operations on ARCTIC and ART, starting from an empty tree.

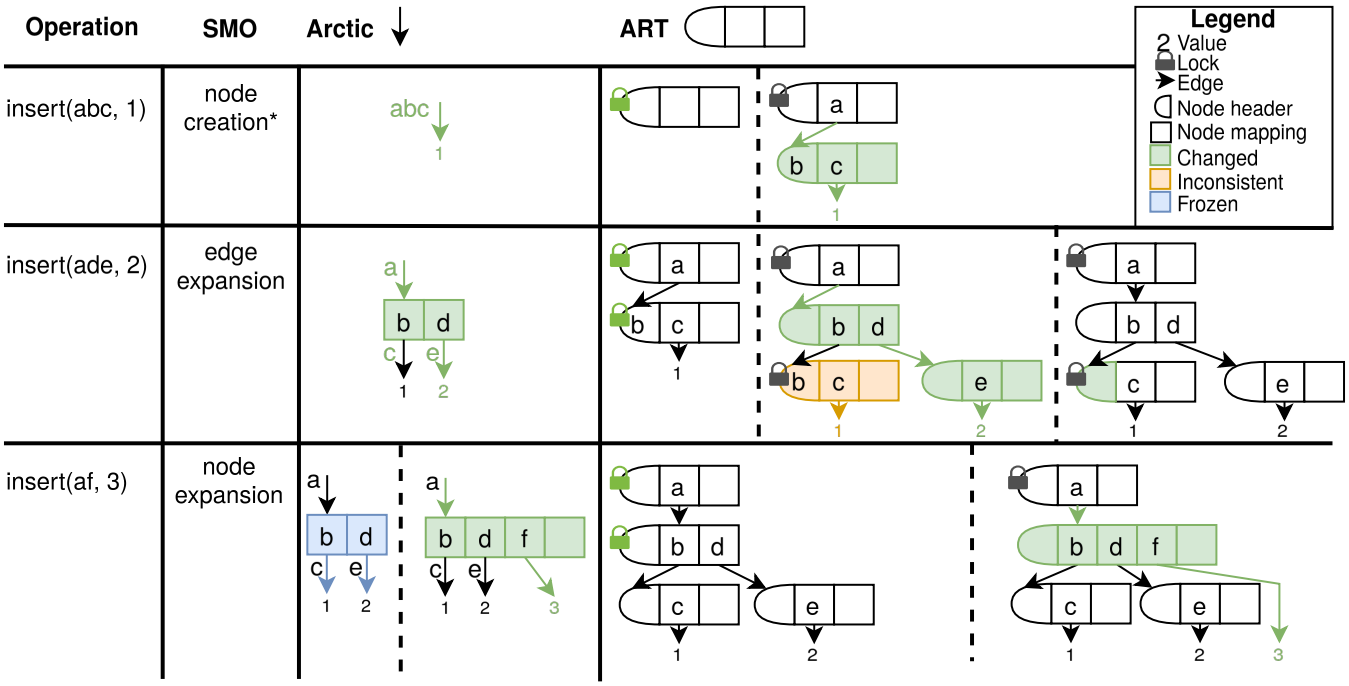

Figure 4: Walkthrough showing a series of insertions in ARCTIC and ART, starting from empty trees. Each insertion requires a different SMO (except the first insertion, which ARCTIC handles without an SMO). Each data structure undergoes atomic transitions between globally visible states, both between rows, and from left to right within a row (separated by dashed lines). To save space, we merge ART's locking and omit its unlocking.

Empty. ARCTIC is rooted at an edge, while ART is rooted at a node because: (1) ARCTIC stores edge bytes alongside edges, (2) ART stores edge bytes in child node headers, and (3) Precondition 1 precludes empty keys. Therefore, ART needs at least one node to represent a non-empty key, while ARCTIC does not.

Insert(abc, 1) (Row 1). ARCTIC can store a value with a non-empty key directly under the root edge, so no SMO is required. ART creates an intermediate node and locks the root node to install it.

Insert(ade, 2) (Row 2). This insertion requires edge expansion. ARCTIC requires only one CAS, but this SMO is painful for ART because ART stores edge bytes in child node headers. As a result, ART takes two locks to update the parent's edge and the child's node header, exposing an inconsistent state in between that readers must detect.

Insert(af, 3) (Row 3). We illustrate this insertion as if it requires a node expansion, though in practice, ARCTIC's smallest node can accommodate 3 entries, and ART can accommodate 4. Node expansion requires unlinking an old node. ARCTIC handles this case by using a freezing-based (§2.4) node replacement protocol (§3.3) that is expensive, but maintains consistency and supports in-place updates. ART takes two locks to prevent updates to the child while updating the parent's child pointer.

Summary. ARCTIC has clear performance benefits just from avoiding locking and unlocking, both in the common case of updates, where ART requires one lock, and in the rarer case of SMOs, where ART requires two locks.

More importantly, by removing ART's node-level locking, ARCTIC achieves much finer-grained concurrency, both vertically—between different levels of the tree—and horizontally—between different edges in a single node. As an example of vertical concurrency, consider two consecutive nodes, where both undergo node expansion. In ARCTIC, these two node expansion SMOs happen fully in parallel (§3.3), while in ART, they conflict on a lock on the second node. As an example of horizontal concurrency, consider updating two edges in a node. In ARCTIC, these two updates also happen in parallel, while in ART, they conflict on the node-level lock.

3.2 Metadata layout

Figure 5 shows the layout of ARCTIC's intermediate node types (Node3, Node15, Node47) which are based on ART's [35] (Node4, Node16, Node48), but ARCTIC (1) reorganizes edge and node metadata to enable atomic SMOs (Figure 2), and (2) ensures all node types have power-of-two sizes to make more efficient use of hardware. We will explain how this layout follows naturally from our constraints.

The biggest constraint on ARCTIC's layout is the edge expansion SMO. As shown in Figure 4, ART's placement of edge bytes in child node headers means edge expansion requires two writes, which is difficult to do atomically without locks. ARCTIC shifts these edge bytes upward into the parent edge. While our design still works with 8B edges and atomics, to fit more edge bytes, we make our edges 16B and require

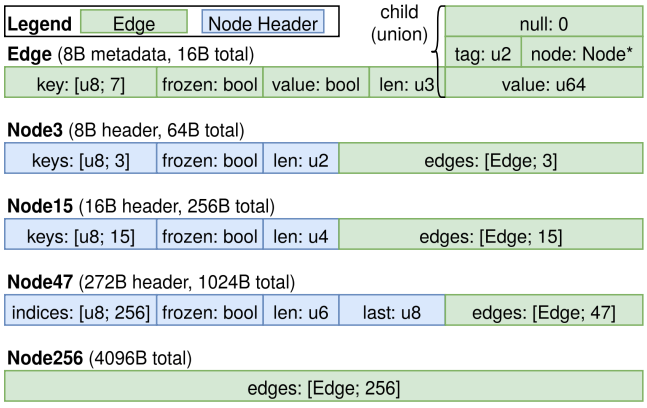

Figure 5: The memory layout of ARCTIC's edge and node types. The child of an edge is a union between a user value (if the `value` bit is set), null, or a node pointer with its type tag in the lower two bits, which are zero due to alignment. We ensure that all types have power-of-two sizes, which works well with hardware and memory allocators, and that our smallest node type (Node3) occupies exactly one cache line to avoid false sharing between different nodes.

the system to support 16B atomic operations.

With 16B edges in place, our next constraint is Node256, which must contain an array of 256 edges, exactly 4KiB. We cannot fit any metadata without causing Node256 to span two pages (bad for memory allocator, page table, TLB); luckily, the only metadata Node256 needs is a node type tag, so we shift node type tags into parent edges as well. (As a side benefit, this eliminates a cache miss: ART unconditionally loads child node headers to determine the type, but ARCTIC avoids this load when the child is a Node256).

Our final constraints come from node replacement and node append SMOs. Our node replacement protocol (§3.3) requires every edge and node header to have a frozen bit (§2.4). For node append, Node3 and Node15 need no additional changes, because their headers fit into 16B and can be CASed atomically, but Node47's header is too large. We add a field—(`last`, the last appended key byte)—and explain how we use it to achieve atomic node appends in §3.3.

3.3 SMOs

We now revisit our adaptive radix tree SMOs (Figure 2) and explain how ARCTIC's layout enables us to implement each SMO atomically. We focus on successful SMOs for now, as failed SMOs are handled at a higher abstraction level (e.g., insertion or deletion). Failed SMOs have no globally visible effects.

Edge expansion. ARCTIC places edge bytes in edges, which makes this SMO straightforward. Following the example in Figure 2, we expand an edge with bytes `def` to some child c. This can be done atomically as follows: (1) create a new Node3 n that maps byte `e` to edge with bytes `f` and child c, and (2) CAS the original edge to bytes `d` and child n.

Node replacement. Four SMOs—node expansion, node compression, edge compression, and node deletion, displayed on the right side of Figure 2—are similar in that they (1) scan an old reachable node to determine the contents of the new replacement node, (2) construct the new node in local memory, and (3) CAS to atomically unlink the old node and link the new node. However, this becomes complicated in the presence of in-place node updates: any number of concurrent updates to the old node may take place between steps (1) and (3), which may not be reflected in the new node when it is successfully linked in step (3).

We address this race condition in two ways. First, we prevent the old node from being updated between steps (1) and (3) through freezing (§2.4): we iterate over every CASable location in the node (header, edges) and CAS to set the frozen bit. The node is frozen once every frozen bit is set, and guaranteed to be immutable. Second, we avoid stale SMOs—for example, one thread starts freezing a full node in order to expand it, but every child is removed before freezing completes—by unifying all four SMOs into a single node replacement SMO. Threads may initiate a node replacement for any reason, but the new node (and SMO) is a deterministic function of the node's contents *after* freezing, instead of being decided up-front. Revisiting the previous example, the thread now deletes the node instead of expanding to a larger node type with zero children.

We wish to highlight some nice properties of freezing and node replacement. Freezing is infallible, as each CAS is retried while the frozen bit is not set (it could be set by another thread concurrently freezing). Freezing is idempotent, and every thread that freezes a node, potentially concurrently, will see the same node contents after freezing. Finally, node replacement is symmetric: every thread that concurrently replaces a node will construct a logically identical replacement node, because the replacement is determined solely by the immutable contents of the old node after freezing.

Node append. Node256 is a total map from byte to edge; it does not need a node append SMO to create more byte to edge mappings. But smaller node types (Node3, Node15, Node47) are partial maps, and do require an SMO to create new mappings.

We note that node append operations always append an edge with a null child, which does not change the tree's logical contents. Updating this newly appended edge is a separate operation. We also note that, like ART, our partial maps grow monotonically (which is why there is only a node append SMO). Unnecessary mappings are removed during node replacement.

Node3 and Node15 are similar: their headers comprise an array mapping from edge index to key byte, and the length, i.e., number of valid mappings. Because their headers are less than 16B, we can atomically CAS the header to update the mapping and the length.

Node47 is different; while its header also contains the length, it uses an array mapping from key byte to edge index (this inverse mapping avoids sorting during range operations). This is too large to be updated in one CAS, yet requires writing both the array and the length atomically to maintain consistency. Naively performing two CASes does not work: CASing the array first can result in two key bytes mapping to

the same edge index, while CASing the length first can result in the same key byte being assigned two edge indices.

We solve this by introducing a `last` field containing the last appended key byte, adjacent to `len`. Now, before inserting, a thread first helps [17] ensure consistency of the `len` and `last` fields. These fields are consistent if the array entry at index `last` is equal to `len` − 1; if they are not consistent, then the thread CASes the array itself. This helping is infallible: if the CAS fails, it is safe to ignore, as another thread must have helped. After helping, the thread appends its own mapping by CASing `len` and `last`, and finishes by helping itself.

This Node47 append algorithm requires some scrutiny: unlike the other SMOs we have discussed, it requires two CASes (one to update `len`/`last`, and one to update the array) and is not obviously atomic. Intuitively, this SMO completes after the second CAS, when the array is updated: readers do not check `len` and `last` at all, and writers ensure the array is always consistent, including before freezing. This means that the intermediate state between two CASes is not observable by any other operation or SMO, and our append is atomic.

3.4 Traversal

Algorithm 1 Traversal algorithm

```
1:  root: &Edge
2:  key: &[u8]
3:  i ← 0
4:  j ← i + LEN(root.bytes)
5:  while key[i..j] == root.bytes do
6:      match root.child? with
7:          Value(value) ⇒ return Some(value)
8:          Node(node) ⇒
9:              root ← node[key[j]]?
10:             i ← j
11:             j ← i + LEN(root.bytes)
    return None
```

Without loss of generality, we focus on traversal to a full key. (Traversal to a key prefix is analogous, except it may end at an intermediate edge or node.) We present pseudocode in Algorithm 1; the `?` operator is Rust syntax for returning early if `None`. Traversal is wait-free, never back-tracks, and does not interact with freezing. Traversal can terminate unsuccessfully in three different ways: (1) when *key*[*i*..*j*] does not match *root.bytes* in line 5, (2) when *root* has no child in line 6, and (3) when *node* has no mapping for byte *key*[*j*] in line 9 (note that *j* is a valid index into *key* here due to Precondition 1).

3.5 Insertion

The happiest path for insertion is when all intermediate edges, nodes, and node mappings for a key already exist—in other words, traversal proceeds until terminating at an edge with no child, which we will call the *final* edge. To insert, we atomically CAS the final edge from null to the new value.

Now, let us consider all the ways in which the happy path might become sad. We will distinguish between two levels of sadness: the first level is when an SMO is necessary to continue traversal, but we still assume all of our CASes succeed. The second level considers when any CAS may fail; thankfully, this level is recursive, so we will not need more.

A little sad. In §3.4, we list the three ways traversal can terminate unsuccessfully. In each case, we perform an SMO, and then continue traversal: (1) if the key bytes do not match the edge bytes, perform edge expansion; (2) if there is no child, and the remaining key bytes do not fit in one edge, perform node creation; (3) if there is no node mapping for the key byte, perform node append, or node replacement if the node is full.

Very sad. We now consider what happens when CASes fail, recalling that the only locations we CAS in ARCTIC are node headers (node append SMO) and edges (everything else). The first thing we do on CAS failure is to deallocate any new node that was created (SMOs with new nodes in Figure 2). This does not require SMR, as these nodes are still local (Figure 3). Then our response depends on whether or not the CAS failed due to freezing.

Case CAS-UF (CAS failure, unfrozen) Somewhat surprisingly, we can handle all of these failures the same way, regardless of what SMO or operation the CAS is a part of, by simply continuing traversal from the current edge. To understand why this works, we can look at some concrete examples. If the CAS failure was due to a concurrent (1) edge expansion, we will match the new edge bytes and child and traverse into the new intermediate node; (2) insert or delete, we will match the same edge bytes and child and retry our operation; (3) node append, we will match the same edge bytes and child and retry our node append.

Case CAS-F (CAS failure, frozen) We can infer in this case that the node that contains this edge or node header is undergoing node replacement, since that is the only time we freeze. We cannot just wait for the node replacement to finish, since that would violate lock-freedom (suppose the thread that started node replacement died), so we help by performing node replacement ourselves.

This case may require back-tracking, which we implement by keeping a stack of edges during traversal: if we failed to CAS an edge, we need to go up to the containing node, and then up to the node's parent edge; if we instead failed to CAS a node header, we do not need to back-track, as we are already at the node's parent edge. Then we perform node replacement, handling CAS failures recursively according to **CAS-UF** and **CAS-F**. Intuitively, this algorithm is correct because node replacement is always safe (§3.3), so even if the current edge has changed since we first traversed it (e.g., a concurrent edge expansion SMO created a new node in between), node replacement will at worst be a no-op. We can tell if the current edge is now unreachable because its frozen bit will be set, in which case we recurse, potentially all the way to the root—but no further,

because the root edge is never frozen; it is not inside a node.

In practice, we almost never hit case **CAS-F**, let alone recursively. Backtracking more than one level requires multiple node replacement SMOs to occur *simultaneously* at *consecutive* levels of the tree. For perspective, we present some numbers from our YCSB insert-only workload (§ 4.1) with 100M random 8B integer keys and 80 threads, which induces the highest number of SMOs and conflicts. Only 324 of these 100M inserts reach case **CAS-F**, and none of them backtrack more than one level. We have never observed more than two levels of backtracking.

3.6 Deletion

Deletion itself is straightforward due to our update-in-place design: traverse to the value and CAS the final edge to null. The difficulty comes from garbage collecting empty nodes. There is a spectrum of viable options, ranging from fast—assume deletion is rare and do no garbage collection—to slow—scan node after deletion and perform node replacement if it can be deleted or compressed, recursing upward if deleted. Garbage collection can require more memory as garbage builds, while node scanning insures that only in-use nodes occupy allocated memory.

A node scan is required because we have no counter of non-null children, because having one would create a single contention point for each node (node header mappings are orthogonal to whether the edges have non-null children). Scanning small nodes (Node3, Node15) is cheap, but it is expensive to scan large ones (Node47, Node256). Another option is to asynchronously scan the tree and perform node replacement, which can be done at any time by any thread.

3.7 Scan

Like most concurrent indexes [18, 37, 38, 57], ARCTIC's range (and prefix) scans are not linearizable [31]. This is acceptable in many use-cases; for example, LSM trees [46] in key-value stores [26] scan when there are no writers, and databases can use multi-version concurrency control [11, 25]. ARCTIC does guarantee some weaker properties: a scan observes keys at most once, in lexicographic order, and observes all keys (within range) that were inserted before the scan starts, and not removed before the scan ends.

3.8 Correctness

We first show that our SMOs preserve the prefix tree invariants (§2.2), namely that for a given prefix there is at most one node in the tree and that each node in the tree has exactly one prefix. We also show that we preserve the freezing invariants (§2.4), i.e., frozen CAS locations are immutable, and nodes are frozen before unlinking.

For prefix tree invariants, we first observe that the only way to violate the uniqueness of node prefixes is for a node to contain an inconsistent mapping, i.e., mapping the same byte to more than one edge. As explained in §3.3, Node3 and Node15 prevent this because their mappings fit within a single CASable header and are updated atomically. Node47 maintains consistency through its helping protocol and Node256's mapping is trivially consistent. A node can only have more than one prefix if it is reachable from multiple parents. This is impossible because ARCTIC SMOs either allocate new nodes or copy existing children while preserving their prefixes.

For freezing invariants, every CASable location contains a frozen bit in headers and edges (§3.2), and all update operations respect it. Furthermore, node replacement freezes all CASable locations before unlinking, ensuring that no node can become unreachable before it is fully frozen. Once a node is fully frozen, no further updates to its CASable locations can succeed, and therefore its contents become immutable. Consequently, invariants (§2.4) are satisfied.

Claim 1 (Locality)**.** *SMOs in* ARCTIC *preserve the reachability and prefixes of their parents and non-null children.*

Sketch proof. No SMO modifies memory above its containing node, so parents are unaffected. Node append and node creation only make new mappings visible. Edge expansion introduces a new intermediate node and edge while preserving the reachability and prefix of the existing child. Node replacement copies all non-null mappings from the frozen node into the replacement node before unlinking the original node. Since the node is fully frozen beforehand, its contents cannot change during replacement and no reachable mapping can be lost. Therefore every non-null child remains reachable with the same prefix. □

This property allows us to reason locally about operations and ignore interference from concurrent SMOs occurring elsewhere in the tree.

3.8.1 Linearizability

Claim 2. *A successful insert of key $k+[b]+k'$ linearizes at the successful CAS that changes the child of the reachable edge with prefix $k+[b]$ and key k' from null to the inserted value. If a value for the same key already exists, then the failed insert linearizes at the load that observes the existing non-null value.*

Sketch proof. After traversal and any required SMOs (§3.5), insertion reaches an unfrozen reachable edge whose prefix matches the key.

The successful CAS makes the value reachable from the root and therefore inserts the key into the logical map. By the prefix-tree invariants, e is unfrozen and therefore reachable, and no other reachable edge can correspond to the same key, so this CAS is the linearization point.

If the child of e is already a non-null value, insertion fails without modification. Therefore the failed insert linearizes at the load that reads the existing value. □

Claim 3. *A successful delete of key $k+[b]+k'$ linearizes at the successful CAS that changes the child of the reachable*

edge with prefix $k+[b]$ and key k' from a value to null. If no value or key exist, then the failed delete linearizes at the load that observes the longest matching prefix and determines that traversal cannot continue or the value does not exist.

Sketch proof. The argument is identical to insertion. The edge is reachable and uniquely identified by the key prefix. The successful CAS atomically removes the value and therefore serves as the linearization point.

If traversal instead observes that the key has no associated value, either because traversal terminates unsuccessfully or because the final edge contains a null child, then deletion fails without modification. The operation linearizes at the load that observes this absence. □

Claim 4. *A get of key $k+[b]+k'$ linearizes at the load of the matching edge when traversal reaches an unfrozen reachable edge with prefix $k+[b]$ and key k'. If no such edge exists, the linearization point is when the operation observes the longest matching prefix and determines that traversal cannot continue. Otherwise, the traversal reaches a frozen matching edge, and the linearization point is the latest point between when the edge was frozen and when the get operation starts.*

Sketch proof. If the edge is not frozen, the claim follows from the same logic as insert (without executing any SMO operations). In the second case, traversal terminates at the first point where the searched key diverges from the tree structure, either due to a byte mismatch, a missing child, or a missing node mapping. If the edge is frozen, the reasoning is more delicate. We know the containing node is reachable (because we reached it through traversal). The edge is immutable after being frozen (freezing invariants). This edge must be the *only* reachable edge with prefix $k+[b]$ until the containing node is replaced (prefix tree invariants). Then we have a window between when the edge is frozen and when the containing node is replaced where the value under this edge cannot change; we choose the earliest time in this window as our linearization point. □

3.8.2 Lock freedom

We prove by contradiction. Assume there is some execution for which no executing operation terminates after a certain point α. In this case, we assume that no operation is invoked after this point, and given a finite number of running processes, the set of running operations is also finite. Then:

Claim 5. *There is a finite number of freezings of reachable nodes after α.*

Proof. A traversal operation must terminate after finding the closest prefix of the searched key traversing from the root, an insert operation must terminate after inserting the relevant key, or updating the value of that key if it already exists, and a delete operation terminates once updating the value of the relevant key edge to null, if it exists. The freezing happens when a node needs to be expended or compressed during an insertion or deletion. Therefore, since we have a finite number of inserted and deleted nodes after α, and since freezing is sequentialized on a node level and irreversible, we can conclude that the number freezings of reachable nodes after α is finite as well. □

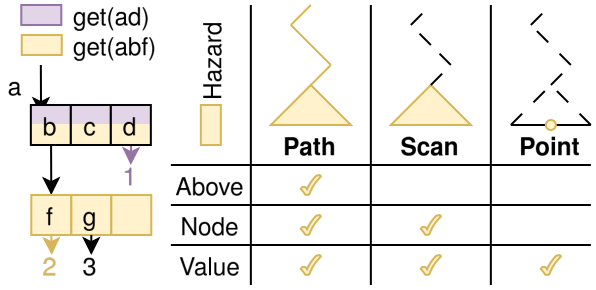

Figure 6: On the left, we show a concrete example of how an operation's key can be correlated with the structure of the tree; the two get operations in the top left will only access the nodes and values of their color. On the right, we show how a hazard key could be refined after traversal to a subtree for a scan operation, or a value for a point operation.

Claim 6. *There is a finite number of reachable node and edges changes after α.*

Proof. The nodes and edges only change along the insertion or deletion paths. They are caused due to SMOs or edge updates. We always keep traversing down the tree, even when CAS operations fail, unless we spot a freeze. Since freezing is finite (by Claim 5), we will backtrack up the tree a finite number of steps, and keep traversing down again. As the number of nodes and edges in the tree is finite, there is a finite number of reachable node and edge changes after α. □

Claim 7. ARCTIC *is lock-free.*

Proof. From Claims 5 and 6, after a certain point, there are no freezings or node and edge changes in the tree. Therefore, we consider the continuation of the execution that contains no state or pointer changes of reachable nodes and edges. From this point, ARCTIC does not change anymore. Since ARCTIC is finite, every traversal operation eventually ends. Furthermore, every insert and delete operation must be unsuccessful since no changes were applied, and so they also terminate. We get a contradiction and therefore, the implementation is lock-free. □

3.9 Hazard keys

We propose a new class of safe memory reclamation schemes by exploiting the correlation between prefix tree operations and structure. We will briefly introduce the key idea before discussing tradeoffs relative to existing schemes.

Recall that each node in ARCTIC is labelled with a prefix p (§2.2). A point operation on key k will only access nodes where p is a prefix of k; contrapositively, if a node's prefix p is *not* a prefix of k, then operation k will not access that node. The left side of Figure 6 shows a simple example: here, we can see that

no operation on key "ad" will access the bottom node (prefix "ab"), value 2 (prefix "abf"), or value 3 (prefix "abg"). Similarly, no operation on key "abf" will access value 1 (prefix "ad").

With this observation in mind, we propose the following SMR scheme: (1) include a prefix along with retired nodes or values, (2) publish a hazard key before each operation, and (3) reclaim allocations that are not protected by a hazard key, where an allocation with prefix p is protected by a hazard key k if p is a prefix of k. In other words, hazard keys use logical operations to cheaply approximate a set of physical hazard pointers [43].

The unique property of hazard keys is that their reclamation efficiency—how tightly an SMR scheme can bound the number of retired but unreclaimed allocations—is dependent on the request and key distribution. Hazard keys can tolerate thread stalls or oversubscription more gracefully than epoch-based schemes [29, 47], because a stalled thread prevents reclamation of a subset of allocations rather than all allocations. The same distribution-dependence is a liability under skew: a prefix is unlikely to be protected for long by uniformly random hazard keys, but could be protected indefinitely if the hazard keys are heavily skewed (so hazard keys, unlike their namesake hazard pointers, are **not robust**; they admit unbounded unreclaimed memory).

Hazard keys have lower overhead than hazard pointers, as a single hazard key can be published before an operation, whereas a hazard pointer must be published (and validated) before each pointer load. But hazard keys have higher overhead than epoch-based reclamation, as each retired allocation prefix must be matched against O(thread count) hazard keys, whereas an epoch comparison allows an entire batch to be freed.

We demonstrate these tradeoffs in our evaluation (§4.3), which suggests that hazard keys provide a reasonable balance of throughput and reclamation efficiency for low to moderately skewed workloads. There are many extensions outside the scope of this paper: for example, the right side of Figure 6 depicts how a hazard key could be refined at runtime to protect a subtree or single pointer, reducing the chance of false positives. Hazard keys could be hybridized with epochs to improve reclamation efficiency under high skew. And hazard keys could be adapted to comparison-based data structures like skiplists, with retired allocations associated with a key range, and protection determined by key comparison rather than prefix matching.

ABA problem. ARCTIC contains pointers to nodes and values. For nodes, we only CAS node pointers during node replacement (§3.3), after we have traversed into the node and while we hold a reference to the node, so any SMR scheme is sufficient to prevent the ABA problem. For values, the value could similarly be protected by SMR before CASing.

3.10 Optimization

Optimistic traversal. Back-tracking up the tree requires maintaining a stack of edge pointers during traversal. But a thread only needs to back-track in the rare case that it fails a CAS due to freezing. So we always try to perform operations first without keeping a stack; if we need to back-track, we restart the operation from the beginning with a stack.

Native integer support. Most radix tree implementations note that the memory representation of little-endian integers is not lexicographically ordered, and proceed to byte swap integers at their API boundary so they work well with internal byte arrays. Because integer keys are ubiquitous, we instead implement edge bytes as 8-byte integers, with endianness matching the key type. Integer keys store bytes from MSB to LSB independent of endianness, using a big-endian edge, while string keys use the system endianness. Integer edge bytes allow for branchless prefix matching, using XOR to diff the bits and counting leading or trailing zeros.

SIMD. We apply SIMD acceleration in two new places relative to ART: bitonic sorting [19] of Node15 headers, and iterating over Node47 headers. We also use SIMD within a register (SWAR) [34] for branchless lookup in Node3 headers.

System	Kind	Language	Lock-free
ARCTIC	Trie	Rust	Y
ART [35, 37]	Trie	C++	N
DashMap [4]	Hash map	Rust	N
FB$^+$-tree [18]	Hybrid	C++	N
Wormhole [57]	Hybrid	C	N

Table 1: Properties of the baseline systems in our evaluation.

4 Evaluation

Our evaluation seeks to answer the following questions:

- How does ARCTIC perform under different key distributions?
- How does ARCTIC affect the end-to-end performance of larger systems?
- When are hazard keys a viable option for safe memory reclamation?
- How effective are ARCTIC's optimizations?

We will present performance on YCSB [24] workloads under a variety of key distributions, performance on RocksDB [26] and Turso [11] benchmarks after integrating ARCTIC, memory reclamation efficiency on allocation-intensive workloads, and an ablation study on basic operations.

Experimental setup. We evaluate on a Chameleon [32] compute_icelake_r650 instance running Ubuntu 22.04.5 LTS and Linux kernel version 5.15. These instances have two Intel Xeon Platinum 8380 CPUs; each CPU runs at 2.30 GHz and has 40 cores, 120 MiB LLC, and 128 GiB of DDR4 3200 DRAM.

For reproducibility, we disable hyper-threading and turbo boost, set the CPU scaling governor to performance, and pin threads to cores.

Baselines. We compare against the latest ordered indexes we could find in the literature, along with the best-performing indexes in their evaluation, summarized in Table 1. ART [35] is the adaptive radix tree that ARCTIC is based on, using

Integer	Count	Description			
ipv4 [8]	139M	4 byte IPv4 addresses			
seq-u64	100M	Sequential 8 byte integers			
rand-u64	100M	Random 8 byte integers			
twitter [2]	100M	8 byte Twitter user IDs

Table 2: Key distributions, with length distributions for string keys.

ROWEX [37] for synchronization. DashMap [4] is a concurrent hash map written in Rust with consistently high throughput in open-source benchmarks [56]. FB$^+$-tree is a hybrid B+-tree and trie that supports wait-free search and lock-free update, but requires locks for SMOs. Wormhole is a hybrid B+-tree, trie, and hash map with O(log$L$) search complexity (where L is the key length). We exclude RDMA indexes ([38,51,52]) because their optimizations do not make sense for local shared memory.

4.1 YCSB

We run six YCSB [24] workloads across six key distributions (Table 2). Our YCSB workloads are standard: Load is 100% insert, YCSB-A is 50% read and 50% update, YCSB-B is 95% read and 5% update, YCSB-C is 100% read, YCSB-D is 95% read and 5% insert (skewed toward latest insertions), and YCSB-E is 95% scan and 5% insert. We use the default Zipfian request distribution with skew factor 0.99 and execute 100M operations. For values, we use 8-byte integers to reduce noise from memory allocation. In order to demonstrate ARCTIC's scalability, we evenly interleave memory and cores across NUMA nodes; in order to demonstrate scalable performance and lock-freedom, we evaluate at thread counts up to double the physical core count. We will briefly describe some of the key distributions (summarized in Table 2) before analyzing the YCSB results.

IPv4. We use 139M IPv4 addresses from the Stanford Internet Research Data Repository [50], extracted from the `saddr` field of `trial1_http_stanford64_zmap.json.lz4`.

Twitter. We use 100M Twitter user IDs from a public Kaggle dataset [3], extracted from the `ID` field of `twitter_users_20[0-9].idscreenname.csv`. Twitter user IDs (snowflake IDs [2]) are 63 bits, and can be generated without global coordination while providing a meaningful total order. An ID consists of—from most significant bit to least—a 41-bit timestamp, 10-bit machine ID, and a 12-bit machine-local sequence number.

Email. We use 100M emails from a public dataset [28], which we clean by matching against a regex [7], and preprocess by reversing the domain [38].

Url. We use 38M URLs from a public dataset [13], which we clean by removing URL query parameters.

For each combination of YCSB workload and key distribution, Figure 7 presents throughput vs. thread count (left columns) and peak memory usage (right-most column). ARCTIC excels at operations on integer keys, only losing a few times to DashMap. For string keys, ARCTIC provides competitive throughput on write-heavy workloads, but its read performance falls off as tree depth grows linearly with key length. Note that seq-u64 keys are optimal for ARCTIC structure (minimal depth, maximal Node256 count) and performance; we established with perf that YCSB-Load and YCSB-A with seq-u64 keys bottleneck on kernel-level page table contention (allocating new Node256 nodes) and hardware-level cache line contention (CASing final edges), respectively.

ARCTIC performs notably well on YCSB-A because updates modify minimal shared memory, only CASing the final edge to a value. We estimate cache line contention with hardware performance counters for hit modified events (mem_load_l3_hit_retired.xsnp_fwd + mem_load_l3_miss_retired.remote_hitm): ARCTIC averages 0.5 events per YCSB-A operation across all keys, which is consistent with a single CAS per update, and is a geomean reduction of 2.6× relative to DashMap, 3.0× relative to FB$^+$-tree, 3.8× relative to Wormhole, and 1.2× relative to ART.

ARCTIC achieves high throughput on YCSB-C in part through native integer key support, replacing `memcpy` and `memcmp` with efficient register moves and branchless prefix matching (§3.10), respectively. For example, for uuid-v4 keys, ARCTIC averages just 0.17 branch misses per operation, which is an increase of 1.14× relative to DashMap, but a decrease of 12× relative to FB$^+$-tree, 7.8× relative to Wormhole, and 2.5× relative to ART.

ARCTIC maintains throughput when threads are oversubscribed (past 80 threads), demonstrating its lock-free progress guarantees. Lock-based baselines exhibit some noticeable throughput losses, like ART in YCSB-B, and DashMap and Wormhole (which uses spinlocks) in YCSB-D. FB$^+$-tree locks for insertion and removal, but not reads or updates; its throughput is stable because its SMOs are infrequent and its spinlocks implement backoff.

ARCTIC's memory overhead is highly dependent on the key distribution, but generally comparable to ART and higher than other indexes. ARCTIC has low memory overhead for seq-u64 keys due to its dense Node256 nodes, and for string keys due to key bytes being shared along edges. ARCTIC has higher memory overhead for integer keys because its nodes and edges are large relative to the key size.

4.2 RocksDB and Turso

RocksDB [26] is a widely used persistent key-value store backed by an LSM tree [46]. LSM trees typically have an in-memory index component (memtable in RocksDB). RocksDB's default memtable is a lock-free concurrent skiplist, which we swap out for ARCTIC. We run RocksDB's bulk load benchmark, which inserts 100M randomly generated 20-byte keys and 400-byte values with write-ahead logging disabled.

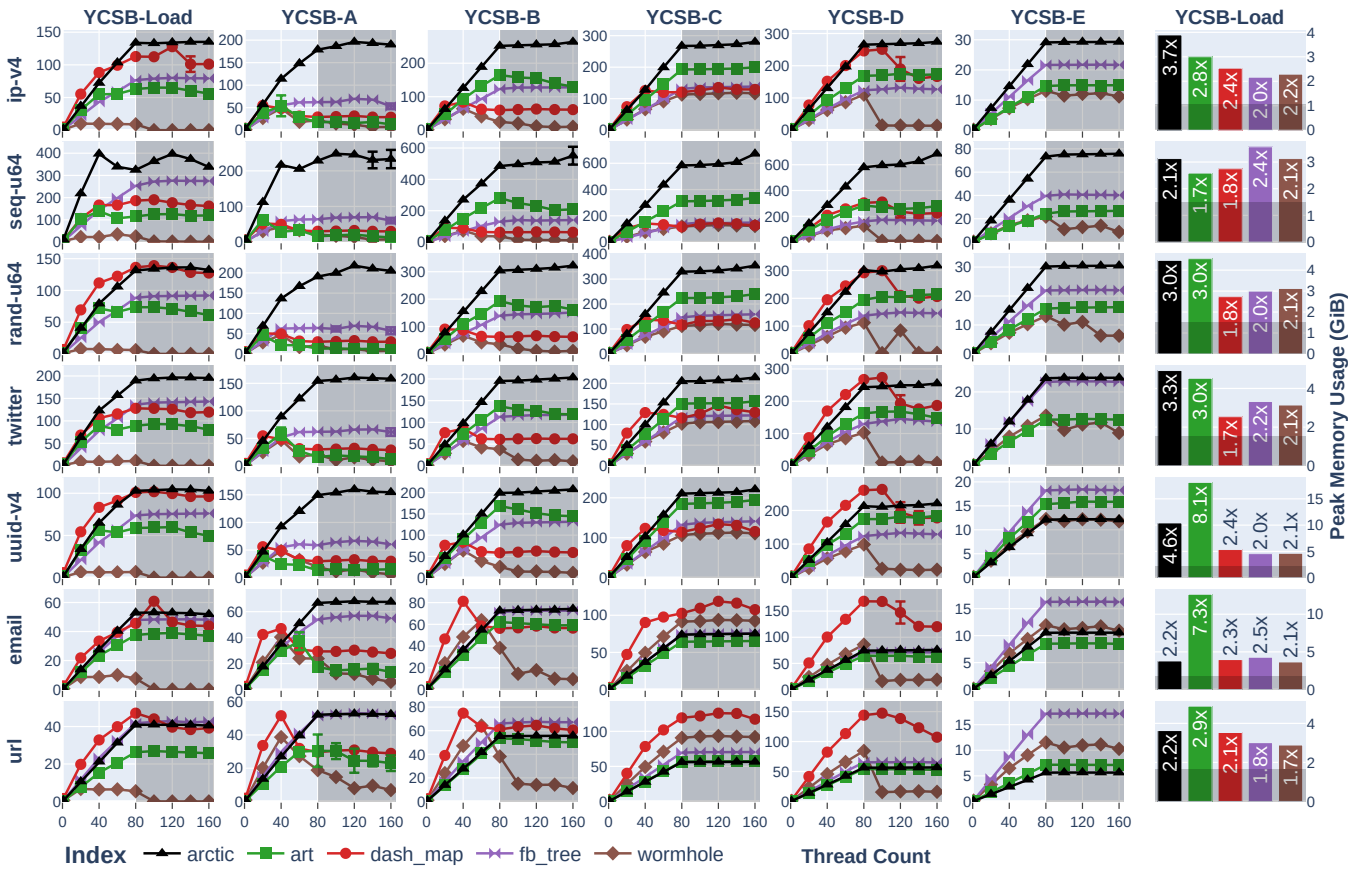

Figure 7: Throughput on YCSB workloads across different key distributions. Each row is a key distribution, and each column is a YCSB workload. The right-most column indicates the peak memory usage (measured by mimalloc) after loading with 80 threads. For the throughput graphs, the shaded area indicates thread oversubscription. For the memory graphs, the shaded area indicates the baseline size of inserted keys and values, and the text indicates memory usage relative to this baseline.

RocksDB Throughput (ops/sec)

Threads	1	2	4	8
skiplist	337K	413K	535K ± 10%	754K
arctic	1.36×	1.40×	1.13× ± 16%	1.05×

Turso Throughput (ops/sec)

Threads	1	2	4	8
skiplist	160K	240K	269K	254K
arctic	1.08×	1.10×	1.08×	1.12× ± 7%

Table 3: Average end-to-end throughput of RocksDB and Turso bulk load benchmarks when using original skiplist indexes vs. ARCTIC. Standard deviations under 5% are omitted.

Turso [11] is an open-source rewrite of SQLite in Rust. Turso supports concurrent writes via multi-version concurrency control (MVCC). The MVCC index uses a lock-free skiplist [6] to (1) map 16B row IDs to lock-synchronized row version data, and (2) map 8B transaction IDs to transaction metadata. We substitute these skiplists for ARCTIC and run Turso's multi-writer benchmark, which transactionally inserts 100K batches of 100 rows (one sequential integer and one short string per row).

Table 3 displays the end-to-end throughput of these two benchmarks using the original skiplists, and the relative throughput after switching to ARCTIC. On these workloads, ARCTIC improves RocksDB throughput by up to 1.40×, and Turso throughput by up to 1.12×. To better understand these results, we run RocksDB with internal performance counters enabled, and Turso with perf record. Figure 8 shows how ARCTIC consistently reduces time spent in index operations at all thread counts, but has less impact on end-to-end throughput at higher thread counts due to other system bottlenecks.

4.3 Hazard keys

To explore how hazard key reclamation efficiency varies with request distribution (§3.9), we run some SMR-intensive workloads—YCSB-A and YCSB-B with rand-u64 keys and 8-byte allocated values—and measure the peak number of retired but unreclaimed allocations. As baselines, we substitute hazard keys with crossbeam-epoch [5], a popular implementation of epoch-based reclamation [29] (EBR), and seize [12], a third-party implementation of Hyaline [45] (a hybrid of EBR and reference counting). For fairness, we configure all three with a retired batch size of 256 (crossbeam-epoch defaults to

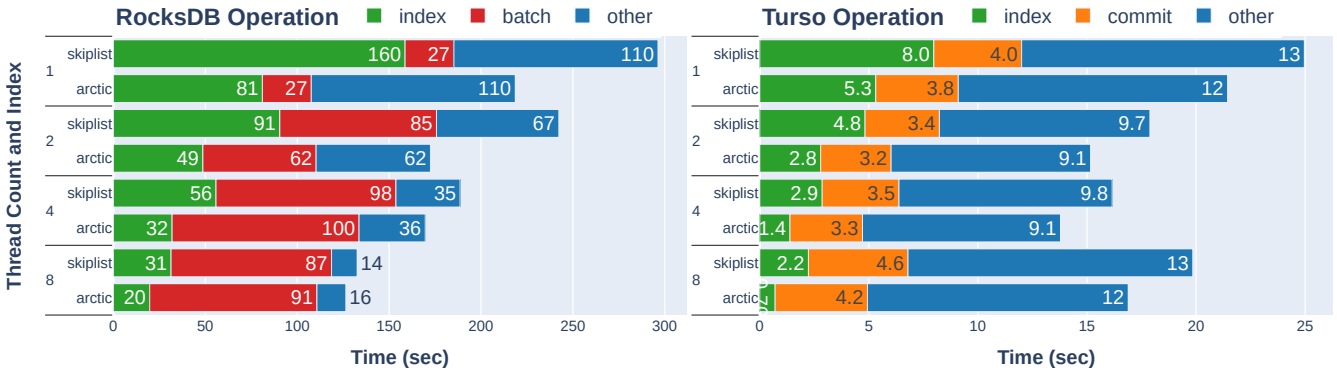

Figure 8: Performance breakdown of RocksDB and Turso bulk load benchmarks, showing how switching to ARCTIC reduces time spent in index-related operations. RocksDB measurements use internal timer metrics; Turso measurements use perf record.

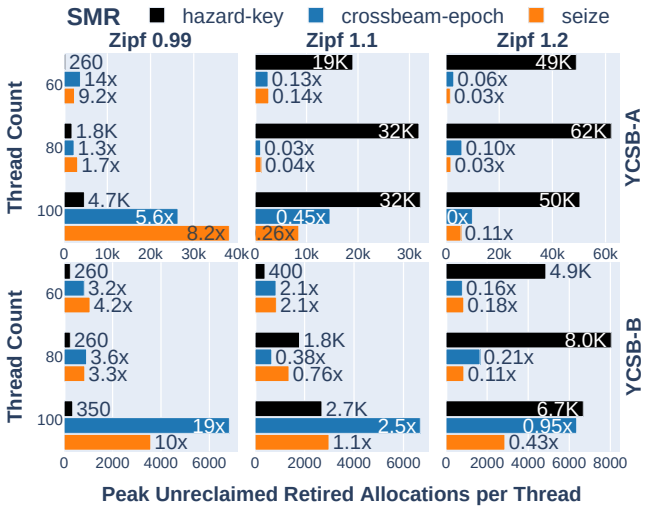

Figure 9: Reclamation efficiency of safe memory reclamation (SMR) schemes on SMR-intensive YCSB workloads with rand-u64 keys and allocated 8-byte values, varying skewness (Zipfian constant) and thread count. At Zipf 0.99, 17% of requests hit the top 10 (of 100M) keys, increasing to 33% and 48% at Zipf 1.1 and Zipf 1.2, respectively.

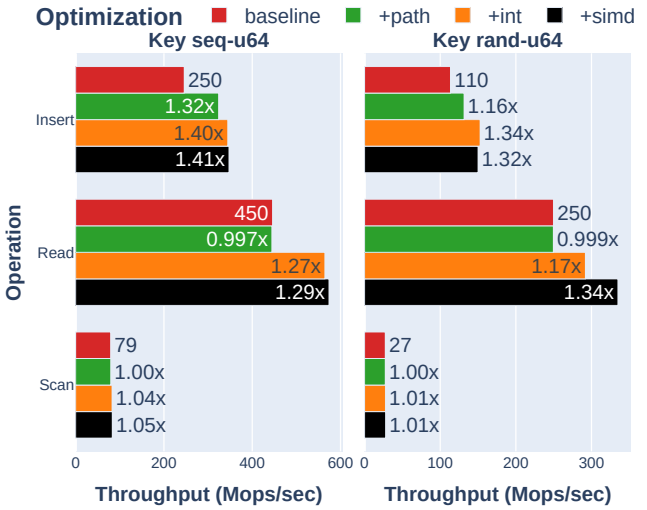

Figure 10: Effect of optimizations on ARCTIC operation throughput at 80 threads. Reads and scans use the default Zipf 0.99 skew from YCSB. *baseline* disables all optimizations; *+path* is optimistic traversal, which avoids maintaining a stack during insertion; *+int* is native integer support, as opposed to treating integer keys as byte arrays; and *+simd* uses SIMD for node header lookups and scans. The baseline is annotated with the absolute throughput; other bars are annotated with throughput relative to the baseline.

64, and seize to 32). (On YCSB-A at 80 threads, this batch size improves throughput by a geomean of 9.5% and 2.8× for crossbeam-epoch and seize, respectively, and affects peak garbage by -24% and +38%.)

Figure 9 shows that hazard keys can reclaim memory more efficiently than epoch-based alternatives when threads are oversubscribed, but only if the skew is low. At Zipf 0.99 and 100 threads, hazard keys reduce peak garbage by 5.6×-19× relative to baselines while retaining throughput close to crossbeam-epoch (+1.3% for YCSB-A, -12% for YCSB-B). Hazard keys can tolerate higher skew as the read proportion increases. The gap widens with thread count: EBR and Hyaline leave progressively more garbage as threads are added, and especially once they oversubscribe physical cores, because a single stalled thread blocks reclamation globally.

Under ideal conditions for all SMR schemes (Zipf 0.99, 80 threads), hazard keys incur throughput decreases of 7.2% and 6.3% relative to crossbeam-epoch for YCSB-A and YCSB-B, respectively, which is similar to seize (12% and 8.4%).

4.4 Ablation study

Figure 10 shows the effect of ARCTIC's optimizations (§3.10), applied cumulatively. Optimistic traversal (*+path*) helps only insertion (1.3× for seq-u64 keys, 1.2× random), as reads never back-track; the effect is larger for seq-u64 keys as threads insert disjoint key ranges, and almost never take the pessimistic path. Native integer keys (*+int*) reduce branches and instructions in the critical path of traversal, benefiting all operations and both keys. SIMD (*+simd*) has little effect on seq-u64 keys—these trees are primarily composed of dense Node256s that can be directly indexed by key bytes—but rand-u64 keys see more benefit due to SWAR acceleration of

Node3 header lookup. Scans, bounded by memory bandwidth, are insensitive to all three optimizations (under 1.05×).

5 Related Work

Lock-free adaptive radix trees. To the best of our knowledge, there are three other ART variants that claim lock-freedom: DART [61] (published concurrently with ARCTIC) and SMART [38] target remote direct memory access (RDMA), while HEART [44] targets persistent memory (PM). SMART side-steps read-unlink races at the cost of memory usage: it uses a single (maximally sized) layout for all nodes, and does not reclaim empty nodes. DART and HEART make a similar observation to ARCTIC that edge expansion SMOs can be made atomic by shifting edge bytes from child node headers to parent edges, but neither takes advantage of 128-bit atomics, and neither system is truly lock-free. HEART embeds versions in parent edges to coordinate unlinking of child nodes, but writers can block between version changes. DART similarly uses parent edges to coordinate, but embeds a frozen bit instead of a version. DART also introduces a grace period mechanism to allow progress in the common case, but writers can still block if node replacement stalls. The key distinction between ARCTIC and DART, which both nominally freeze nodes, is that ARCTIC freezes the *contents* of a node, while DART freezes the *parent edge* of a node. ARCTIC ensures every future update to a node will fail, guaranteeing immutability, whereas DART (and HEART) have a fundamental race condition between updating a node and loading its parent edge. ARCTIC also proposes a deterministic node replacement algorithm that any thread can use to help complete an in-progress node replacement without blocking.

Lock-based and lock-free designs. Concurrent ordered indexes have a long history of trading performance for progress guarantees. Classic high-performance trees such as Masstree [40] and other B+-tree variants rely on fine-grained locking or optimistic lock coupling: they scale well in practice on read-heavy workloads, but contended updates can still block, and careful engineering is required to avoid deadlock and priority inversion. Lock-free designs such as Bw-tree [55] reduce blocking by replacing in-place updates with delta records and indirection through mapping tables, but this complicates traversal and increases pointer chasing.

Other index families like skiplists and binary search trees are typically composed of smaller nodes relative to B+-trees, which makes lock-freedom easier to achieve, but ultimately limits their performance on modern hardware.

ARCTIC provides lock-freedom while preserving the cache efficiency of non-concurrent adaptive radix trees.

Safe memory reclamation (SMR). Safe memory reclamation (SMR) for lock-free data structures is vital for high performance. Hazard pointers [43] provide portable lock-free reclamation but incur per-access pointer publishing and global scans, imposing performance overheads on read-heavy workloads [23]. Epoch-based reclamation (EBR) amortizes costs by tracking quiescent states, but can leak memory in the presence of stalled threads [21, 30]. New SMR schemes like Optimistic Access [23] and AOA [22] automate or streamline reclamation for normalized lock-free algorithms. Hyaline attains near-EBR throughput with hazard-pointer-like robustness and bounded memory usage [45].

SMR and persistent memory. Several systems co-design their data structures with safe memory reclamation (SMR) and persistent memory (PM) constraints in mind. NBTree [60] introduces a lock-free B+-tree tailored to eADR-enabled PM. Elimination (a,b)-trees [49] (OCC-ABtree and Elim-ABtree) feature publishing elimination so concurrent inserts and deletes on the same key can cancel each other, dramatically cutting writes. These trees are durably linearizable and still nearly as fast as the volatile versions. Jiffy [33] is a lock-free skiplist–based ordered index that supports batch updates and linearizable snapshots. UPSkipList [20] provides a recoverable lock-free skiplists by adding epoch tags to nodes so that after a crash, threads can distinguish in-progress updates from stale, inconsistent state and repair accordingly, preserving correctness and scalability on NUMA PMEM machines. Easy Lock-Free Indexing in NVM [53] uses a persistent multi-word CAS primitive to build both a lock-free Bw-tree and a lock-free skiplist record store on PM.

6 Conclusion

ARCTIC is a lock-free adaptive radix tree that supports range and prefix scans while preserving a cache-friendly, low-indirection layout. By reorganizing its metadata to accommodate 128-bit atomic operations, ARCTIC maintains its structural invariants without extra pointer chasing or read-copy-update, making it practical to deploy in latency-sensitive, highly concurrent software.

Abstract

We explore the design of efficient and scalable synchronization for disaggregated shared memory. Porting existing synchronization primitives to such architectures results in poor performance scaling due to redundant inter-cache communications, exacerbated by high cache-coherence latency in disaggregated shared memory.

Driven by our insight that synchronization is a generalization of cache coherence in time and space, we argue for minimally extending existing cache coherence protocols to support synchronization primitives, thereby eliminating the redundant inter-cache communication inherent in layered synchronization. We propose a novel *G*eneralized cache-*C*oherence *P*rotocol (GCP) that realizes this insight by leveraging wait queues and variable-size cache lines directly at the cache-coherence layer for temporal and spatial generalization, respectively. We have verified GCP's correctness using model checking. We present Soul, an end-to-end system implementation of GCP atop a disaggregated shared-memory platform. Soul supports popular lock APIs through a user-space library that offers improved performance without requiring any changes to application code. Our evaluation of Soul against state-of-the-art locks shows that it improves the performance of unmodified real-world applications at scale by 1–2 orders of magnitude while incurring $< 8\%$ storage overhead.

1 Introduction

With the end of Moore's Law and challenges in scaling DRAM technologies [1], recent years have seen a push towards rack-scale compute-memory disaggregation [2–16], where server resources are physically decoupled into compute and memory blades connected via a high-speed network fabric. Several recent efforts have also focused on enabling cache-coherent shared-memory abstractions over the same high-speed networks for application transparency via a unified, consistent memory view [16–21]. We focus on page-based cache-coherent shared memory [16–18,20] in this work, where local DRAM on compute blades serves as cache for disaggregated memory, and these caches are kept coherent over high-speed Ethernet (§2.1).

In such systems, synchronization primitives such as locks [22–35] are crucial for the performance scaling of multi-threaded applications such as key-value stores [36–38] and databases [39–42]. Since such locks are already implemented atop cache-coherent substrates in multi-core CPU architectures (Fig. 1 (left)), it follows that these lock algorithms could also be ported to cache-coherent disaggregated memory.

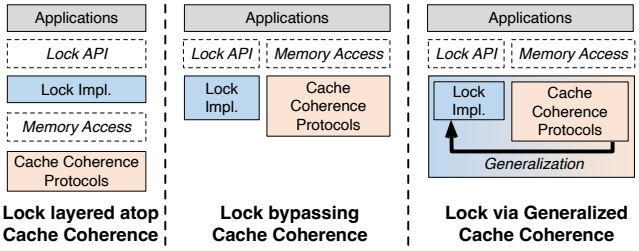

Fig. 1: **Different approaches for realizing synchronization.** Layered approaches (left) incur redundant coherence transactions while standalone approaches (middle) preclude key optimizations, both significantly degrading application performance over disaggregated memory's slower inter-compute and compute-memory interconnects. Our approach (right) *generalizes* cache coherence for efficient locks.

Unfortunately, despite improvements in network speeds, the higher latency of inter-compute and compute-memory links in rack-scale disaggregation renders cache-coherent substrates inadequate for the efficient implementation of lock algorithms, thereby limiting application performance at scale. While inter-core communication in multi-core and NUMA architectures exhibits latencies of 20–100 ns, page-based disaggregated memory exhibits latencies of 5–10 μs [16–18]. We find that even the most performant lock algorithms layered over state-of-the-art disaggregated memory coherence substrates [16,43] lead to poor application performance scaling, degrading performance for real-world synchronization-heavy workloads by as much as 1000×, due to redundant inter-cache coherence messages over higher-latency Ethernet links (§2.2).

To avoid such coherence overheads, prior distributed shared memory (DSM) [17,20,44–47] developed lock services that bypass the cache coherence substrates altogether (Fig. 1 (middle)). Unfortunately, porting such lock services to state-of-the-art disaggregated shared memory systems [16–18,20,21] still incurs intractable performance overheads. On the one hand, software-based lock services remain orders of magnitude slower than shared-memory accesses accelerated via programmable networks [16,18]. On the other hand, implementations of such lock services that leverage programmable networks suffer from stringent processing and storage constraints [48,49], precluding the adoption of many optimizations employed by prior DSM lock services (§3.3).

Toward scalable and performant locks for disaggregated shared memory, we pursue a third approach as shown in Fig. 1 (right), based on the insight that *lock-based synchronization is essentially a generalization of cache coherence in time and space*. Specifically:

Temporal generalization. Cache-coherence protocols guarantee the single-writer-multi-reader (SWMR) invariant [50], i.e., either a single exclusive writer or multiple concurrent readers can access a cache line (a 4KB page in page-based disaggregated memory) for a single instruction. Lock-based synchronization extends this property for an arbitrary number of instructions: the critical section.

Spatial generalization. Cache-coherence protocols ensure the SWMR invariant at a cache line granularity (i.e., a 4KB page), while reader-writer locks require this property for shared states of arbitrary sizes.

Therefore, extending existing coherence protocols to support these generalizations would provide the necessary semantics to enable lock primitives directly, eliminating the redundant communication seen in a layered design. Moreover, generalizing cache coherence protocols not only allows the lock realization to inherit decades of optimization from today's cache coherence protocols but also creates new opportunities to further improve lock scalability. These include directly moving the data associated with a lock during its acquisition and exploiting locality by caching both the lock and the associated data until they are explicitly invalidated.

We incorporate the above insights into GCP (§3), a novel class of *G*eneralized cache-*C*oherence *P*rotocols for lock-based synchronization. GCP minimally extends directory-based cache-coherence protocols using two key approaches:

Wait queues for temporal generalization (§3.1). Cache coherence guarantees that a cache line requested by a node will be held in the requestor's cache for a single instruction — subsequent requests from other nodes may immediately invalidate or downgrade the cache line permission on the original requestor. To allow a requestor to hold the cache line for more than one instruction, GCP prevents other requestors from invalidating or downgrading the cache line until the original requestor explicitly releases it, by suspending their cache coherence transactions in a wait queue.

Variable-size cache lines for spatial generalization (§3.2). While coherence protocols typically track fixed-sized cache lines, our spatial generalization lets each cache line track a list of arbitrarily sized memory regions (dubbed 'the shared memory list'). All shared regions tracked by a single cache line are atomically moved or invalidated from the target cache. This allows requestors to achieve SWMR semantics for arbitrary-sized shared regions during their critical sections.

These generalizations allow transforming some cache lines in the cache-coherence protocol into locks for synchronizing shared state in GCP; the remaining 'regular' cache lines still operate at a fixed size and single-instruction granularity. Moreover, since all our modifications are limited to the cache coherence protocol, GCP imposes no restrictions on the memory consistency model. We have verified GCP's correctness for a broad range of directory-based cache coherence protocols via model checking (§3.4).

We present Soul as a high-performance, end-to-end system implementation of GCP atop a state-of-the-art, Ethernet-based, disaggregated shared-memory platform [16], with minimal metadata overhead. Soul supports standard lock APIs via a user-space library, providing complete application transparency without requiring programmers to interact with low-level GCP interfaces. Soul also provides a lock manager to track the allocation of GCP cache resources and to handle application and system failures. Our evaluation (§5) shows that Soul enables scalable, high-performance synchronization across disaggregated memory. Compared to state-of-the-art lock algorithms, Soul improves real-world application performance at scale by 1–2 orders of magnitude without application modifications.

We also conduct a case study to validate GCP's generalizability to emerging CXL 3.0-based disaggregated shared memory systems [21] via a gem5 [51] simulation of Soul (dubbed SoulCXL; §6). While we demonstrate that the benefits of GCP also extend to hardware-based cache-coherence protocols, we leave a full adaptation to future work.

2 Background & Motivation

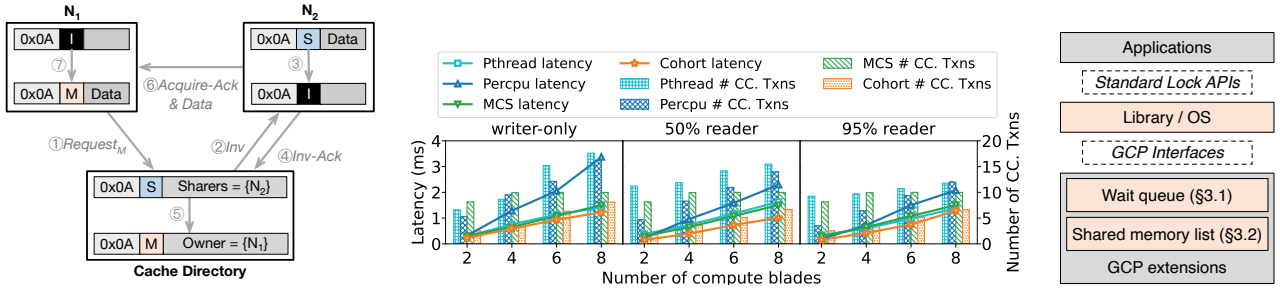
2.1 Page-based Disaggregated Shared Memory

As compute and memory resource scaling within a single server has started to stagnate, several recent efforts have argued for rack-scale memory disaggregation [13–18, 20, 52–56], where physical servers are disaggregated into compute and memory blades connected via a single network switch. To ensure application performance, these approaches adopt a partial disaggregation model, in which most of the memory is disaggregated, while compute blades retain a small amount of local DRAM as cache. In particular, these approaches leverage the OS's swap subsystem on the compute blade to cache memory from Ethernet-attached memory blades (*e.g.*, using RDMA) at page granularity in its local cache.

Increasingly, a large subset of these approaches [16–21, 57] have argued for a cache-coherent shared-memory abstraction over disaggregated memory to enable applications to transparently scale across compute blades. This effectively permits application threads to be placed across arbitrary compute blades and still access disaggregated memory via a unified, consistent memory view — akin to transparent Distributed Shared Memory (DSM) approaches [44–46].

While different systems vary slightly in how they implement disaggregated shared memory, they share a common core set of design elements. We illustrate these elements using MIND [16], an open-source, state-of-the-art disaggregated shared-memory system, on which our approach is implemented.

MIND comprises compute and memory blades connected via



(a) Directory-based MSI Protocol (b) Overheads of layering design (c) Overview of our design

Fig. 2: **Background & motivation (§2)** (a) Coherence example with a single cache line at address `0x0A`, a cache directory, and two compute blades (§2.2). (b) Lock acquisition latency and # of coherence transactions for locks layered atop coherence on disaggregated memory for different reader-to-writer ratios (§2.2). (c) GCP *generalizes* existing coherence protocols to realize locks (§2.2).

a programmable network switch. It keeps DRAM caches on compute blades coherent for transparent memory sharing.

Cache coherence. Similar to traditional DSM [44–47] and other disaggregated shared memory systems [17, 18, 20, 21], MIND uses *directory-based* cache-coherence due to its scalability. These protocols employ a cache directory to track the state of fixed-size memory units — typically referred to as *cache lines* and realized as 4KB *pages* in MIND — across the distributed caches. MIND places the directory on the programmable network switch because of its central location. The per-page state includes the list of compute blades currently holding the page (*sharer list*) and the permissions under which they hold it. When a compute blade attempts to access a page not present in its cache, the page fault handler first contacts the directory to check its current state, then notifies other compute blades on the sharer list of its intent to access the page, and ultimately coordinates subsequent data movement.

Specifically, MIND employs the directory-based MSI protocol, where each page can be in one of the three permissions: **M**odified (**M**), indicating a single compute blade has *exclusive* read and write permissions for the page, **S**hared (**S**), where multiple compute blades have *shared* read permission to the page, and, **I**nvalid (**I**), i.e., the page is not present in any compute blade cache. Fig. 2(a) shows an example with a single page at address `0x0A`, a cache directory, and two compute blades N_1 and N_2. The page is initially cached at N_2 with **S** permission. N_1 then requests it with **M** permission from the directory (①). The directory looks up the sharer list for the page and contacts N_2, its current holder, to *invalidate* it since N_1 needs exclusive access to it (②). Once invalidated (③), N_2 informs the directory (④), which then updates the page's permissions to **M**, records N_1 as the owner (⑤), and acknowledges N_1 with the page data (⑥). N_1 then accesses the page (⑦). While this example demonstrates the **S**→**M** transition in cache permission, other transitions are similar. We refer to these transitions as cache-coherence transactions. Minimizing the number of coherence transactions in synchronization primitives is essential for scaling the performance

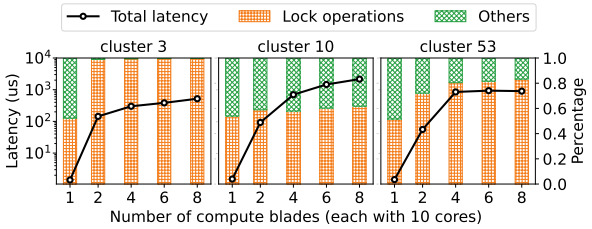


Fig. 3: **End-to-end request latency (left y-axis, log-scale) and %-age of time spent in synchronization (right y-axis)** for the state-of-the-art `Cohort` lock [27] on Twitter KV store workloads [58] atop MIND [16], a disaggregated shared memory system.

of parallel applications on disaggregated memory, since each transaction incurs multiple Ethernet round trips (§2.2).

2.2 Enabling Scalable Synchronization in Disaggregated Shared Memory Systems

Despite improvements in scalable cache coherence for disaggregated shared memory, lock-based synchronization remains a critical performance bottleneck in such systems.

Lock algorithms atop cache coherence. Scalable lock algorithms are typically built atop hardware coherence substrates in multi-core and NUMA architectures to permit either a single exclusive writer or multiple concurrent readers to access a critical section. Most scalable lock designs minimize the number of coherence transactions required for lock acquisition. For instance, queue-based lock algorithms [25, 26, 59] let each requestor thread spin on a core-private cache line, reader-writer locks partition reader-indicators [32] to avoid coherence transactions for concurrent readers, while memory-hierarchy-aware locks [27–31] exploit memory locality to avoid coherence transactions across NUMA nodes.

Unfortunately, even with optimized designs, lock algorithms layered atop cache coherence tend to severely limit application performance at scale in disaggregated shared memory systems. Fig. 3 shows the total request handling latency

and the percentage spent in lock operations for three Twitter key-value (KV) store workloads [58] using `cohort` locks [27], a state-of-the-art high-performance lock, atop MIND [16] (setup in §5). While request handling consumes under 10μs on average on a single compute blade, it can increase to over 1ms at 8 blades, with most of the time spent in lock operations! This is because each lock operation must trigger multiple expensive cache coherence transactions over Ethernet.

These coherence overheads are not limited to `Cohort` locks; they apply to all state-of-the-art locks built atop cache-coherence substrates. Fig. 2(b) shows that representative locking algorithms trigger many coherence transactions with multiple blades for workloads with varying degrees of read-write contentions, translating into milliseconds of lock acquisition and data access latency. Similar overheads have been demonstrated in prior studies [60–63] for multi-core architectures, even with much shorter inter-cache latency.

Locks bypassing cache coherence. To circumvent the inefficiencies of layering locks atop cache-coherence substrates, DSM systems [17, 20, 45–47] employ standalone software-based lock services that *bypass* the cache-coherence layer altogether, *e.g.*, via lock managers that serve lock requests using a client/server model [45], or distributed lock protocols that bypass shared memory [46, 47]. However, with recent disaggregated shared-memory systems [16, 18] that use programmable network hardware to accelerate cache coherence, software-based lock services incur latency that is orders of magnitude higher than cache-coherent memory accesses, making them an inadequate choice for synchronization.

Although programmable network-accelerated lock services [48, 49] can potentially deliver latency comparable to network-accelerated cache-coherent memory accesses, they require additional resources in an already resource-constrained programmable network switch. In fact, even if all of the programmable switch resources were allocated solely to the lock service, it would still fail to support critical performance optimizations that require complex coherence logic to be realized within the lock service [48, 49, 64] (§3.3).

Our approach. Fundamentally, cache coherence and lock-based synchronization strive for the same goal: single-writer, multi-reader (SWMR) invariant [50] over some shared state, i.e., at any point, either a single entity that intends to modify the shared state has *exclusive* access, or multiple entities that intend to read the state have *shared* access. However, while cache-coherence protocols enforce it at a single-instruction granularity (in time) and a fixed cache-line granularity (in space), lock algorithms strive for an SWMR invariant at arbitrary instruction counts (in a critical section) and data-size granularities. In other words, lock-based synchronization *is a generalization* of cache coherence in time and space.

Our approach builds on this observation and argues for *minimal* extensions to cache-coherent substrates to realize generalized coherence protocols (GCP) that can natively support lock primitives (Fig. 2(c)). Our extensions — a wait queue for temporal generalization (§3.1) and a shared memory list for spatial generalization (§3.2) — permit all lock operations to be realized using a single coherence transaction, avoiding overheads of layered designs. Moreover, unlike approaches that bypass coherence, GCP enables new optimizations that leverage the interplay between synchronization and coherence, while still allowing synchronization to benefit transparently from coherence protocol optimizations (§3.3). Finally, minimal extensions to coherence protocols permit easier verification (§3.4) and adoption in emerging coherent interconnects [43] (§6).

3 GCP Design

We provide an architecture-agnostic description of GCP design (§3.1 and §3.2). We then present GCP optimizations enabled by generalizing cache coherence protocols (§3.3) and conclude with a verification of GCP's correctness (§3.4).

3.1 Wait Queue for Temporal Generalization

As we saw in §2.2, a directory-based cache-coherence protocol ensures the SWMR invariant at a single instruction granularity by tracking the permission of the requested cache line (*e.g.*, **M**, **S**, or **I** in the MSI coherence protocol[1]). If an instruction's execution on one blade requests a cache line with a specific permission, the protocol triggers a transaction that immediately makes the cache line available to that instruction with that permission. To enable the temporal generalization of the protocol, where a blade can hold the cache line with its requested permission for an arbitrary number of instructions, GCP defers cache requests with conflicting permissions by enqueuing them in a *wait queue* and dequeuing a request only when the previous blades release the cache line.

Added cache interfaces. We add three new cache request types to interact with the wait queue (Table 1): `GCP_acquire` to request the cache line with the provided permission and mark the beginning of the critical section, `GCP_is_acquired` to check whether the line has been acquired with the provided permission, and `GCP_release` to release the cache line and mark the end of the critical section. To avoid blocking while a blade waits for a lock, the `GCP_acquire` request is *asynchronous*, i.e., the initiating blade does not block while it waits for completion. Once the corresponding transaction completes, the cache line's permission is updated to indicate that it has been acquired, and the blade can check this status via `GCP_is_acquired`. As we show in §4.3, this allows context switching to another thread while waiting for a GCP lock.

[1] While we use the MSI coherence protocol to illustrate our extensions, they apply to any directory-based cache-coherence substrate.

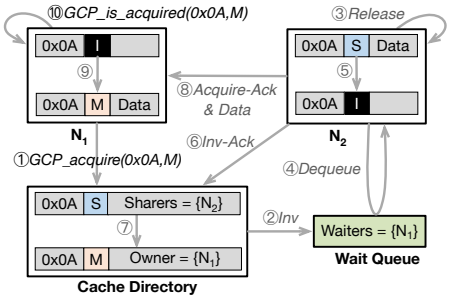

Fig. 4: **Temporal generalization with wait queues (§3.1).**

Shared memory list interfaces
`int GCP_create(size_t len, addr_t *addrs, size_t *sizes);`
`int GCP_destroy(size_t len, addr_t *addrs, size_t *sizes);`
Wait queue interfaces
`int GCP_acquire(addr_t addr, int perm);`
`int GCP_is_acquired(addr_t addr, int perm);`
`int GCP_release(addr_t addr);`

Table 1: **GCP interfaces (§3.1, §3.2).**

Handling evictions. Evictions of cache lines to memory used as locks require careful consideration since they can inadvertently terminate the current lock ownership. A naïve solution could pin such cache lines to prevent them from being evicted, but this can result in starvation or deadlocks. For instance, if a thread holding a lock is switched out by the scheduler, its cache lines used as locks would block space in the cache, starving the currently running thread of cache resources. Moreover, if a blade's entire cache is used as locked cache lines, no more regular or lock-based cache lines can be brought into cache, resulting in a deadlock!

To this end, GCP enables eviction of lock-based cache lines by adding a set of new transient states to the directory entry that can mark a cache line as both evicted and locked after it is cleared from local cache. This allows a thread to retain its lock ownership even when it is switched out, or a cache line is evicted. Any new request for such a cache line from another thread is granted if the requested and currently held permissions for the cache line are compatible (*e.g.*, both are **S** in an MSI protocol); otherwise, it is directed to the wait queue.

Example. Fig. 4 demonstrates how a wait queue can enable temporal generalization for the same example in Fig. 2(a). The target cache line is initially cached at N_2 with **S** permission. N_1 then issues an `GCP_acquire` request for the same cache line with **M** permission to the cache directory (①). The directory looks up the current cache line permission (**S**) and sharer list ($\{N_1\}$), realizing that the request requires N_2 to relinquish the cache line via invalidation. In contrast to standard MSI protocol execution, the directory defers the invalidation and instead enqueues N_1's request in a wait queue associated with the cache line (②). Only when N_2 finishes its critical section and voluntarily releases the cache line via `GCP_release` (③) is the request dequeued (④) and the invalidation performed at N_2 (⑤). The remainder of the cache-coherence transaction proceeds as per the standard MSI protocol — N_2 informs the directory (⑥), which updates the cache line's permission to **M** and marks N_1 as the only sharer (⑦), and sends N_1 an acknowledgment along with the cache line data (⑧). N_1 then transits to **M**, which is detected via `GCP_is_acquired` (⑩).

As with cache coherence, other permission transitions are similar or simpler. **M**→**M** and **M**→**S** transfers require similar deferred invalidations, enqueuing the transfer requests in the wait queue until the blade holding the cache line with **M** permission explicitly releases the cache line. **S**→**S** transfers do not require enqueuing the request since multiple readers can hold the cache line simultaneously under the SWMR invariant. **I**→**S** and **I**→**M** transfers also do not require enqueueing requests since no blade has the cache line to begin with.

The wait queue's location does not affect correctness but does affect performance; we discuss how our implementation navigates performance tradeoffs for queue placement in §4.1.

3.2 Shared Memory List for Spatial Generalization

Unlike coherence protocols that track permissions for a fixed-size cache line, locks must preserve the SWMR invariant across arbitrary amounts of shared state. The shared state may be fragmented and even empty. This requires extending cache-coherence protocols to track multiple shared memory locations of arbitrary size. Specifically, instead of a single address with a fixed size, each address tag in GCP is logically a list of (m_i, s_i) pairs, where m_i and s_i are the base address and size in bytes of a shared memory region, respectively. Note that the *shared memory list* is a cache-movement optimization rather than a lock enforcement mechanism: the wait queue (§3.1) alone enforces the lock semantics, and the shared memory list merely bundles the shared state into a single coherence domain — without it, the lock remains correct, but accesses to shared state incur additional coherence transactions.

Added cache interfaces. We add two new cache interfaces (Table 1) for creating and destroying shared memory lists. `GCP_create` associates a list of address ranges with a shared memory list (to be tracked via GCP), while `GCP_destroy` destroys the shared memory list, marking the associated address ranges as regular cache lines (tracked via regular coherence transactions). To ensure consistency in the shared memory list's creation and destruction, both interfaces are broadcast to all blades and the cache directory, regardless of which blade triggers them, and they force a cache flush for all involved lines at all blades. In addition, GCP requires that all shared memory lists contain non-overlapping memory regions; i.e., `GCP_create` returns an error if any of the involved regions are already associated with another shared memory list.

Example. Fig. 5 shows our spatial generalization for the

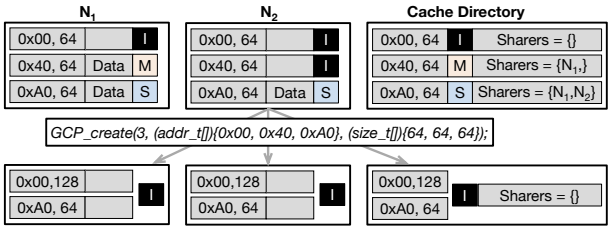

Fig. 5: **Spatial generalization with shared memory lists (§3.2).**

same example as Fig. 4. N_2 initializes the shared memory list by issuing `GCP_create` over three 64*B* cache lines at `0x00`, `0x40` and `0xA0`, which are merged into a list of two shared memory regions (`0x00`, 128) and (`0xA0`, 64) with their cache permissions reset to **I**. Coherence transactions over the shared memory list are identical to Fig. 4, except the invalidation step ⑤ now requires N_2 to remove two memory regions of different sizes from its cache, and in step ⑧, the directory sends N_1 the data for both regions with the acknowledgment. We discuss its implementation in §4.2.

3.3 Cache-coherence Optimizations

Since GCP realizes synchronization by generalizing cache coherence, it automatically inherits optimizations from traditional cache-coherence protocols, which are intractable with stand-alone lock services due to resource constraints (§2.2). We show in §5.3 that each optimization can improve lock acquisition performance by over an order of magnitude.

Acquiring data along with lock. GCP can acquire the lock and the associated data in a single cache coherence transaction, reducing delay and coherence traffic when placing the corresponding data in the requestor's cache. In contrast, even with prefetching, such coupling is impossible with traditional lock algorithms, since they can fetch the shared state only after the lock is acquired, delaying the requestor by at least one coherence transaction.

Exploiting temporal locality for locks. In traditional coherence protocols, once a cache line is placed in a requestor's cache, it remains there until it is invalidated to exploit the temporal locality of data accesses. In extending such protocols, GCP inherits the same optimization: both the lock and the associated data remain in the requestor's cache until another request invalidates them.

3.4 Correctness

Theorem 1. *GCP locks are correct, i.e., GCP satisfies mutual exclusion and deadlock-freedom.*

Intuitively, the mutual exclusion property for reader-writer locks implies that no two writers, or a reader and a writer, can enter the critical section concurrently — which is equivalent to the temporally generalized SWMR invariant of cache coherence. Due to the complexity of the underlying cache coherence protocols, we validate GCP's correctness (mutual exclusion and deadlock-freedom) via model checking. We used ProtoGen [65], a state-of-the-art cache coherence protocol synthesis tool, to generate specifications for four representative directory-based protocols: MSI [66], MESI [67], MOSI [68], and MOESI [69], and to integrate GCP into these specifications. We then used the Murphi [70] model checker to verify deadlock freedom and mutual exclusion in all reachable states. Like many prior works on cache coherence validation [19, 65, 71–73], our model checker is limited to a single address, two data values, three blades with private caches, and a directory to validate protocol correctness, thereby avoiding a state-space explosion. Our microbenchmarks (§5) on up to 8 blades with 80 cores over many addresses also serve as correctness "stress" tests for GCP implementations. While we guarantee correctness at the protocol level, it is still the programmer's responsibility to avoid application-level deadlocks, as we detailed in §4.3.

Finally, we note that GCP locks are also starvation-free (fair) if the wait queue policy is starvation-free (*e.g.*, FIFO). Intuitively, starvation-freedom requires that any lock requests will eventually succeed. GCP can only block lock requests in the wait queue: the remainder of the cache coherence transaction execution is non-blocking by design. As such, if the wait queue is starvation-free, any queued lock requests will eventually be processed, i.e., GCP locks are starvation-free.

4 Soul: An Implementation of GCP

We present Soul, a high-performance end-to-end system realization of GCP atop MIND, a state-of-the-art page-based, disaggregated shared-memory platform (Fig. 6). Soul realizes GCP atop MIND's inter-blade DRAM cache coherence to facilitate inter-blade synchronization. Soul does not affect MIND's regular pages[2] (i.e., those not used as locks), and retains MIND's x86-TSO memory consistency model since all modifications are restricted to cache coherence. Soul makes minimal extensions to MIND's programmable cache coherence substrate to implement GCP's wait queue (§4.1) and shared memory lists (§4.2). To ensure application transparency, Soul provides a user-space lock library as a shim atop its GCP implementation, exposing standard lock APIs (§4.3). Finally, Soul's lock manager allocates GCP cache resources to ensure cache integrity and handle failures (§4.4).

4.1 Implementing the Wait Queue

A natural way to implement the wait queue in Soul is to reuse the coherence protocol's message buffers, blocking cache

[2]Throughout this section, we use *page* as the unit of inter-blade coherence to reflect MIND's 4KB cache granularity.

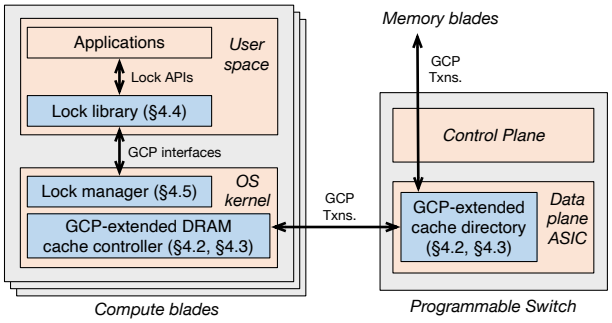

Fig. 6: **Soul is a full-system realization of GCP atop MIND (§4).**

requests at MIND's in-kernel cache controllers or in-network directory. However, this adds significant network delays to lock acquisition due to Ethernet's high latency. When the lock owner releases the lock, additional network trips are needed to dequeue the next request if it is stored in the directory. Instead, placing the queue with the page's current owner (compute blade) avoids these delays and bypasses the limited compute and storage resources of switches [16, 18, 48, 64, 74]. The directory only tracks which compute blade holds the queue (the queue holder) so it can forward access requests accordingly.

However, if multiple compute blades (readers) hold the page, the wait queue must be replicated across all readers so they can locally dequeue the next request, requiring a mechanism to ensure consistency across queue replicas. The problem is further exacerbated when the page ownership changes over time. We address this with **a novel queue transfer protocol** between compute blades, which guarantees (i) no network delay in processing the next request in the queue and (ii) consistent access to the queue itself.

Queue holders: A queue holder enqueues any requests for a page until it is voluntarily released. The directory tracks the queue holder and forwards access requests to it. Soul ensures that there is only one queue holder per page at any time, avoiding consistency issues associated with replication. To achieve this, we leverage GCP's SWMR invariant: since only a single writer (i.e., a thread requesting the page with **M** permission) can hold a page at a given time, only one blade (the one hosting the writer) needs to track the queue at that time. While multiple readers (i.e., threads requesting the page with **S** permission) can hold a page concurrently, placing the page at additional readers does not require enqueuing requests (§3.1), i.e., no queue is required for a page that is only requested by readers. However, if a writer subsequently requests a page that is initially held by multiple readers, a queue is created on the compute blade hosting the writer.

Fig. 7 shows three possible cases for a page's wait queue:
Case (i): The wait queue does not exist when no writers are requesting the page (i.e., for a page with **I** or **S** permission that has no waiting writers).

Case (ii): The wait queue is at the current writer (i.e., for a page with **M** permission)

Case (iii): The wait queue is at the next writer when the page is held by one or more readers (i.e., for a page with **S** permission with a waiting writer).

Queue transfers: When a writer attempts to acquire a page (① in Fig. 4), either the wait queue has already transferred to it (described next) or it must create an empty one (transition to **Case (ii)**). When a writer releases the page (③ in Fig. 4), the writer drops the queue if there is no waiting requestor (transition to **Case (i)**). Otherwise, the writer processes the next queue entry and transfers the queue to the next writer. Specifically, if the next requestor is a writer, the queue is transferred to it (transition to **Case (ii)**). If the next requestor is instead a reader (readers) and a writer is waiting behind it (them), the queue is transferred directly to the writer (transition to **Case (iii)**). If there are no writers behind the reader(s), the queue is dropped (transition to **Case (i)**).

Since readers never hold the queue, the dequeue operation happens only in **Case (ii)**, when the current writer is the queue holder. This property ensures no network delays are incurred when dequeuing and processing the next requestor.

Consistency during queue transfers: If the cache directory forwards an access request to a queue holder transferring its queue to another compute blade, should this request be processed by the original queue holder or the next one? To resolve such ambiguities, Soul employs a versioning mechanism to ensure the queue transfer occurs *atomically*. The directory maintains a version number for each page, tracking the number of access requests it has forwarded to the queue holder. The queue holder maintains its own version number to track the number of access requests it has received from the directory. The switch approves a queue transfer only if the queue holder's version number matches the one in the directory. This ensures that all access requests forwarded by the directory must have been processed at the queue holder before the holder initiates the transfer. If the switch denies a transfer, the queue holder retries after receiving the notification from the switch. On a successful transfer, the version numbers at the switch and queue holder are reset to zero.

Storage overheads: Since the wait queue size is bounded by the number of compute blades (n) in the system, we implement it as a fixed-length array of size n. Each $\log n$-bit entry contains the requestor's ID and the request type, adding $n \cdot \log n$ bits for the entire queue. Each directory entry consumes $2 \cdot \log n$ bits to track the queue holder and version number. Since each page is 4KB and each directory entry's size is 76 bits in MIND, Soul's metadata storage overhead for an 8-blade setup is $< 0.2\%$ at the compute blade kernel and $< 8\%$ at the switch ASIC.

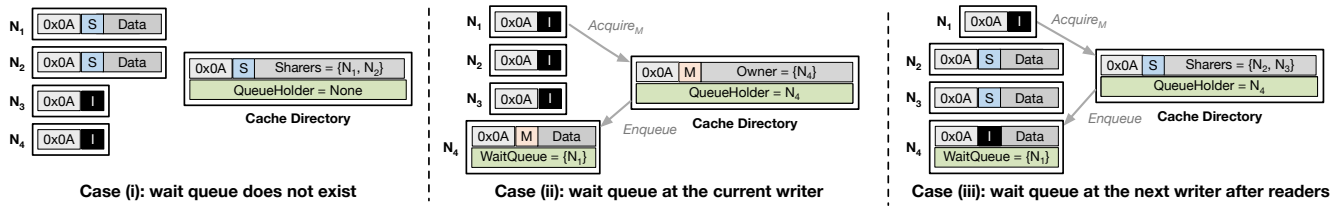

Fig. 7: **Wait queue holders under different cases in Soul (§4.1).** Case (i): the wait queue does not exist without writers; Case (ii): the wait queue is at the current writer; Case (iii): the wait queue is at the next writer after the current readers.

4.2 Implementing the Shared Memory List

To overcome the limited memory and processing constraints of programmable switches, we decouple the shared memory list from the directory entries and maintain them on the compute blades, i.e., as metadata associated with a page in the in-kernel cache controller, incurring no storage overhead on the programmable switch ASIC. The compute blades and the switch identify a shared memory list using its lowest address. Our implementation adds 9 bytes to the metadata associated with each page in MIND: 1 byte to track the region length and 8 bytes for the pointer to the next shared memory list entry. As each shared region is at least 4KB, this incurs $\leq 0.3\%$ storage overhead in the compute blade kernel. Consistent with how MIND tracks regular pages, the shared memory lists are tracked as virtual addresses since address translation in MIND occurs *after* coherence resolution [16].

4.3 Soul Lock Library

While Soul provides a high-performance implementation of GCP, ensuring application transparency requires that Soul be usable via standard lock APIs; otherwise, applications would need extensive modifications to exploit GCP's benefits. As such, Soul provides a lock library that serves as a shim atop its GCP implementation (Fig. 6) and exposes standard lock APIs. We find that bridging the gap between GCP interfaces and the standard lock APIs introduces new implementation

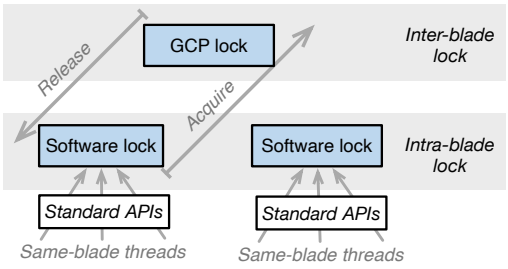

Fig. 8: **Soul lock library's hierarchical design (§4.3).**

challenges. We next describe the standard lock APIs that Soul supports, followed by the challenges and solutions for implementing these APIs in Soul's lock library using GCP interfaces.

Supported lock APIs. Soul lock library supports two standard lock APIs: the POSIX lock (i.e., `pthread_rw_lock`) APIs in C and `std::sync::RwLock` APIs in Rust (Table 2). To use Soul, applications simply link against our lock library rather than the standard libraries (*e.g.*, `libpthread`). The major difference between the two APIs is that while `pthread_rw_lock` provides only locking functionality, `std::sync::RwLock` additionally requires programmers to explicitly specify the lock-protected shared object (*e.g.*, `list` in Table 2) on lock creation for memory safety. Interestingly, this information enables our lock library to transparently implement GCP's combined data optimization (§3.3), that is, the shared object can be prefetched with lock acquisition. Our current lock library does not transparently handle shared objects whose memory footprint changes mid-critical-section (*e.g.*, a Rust write-lock holder calling `clear()` on a lock-protected list, or appending new entries to it); in such cases, the lock holder must destroy the existing shared memory list and create a new one reflecting the updated footprint via `GCP_destroy` followed by `GCP_create` (Table 1). This preserves correctness but is not the most efficient approach: each refresh incurs the broadcast and cache-flush overhead of those interfaces — a current limitation in Soul. A future extension could allow a writer lock holder to modify the shared memory list in place, eliminating this overhead.

Unfortunately, realizing these APIs is not as straightforward as wrapping the corresponding GCP interfaces in Table 1 (*e.g.*, `GCP_acquire with pthread_rwlock_wrlock`). This is

Lock initialization

```
int inter_blade_lock_init(cachepage_t *lock) {
  size_t size = CACHE_PAGE_SIZE;
  return GCP_create(1, &lock, &size);
}
```

Writer lock acquisition

```
int inter_blade_wrlock(cachepage_t *lock) {
  int ret;
  if (ret = GCP_acquire(lock, M))
    return ret;
  while (ret = GCP_is_acquired(lock, M)) {
    if (ret != EAGAIN) return ret;
    /* Spin or yield CPU to another thread */
  }
  return 0;
}
```

Lock release

```
int inter_blade_unlock(cachepage_t *lock) {
  return GCP_release(lock);
}
```

Table 3: **Simplified inter-blade lock implementation for the `pthread_rwlock` API using GCP interfaces (§4.3).**

because GCP only exposes synchronization interfaces between *caches* rather than *software threads* — it is still challenging to distinguish two threads running on the same compute blade, sharing the same cache, as separate lock requestors or holders. Next, we detail how our lock library bridges this gap via *hierarchical locking*.

Supporting thread-level APIs via hierarchical locking. Soul lock library distinguishes threads running on the same compute blades as separate requestors via hierarchical locking. This is akin to lock-cohorting [27], a technique originally used to improve lock acquisition throughput and latency in NUMA machines by prioritizing the lock handover to "nearby" threads (*e.g.*, threads on the same NUMA node) over farther ones (*e.g.*, those on different NUMA nodes). As shown in Fig. 8, a Soul lock acquisition comprises two steps: it first acquires an *intra*-blade lock—implemented as a traditional software-based lock—to enforce SWMR among threads on the same blade, and then acquires an *inter*-blade lock using GCP to enforce SWMR globally. Thus, threads running on the same blade can be identified as different lock requestors or holders since their synchronization is resolved using software-based intra-blade locks. Similar to prior work [31], we bound the number of local lock reuses per global lock acquisition (to 64) to ensure starvation-freedom.

Building inter-blade locks using GCP interfaces. Table 3 shows the simplified inter-blade lock operation for `pthread_rwlock`. On initialization, the page containing the lock variable `lock` is registered as a GCP page via `GCP_create`. On reader or writer lock acquisition (Table 3 only shows writer lock operation for brevity), we first call `GCP_acquire` with corresponding permissions (i.e., Modified (`M`) for write-lock, Shared (`S`) for read-lock), then check for completion of the acquire request via `GCP_is_acquired` — either by spinning on the return value or going to sleep until the return value becomes true. The latter allows the scheduler to context-switch to another thread while the current thread is blocked, and is the default behavior in our implementation. Releasing the lock only requires calling `GCP_release`. We omit the implementation of Rust's `std::sync::RwLock` for brevity, but note that it only differs from `pthread_rwlock` in initialization, where *all* addresses corresponding to the lock-protected shared object (i.e., the shared memory list) are passed to `GCP_create` instead of a single page.

Handling deadlocks. Similar to traditional locks, handling deadlocks is delegated to the application rather than the lock library. For example, an application can enforce certain lock ordering to avoid deadlocks with nested locks. Soul's lock library introduces no new deadlock handling scenarios compared to traditional locks.

4.4 Soul In-kernel Lock Manager

Soul's in-kernel lock manager sits between the lock library and the GCP's DRAM cache controller, also implemented in the kernel in MIND [16] (Fig. 6). It manages allocations of GCP pages and associated metadata (i.e., wait queues, shared memory lists, etc.) in GCP's cache controller via Soul's lock library for two purposes. First, it preserves the integrity and protects the GCP state by rejecting invalid or conflicting requests from Soul's lock library. For instance, it prevents the allocation of two GCP pages that share overlapping memory lists, which can result in locks doomed to deadlock. As another example, it prevents the allocated GCP pages from exceeding a fraction of the system's local DRAM cache size (defaulting to 6% in our implementation) to ensure the system retains effective data caching. If this bound is exceeded, Soul's inter-blade locking protocol falls back to a traditional software-based locking algorithm on top of cache coherence (`pthread_rw_lock` in our implementation).

Second, the lock manager recovers allocated GCP pages (and their associated metadata) upon failure. Soul inherits MIND's failure model, which considers two types of failures: (*i*) *application failures*, where individual processes may crash or terminate unexpectedly, and all resources allocated by the failed process must be reclaimed; and (*ii*) *system failures*, which include failures of compute blades, memory blades, or the network switch. MIND replicates the switch state to facilitate recovery on failure, allowing running processes to resume. However, compute and memory blade failures are not recoverable, analogous to how traditional OSes handle CPU and memory failures. We next describe the additional work performed by Soul's lock manager to recover from application and system failures.

Handling application failures. If a process terminates unexpectedly, the lock manager deallocates all of its allocated GCP pages. This is similar to how Linux resolves unreleased futexes with the robust futex list [75].

Handling system failures. Since the lock manager tracks GCP metadata at the compute blades (i.e., the wait queue and shared memory lists), the only in-switch metadata required for recovery is the wait queue's current holder and version number (§4.1). Our implementation piggybacks on MIND's switch-replication mechanism to recover the GCP directory state upon switch failure.

Packet loss and reordering. Our implementation does not need to cater to failures stemming from coherence messages being dropped or reordered by the network since MIND operates on a standard RoCE deployment over lossless fabric (*e.g.*, via Ethernet PFC [76]), and a reliable, in-order transport (*e.g.*, via RDMA RC [77]).

5 Evaluation

We evaluate Soul to answer the following research questions:

- Compared to state-of-the-art locks, does Soul improve performance for real-world workloads (§5.1)?
- Compared to layered approaches, to what extent does GCP remove redundant coherence messages? (§5.2)
- What are the contributions of GCP's optimizations (§5.3)?

Evaluation setup. We use a cluster with five servers connected via a programmable switch to deploy Soul atop MIND [16]. The switch has a 32-port 6.4 Tbps Tofino programmable switch ASIC. One of the servers is equipped with two 18-core Intel Xeon processors, 384GB of memory, and four Mellanox CX-5 100Gbps NICs, and hosts a single memory-blade VM. The remaining four servers are equipped with two 12-core Intel Xeon processors and two Mellanox CX-5 100Gbps NICs per server, and host two compute blade VMs per server (one per socket), each with 512 MB of DRAM and 10 cores (with the remaining 2 cores dedicated to the OS).

Compared systems. We compare Soul against the two classes of approaches discussed in §2. The first includes several lock algorithms layered atop cache coherence: (i) `MCS` [25], a representative of the queue-based mutex; (ii) `Pthread` [78], the POSIX reader-writer lock with centralized reader-indicators; (iii) `Percpu` [32], a reader-writer lock with decentralized (i.e., per-core) reader-indicators; (iv) `Cohort` [34], a memory hierarchy-aware reader-writer lock.

The second includes standalone locks that bypass coherence. Due to compatibility issues, we were unable to deploy FissLock [49], a state-of-the-art hardware-accelerated rack-scale lock service, on our programmable switch. As such, we reimplemented its logic on our setup, enhancing it with the same lock cohorting technique used in Soul (dubbed `Lock Service`). Consistent with its original design, `Lock Service` does not support combined data and locality optimizations due to switch resource constraints.

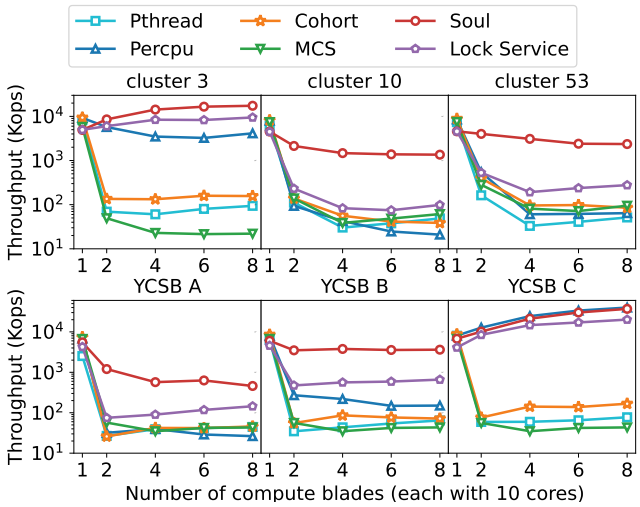

Fig. 9: **Soul throughput scaling for MIND-KVS w/ Twitter cluster 3, 10, 53, and YCSB A, B, C (§5.1).** Y-axis is in log scale.

Real-world workloads. We use two applications: MIND-KVS, the Rust porting of MIND's native in-memory KV store [16] with fine-grained locks, and Kyoto Cabinet [79] with coarse-grained locks. Both use 10 concurrent worker threads per compute blade. Both run on Soul without modifications (§4.3).

MIND-KVS uses a hash table, with a reader-writer lock protecting each hash bucket. We port it to align the hash buckets to 4KB page boundaries, and combine the data in each hash bucket with the lock using Soul's Rust API (§4.3). We evaluate it with both real-world and synthetic workloads. For real-world workloads, we use Twitter's key-value store workloads [58]. We select traces for cluster 3, cluster 10, and cluster 53 for our evaluations as representatives for different proportions of read and write (i.e., `GET`: `SET/ADD/PREPEND`) operations (99% : 1%, 50% : 50%, and 89% : 11%, respectively). For synthetic workloads, we use YCSB workloads A, B, and C [80], corresponding to 50%:50%, 95%:5%, and 100%:0% read-write ratios, respectively.

We run Kyoto Cabinet, a widely used benchmark database system [29, 31, 81, 82], with the TPC-C workload [83], featuring high and low contention (1 and 10 warehouses, respectively). TPC-C transactions hold a global lock to ensure transaction serializability and use the `Pthread` API (§3.3).

5.1 Performance for Real-World Workloads

MIND-KVS. Fig. 9 shows that Soul outperforms the compared systems across various workloads. Soul performs better

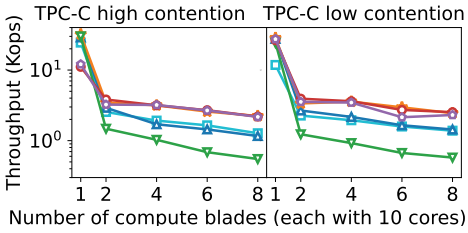

Fig. 10: **Soul throughput scaling for Kyoto Cabinet w/ TPC-C (§5.1).** Y-axis is in log scale.

as the ratio of readers increases, enabling linear scaling for YCSB-C (read-only). It achieves 37.1 Mops at 8 blades, 2-3 orders of magnitude higher than `Pthread`, `Cohort`, `MCS`, and `Lock Service`. These systems write to their lock variables even when acquiring a read lock, causing heavy network-wide cache invalidations. Similarly, `Lock Service` also requires application threads to send acquisition requests over the network for reader locks. In contrast, Soul does not require cache invalidations when there are no writers, as it exploits temporal locality outlined in §3.3. As such, the most frequently accessed locks and data in YCSB can concurrently remain cached across multiple compute blades. Although `Percpu` shows similar performance to Soul for the read-only workload (YCSB-C) due to its per-core reader indicator, it suffers significant performance degradation even with 1% writes (Twitter cluster 3) due to redundant inter-blade traffic in its layered design. Write-heavy workloads (*e.g.*, cluster 10, cluster 53, YCSB-A, and YCSB-B) do not scale with multiple blades with Soul: this is not a limitation of GCP but rather an artifact of long inter-cache latencies over Ethernet. Indeed, GCP may enable performance scaling of these workloads over CXL as we will show in §6.

Kyoto Cabinet. Soul performance is comparable to `Cohort` and `Lock Service` (Fig. 10). Since Kyoto Cabinet's global-exclusive locks allow only one transaction to execute at a time (unlike MIND-KVS's fine-grained locks), its throughput decreases as the number of blades increases. Even so, Soul, `Cohort`, and `Lock Service` outperform other approaches due to their memory-hierarchy-aware design.

5.2 Understanding Soul's Improvements

We investigate Soul's performance improvements — specifically, how it reduces the coherence overheads of layered approaches — by subjecting all schemes under comparison to varying levels of locking contention and read-write ratios. We deploy one thread per compute blade to contend for a single lock; each thread repeatedly acquires the lock, accesses the shared data (4KB), and releases it. We measure the average latency of inter-blade lock and data acquisition (left y-axis in Fig. 11) and the number of cache-coherence transactions per lock and data acquisition (right y-axis in Fig. 11) to highlight the inefficiency incurred by layering. Since `Lock Service` does not use cache coherence for locks, we do not report coherence transactions for it.

Soul observes 100-200 μs lock and data acquisition latency on average at 8 blades — one order of magnitude lower than the fastest compared lock algorithm layered atop cache-coherence. This is because Soul triggers a single coherence transaction for both lock and data acquisition, regardless of the workload. In contrast, locks layered atop coherence trigger coherence transactions proportional to the number of blades (`Pthread`, `Percpu`) or a constant but large number of coherence transactions (`MCS`) as noted in §2.2. While `Lock Service` is not built atop the coherence, it still observes higher latency than Soul because it lacks Soul's combined data optimization and must fetch data over the network separately.

5.3 Effectiveness of Soul Optimizations

We break down the contributions of GCP optimizations (§3.3) by comparing the latency of lock acquisition and data fetch with the same setup in §5.2 for three schemes: (1) Soul with all optimizations, (2) Soul without the optimization for combining lock and data fetch (`w/o combined data opt` in figures), and (3) Soul without the optimization that leverages temporal locality of lock+data (`w/o locality opt`).

The gap between Soul and `w/o locality opt` (Fig. 12) shows that Soul's locality optimization reduces the acquisition latency by 1–2 orders of magnitude by caching the lock and associated data, avoiding expensive network communications. The gap between Soul and `w/o combined data opt` illustrates that Soul's combined data optimization also reduces acquisition latency by avoiding an additional network round trip for data retrieval.

6 Case Study: GCP atop CXL Interconnect

Emerging CXL 3.0 interconnect aims to enable disaggregated shared memory with much finer-grained cache lines and lower latency than the Ethernet-based shared memory we have evaluated. To understand if GCP benefits extend to such interconnects, we conduct a simulation-based study of GCP over CXL 3.0 (dubbed SoulCXL) in the Gem5 [51] simulator, since there is no commercially available hardware for it.

Simulation setup. We evaluate SoulCXL using the same end-to-end applications and compared lock approaches as §5.1. We simulate a cluster with 16 CPU hosts and 1 CXL Global Fabric Attached Memory Device (GFD) connected via a CXL switch. Each CPU host has 8 cores, each employing a 64KB L1 instruction cache and a 64KB L1 data cache. Each core also hosts a 4 MB L2 cache bank. All caches are 2-way set associative. The GFD device hosts sixteen 4 GB DRAM nodes, each with 8× DDR4-2400 channels. Similar to prior CXL-coherence studies [19], we use SynchroTrace [84]

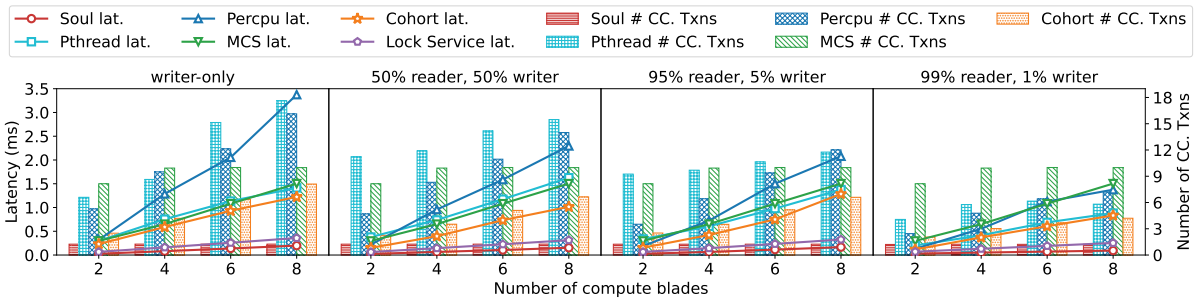

Fig. 11: **Soul avg. latency & # cache-coherence transactions per lock acquisition (§5.2).**

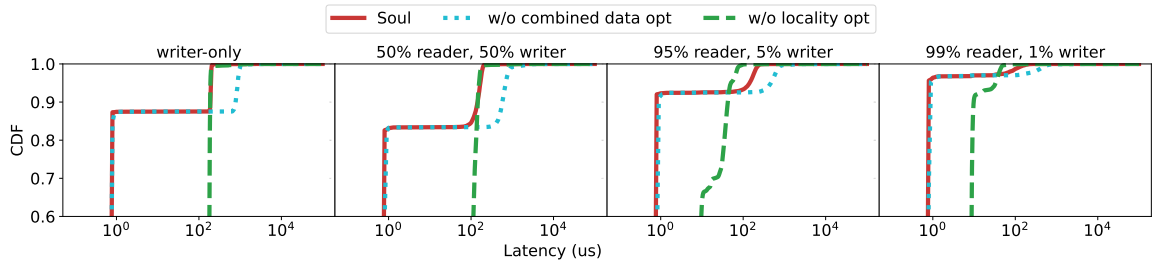

Fig. 12: **Soul latency CDF of lock+data fetch with & without GCP optimizations (§5.3).** X-axis is in log scale.

to capture synchronization-aware traces of all our evaluated workloads and replay them on our simulated CXL cluster. Our simulation models CXL performance as reported in the recent Microsoft study [85], in which the round-trip latency between two hosts is set to an optimistic 300 ns. Since GCP's benefits are more pronounced at larger interconnect latencies, SoulCXL reflects a lower bound on its benefits.

Implementing the wait queue. The low-latency PCIe-based interconnects in CXL 3.0 allow fast access to native coherence protocol message queues at cache controllers and directories. We reuse the CXL.mem M2S channel message buffers in its MOESI protocol to implement GCP wait queues without additional storage overhead. Cache controllers issue `GCP_acquire` requests through the CXL.mem M2S channel, recycling them back to the message buffers if not granted.

Implementing the shared memory list. Since maintaining a general shared memory list in hardware adds non-trivial complexity, our SoulCXL implementation uses a single contiguous memory region instead of a list. We also restrict contiguous regions to power-of-two multiples of 64B to minimize storage overheads. The size of each cache line is embedded within it, using 4 additional bits to indicate the power-of-two multiplier, i.e., `0000` for $2^0 \cdot 64B$ (= 64B) and `1111` for $2^{15} \cdot 64B$ (= 2MB). For regular 64B cache lines, this incurs $< 0.6\%$ storage overhead. Our area estimation using CACTI-7.0 [86] (assuming 22 nm technology) shows that size bits add only 0.0004 mm^2 while the total cache size is 0.0613 mm^2 ($< 0.7\%$) for a 64KB L1 cache.

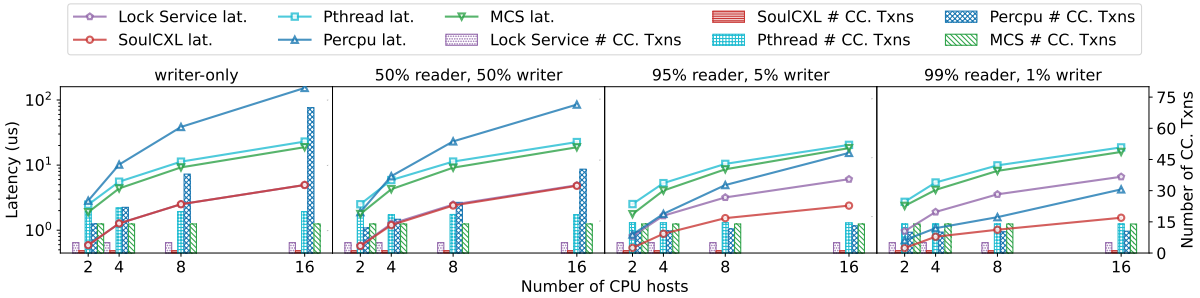

Fig. 15: **SoulCXL avg. latency & # cache-coherence transactions per lock acquire.** Y-axis is in log scale.

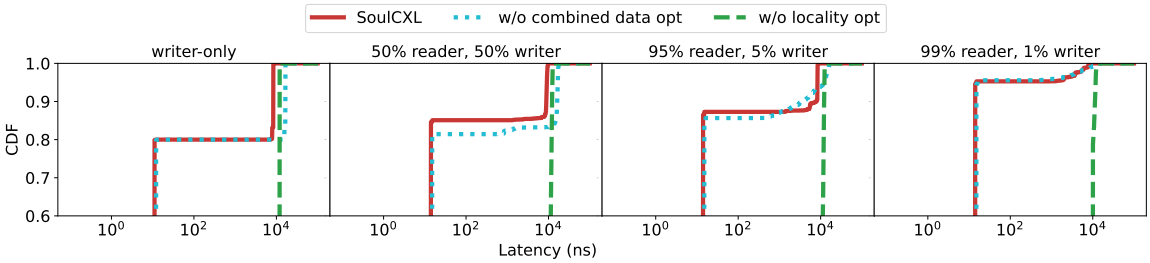

Fig. 16: **SoulCXL latency CDF of lock+data fetch with & without GCP optimizations.** X-axis is in log scale.

6.1 Performance

MIND-KVS. Fig. 13 shows that SoulCXL outperforms the closest-performing compared system by up to 1.7× across Twitter workloads and 2.0× across YCSB workloads. It outperforms `Lock Service` due to the combined data and the locality optimizations. `Percpu` observes much lower throughput than other systems, especially on write-heavy workloads (*e.g.*, cluster 10 and YCSB-A), resulting in worse performance scaling with thread count than on MIND. This is because its per-core lock design is extremely sensitive to contention. CXL's shorter inter-cache latency causes more frequent accesses to lock variables, resulting in higher contention in write-heavy workloads.

Kyoto Cabinet. SoulCXL and `Lock Service` perform similarly because none of SoulCXL's additional optimizations improve performance — Kyoto Cabinet's coarse-grained locks prevent the use of combined data optimization, and since all lock requestors are writers, the locality optimization is not useful either. As with MIND-KVS, `Percpu` observes much lower throughput on CXL than other systems do, due to its sensitivity to lock contention.

Understanding SoulCXL improvements. We conduct the evaluation outlined in §5.3 on the simulated CXL platform. When run on CXL (Fig. 15), while all locks observe lower latency compared to MIND due to CXL's lower latency, they observe more coherence transactions. This is because the lower interconnect latency permits more frequent access to the lock, leading to higher contention. While `Lock Service` observes latency comparable to SoulCXL for write-heavy workloads (*e.g.*, writer-only and 50% writers), it observes higher latency with more readers (*e.g.*, 95% and 99% readers) since SoulCXL's locality optimization reduces latency under writer-reader contentions. `Percpu`'s reduced performance on CXL relative to MIND aligns with our observations in real-world workloads: its per-core lock design is very sensitive to lock contention.

Effectiveness of SoulCXL optimizations. Again, we conduct the evaluation outlined in §5.2 on the simulated CXL platform. The gap between SoulCXL and `w/o locality opt` (Fig. 16) shows that SoulCXL's locality optimization reduces the acquisition latency by 1–2 orders of magnitude by caching the lock and associated data, avoiding expensive network communications. The gap between SoulCXL and `w/o combined data opt` illustrates how SoulCXL's combined data optimization also reduces acquisition latency by avoiding an additional network round-trip for data retrieval.

7 Discussion and Future Research

Supporting flexible queuing policies While Soul's wait queue employs a FIFO queuing policy, it can be extended to support other queuing policies [27, 30, 34] or reader-writer priorities [87, 88]. Since Soul collocates the wait queue and the current lock holder (§4.1), selecting the next candidate to dequeue from the wait queue is performed in the kernel cache controller, which can easily be extended in software. In contrast, supporting flexible queuing policies in the switch ASICs (as proposed in recent hardware lock services [48, 49]) is challenging due to the ASIC's resource constraints.

Supporting other lock APIs. Soul currently only supports basic lock acquire and release APIs as a demonstrator of GCP's performance benefits. It can be extended to support richer lock APIs such as explicit aborts, acquisition with timeouts, try-lock interfaces, etc., via simple modifications to GCP. We leave such extensions to future work.

Related efforts in CPU micro-architectures. Similar to standalone lock services for DSM systems, multi-core architectures have investigated hardware-supported synchronization primitives that either bypass [61,62,89,90] or extend on cache-coherence [63,91–93]. However, the former incurs additional hardware resource consumption and verification complexities, similar to stand-alone lock services for DSMs (§2.2), whereas the latter focuses on specific cache coherence protocols, whereas GCP's applicable to any directory-based cache coherence protocol. Several Hardware Transactional Memory (HTM) systems [94–98] also build on cache coherence protocols. However, they offer different programming models that require modifications to applications. In contrast, GCP's approach ensures transparency for lock-based applications.

8 Conclusion

We observe that lock-based synchronization is a generalization of cache coherence in time and space. We incorporate this insight into a novel *G*eneralized *C*ache-coherence *P*rotocol (GCP) for lock-based synchronization. We provide Soul as an end-to-end system implementation of GCP atop Ethernet-based disaggregated memory and show that it improves performance for real-world applications at scale by 1–2 orders of magnitude over state-of-the-art locks.

Acknowledgments

We would like to thank our shepherd and anonymous reviewers for their valuable comments and insightful feedback. This work is supported in part by NSF Awards #2112562, 2147946, 2118851, 2047220 and a NetApp Faculty Fellowship.

Shaving the Peaks: Taming Tail Latency for Managed Workloads via Disaggregated Garbage Collection

Hongtao Lyu Yuhan Li Mingyu Wu*
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University

Abstract

Language runtimes are essential systems commonly used in multi-tenant cloud scenarios, such as interactive web services and other cloud workloads. They usually provide memory management services, or garbage collection (GC), to automatically reclaim memory and reduce the labor work of application developers. Recent concurrent collectors allow GC to co-run with application threads (mutators), which reduces application pauses and intends to improve the applications' tail latency. However, this work observes that periodic GC workloads remain a primary source of long tail latency, particularly in resource-constrained multi-tenant environments. In such settings, GC threads consume significant CPU resources, leading to severe performance contention with mutators.

To resolve the contention, this work presents DGC, a disaggregated GC architecture that exposes GC as an external service. DGC decouples the most costly marking phase in concurrent GC and offloads it to a disaggregated marking engine. Through a co-design of the GC marking algorithm and an RDMA-based software paging mechanism, DGC's disaggregated marking engine achieves performance on par with local execution while offloading marking to a remote node. To improve resource utilization, DGC introduces a global GC orchestrator to serve multiple runtimes while minimizing the conflicts due to the overlapping of individual GC triggering points. DGC is implemented on the OpenJDK HotSpot Java virtual machine, and the evaluation results on representative latency-sensitive applications show that DGC reduces P99 latency by up to 64.4% under moderate workloads and improves the peak goodput by up to 24.0%.

1 Introduction

Language runtimes provide execution environments for high-level programming languages, including OpenJDK HotSpot (Java), V8 (JavaScript), ART (Kotlin), etc. Such runtimes power a wide range of mission-critical workloads in modern data centers, including cloud services, large-scale distributed systems, and enterprise management platforms such as enterprise resource planning (ERP). One of the most important features in language runtimes is their automatic memory management module (namely garbage collection or GC), which helps identify unused memory resources and reclaim them for later reuse. Recent garbage collectors usually embrace a *concurrent* design, allowing GC threads to execute simultaneously with application threads (or *mutators*). Compared with other collectors inducing stop-the-world (STW) pauses, concurrent collectors do not require mutators to pause during GC and are designed for latency-sensitive applications.

However, the advantages of concurrent collectors are severely compromised in modern multi-tenant cloud environments, where applications are typically containerized with strict CPU resource limits to maximize resource utilization and optimize overall infrastructure cost. In such scenarios, the concurrent execution model creates a fundamental conflict: CPU-intensive GC marking threads must compete directly with mutators for the CPU resources. Our analysis confirms that this resource contention causes application-side CPU starvation. For instance, under the SPECjbb2015 benchmark, Shenandoah (a representative concurrent collector in OpenJDK) introduces a severe latency spike when GC marking is active: as the application's available CPU share drops to 60% of its normal demand, its average latency rises by more than an order of magnitude. However, once GC threads become inactive, the CPU becomes underutilized under the same workload.

To address the issues of resource utilization fluctuations and tail latency caused by periodic GC tasks, this work proposes a novel architecture that decouples GC tasks from the original runtime and abstracts them into a dedicated service. This approach significantly reduces interference with mutators in the original runtimes (referred to as *served runtimes*). Additionally, the service can be time-shared by multiple runtimes; a dedicated scheduler staggers their GC bursts to avoid overlap, smoothing peak demand and improving overall system resource utilization. Thanks to recent high-performance interconnection technologies, the service can also be initiated

*Corresponding author: mingyuwu@sjtu.edu.cn.

remotely and serve language runtimes running on different physical machines. Inspired by the concept of resource pooling and disaggregation, we name this architecture as *disaggregated GC* (DGC).

The design of DGC mainly faces two challenges:

How to achieve correct and efficient remote marking? Cross-machine concurrent marking inherently introduces consistency and data plane overheads typical of distributed systems. To address these challenges, DGC proposes a *disaggregated marking engine*. It first employs a lightweight Snapshot-at-the-Beginning (SATB) protocol, which minimizes the synchronization overhead between GC markers and application threads. Second, to address data plane inefficiencies, it introduces a co-design of the marking logic and the paging subsystems. DGC utilizes the runtime's coarse-grained memory management unit (namely *regions*) to construct a software-based RDMA paging system, which reduces the address translation cost associated with software page tables. Furthermore, DGC proposes a marking algorithm to operate on incomplete object graphs, which ensures overlapping between object marking and RDMA-based data retrieving and thus achieves marking performance comparable to local execution.

How to serve multiple runtime instances simultaneously? Existing language runtimes schedule GC assuming it monopolizes the computation resources. However, the assumption does not hold with DGC, where the computation resources are shared by multiple runtimes, and relying on the original scheduling leads to suboptimal results. To address this, DGC employs lightweight memory allocation monitors embedded within each runtime to formulate a forward-looking DGC orchestration plan. This design enables DGC to fully utilize the marking offload capabilities to accelerate participating runtimes, all while avoiding contention between concurrent DGC tasks.

DGC is implemented on OpenJDK HotSpot, a widely used JVM. It is based atop Shenandoah, a concurrent garbage collector whose SATB marking design is representative and can be easily migrated to other collectors [12, 59]. The evaluation results on various latency-sensitive applications show that DGC can achieve significant (up to 64.4%) P99 latency reduction against two state-of-the-art collectors with identical CPU resource budgets. Despite the network overhead, its remote version can reach 60.3% P99 latency reduction under moderate workloads.

To summarize, the contribution of this work includes the following:

- A comprehensive analysis to illustrate the periodic resource contention between GC and application threads, especially for multi-tenant cloud scenarios. (§ 3)
- DGC, a disaggregated GC architecture to elastically serve GC tasks in an external instance to reduce GC-mutator conflicts. (§ 4-6)
- Experiments on various latency-critical workloads to show how DGC improves applications' tail latency (§ 8).

2 Background

Garbage Collection. Garbage Collection (GC) automates memory management by dynamically tracking object liveness and reclaiming unused resources. This mechanism relieves developers from low-level manual administration and prevents memory-related bugs, such as leaks, which are prevalent in complex software systems.

The mainstream GC algorithm is *tracing*, which identifies live objects by traversing the object graph and marking all reachable ones. During marking, GC threads start with root objects (referred to as *GC roots*) known to be alive (e.g., used by on-stack references) and traverse the heap (or a part of the heap) to locate live objects. After marking, *non-moving* collectors reclaim areas consumed by dead objects and organize them into free lists, while *moving* collectors copy live objects to adjacent locations (known as *evacuation*) to create a large and contiguous free space.

Concurrent Marking. Performance overhead is a key concern of GC. Owing to the consistency issues between GC threads and application threads (referred to as *mutators*), early garbage collectors relied on stop-the-world (STW) pauses, suspending all application threads during object marking, which significantly affects the application latency. In contrast, modern garbage collectors employ advanced techniques such as barriers and sophisticated algorithmic designs, enabling concurrent execution with mutators, especially for the marking phase (namely *concurrent marking*). Nowadays, many language runtimes (OpenJDK HotSpot [41], V8 [17], Go runtime [16], ART [15], etc.) have shifted towards concurrent marking. The reduced pause times achieved through concurrent marking are crucial for latency-critical applications, such as databases and web services, which are mostly written in high-level languages [19].

Marking Algorithm. Marking algorithms rely on the tri-color abstraction to reason about graph traversal correctness. Objects are categorized into three states:

- *White:* Unvisited candidates. Any object remaining white upon termination is unreachable and eligible for reclamation.
- *Grey:* Live objects that have been discovered but not yet scanned for outgoing references. These reside in the collector's work buffers (e.g., queues) and represent the active wavefront of the traversal.
- *Black:* Fully processed objects whose direct children have all been identified.

The marking process proceeds iteratively: the collector pops a grey object, marks its children grey, and colors the object black. To guarantee convergence and idempotency, modern collectors (e.g., Shenandoah) utilize a global mark bitmap. This atomic side-table ensures that each reachable object transitions from white to grey exactly once, preventing redundant processing of cycles or shared references.

Managed Application Clusters and Multi-tenancy. Modern cloud-native deployments are increasingly organized as clus-

Table 1: Results of SPECjbb2015 for different GCs

	Shenandoah	ZGC	G1
(A): Critical-jOPS (req/s) vs. GC Threads			
2 Threads	4937	3481	2530
4 Threads	6710	5512	3745
6 Threads	6569	6262	5208
8 Threads	**6819**	**6474**	**6288**
(B): Pause Metrics (under Critical-jOPS, 8 Threads)			
Pause Count	45	71	49
Avg Pause (ms)	1.91	0.04	51.44
Total Pause (ms)	85.79	3.20	2520.59

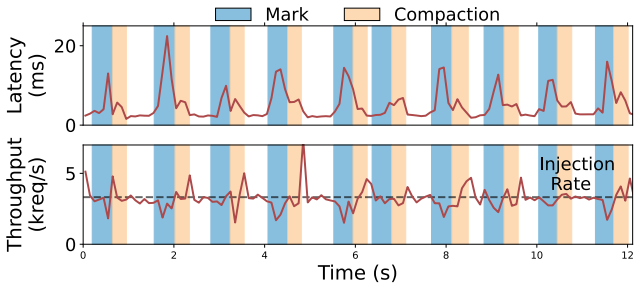
ters of managed application instances such as microservices, FaaS handlers, and partitioned monoliths. These instances share host resources and operate under strict per-instance budgets. Unlike traditional monoliths that rely on vertical scaling (scale-up) of massive, singular instances, modern hyperscale applications are decomposed into thousands of loosely coupled, fine-grained service units. This architectural decomposition is primarily driven by the need for horizontal scalability (scale-out). By breaking down complex logic into smaller components, operators can dynamically provision or terminate replicas of standardized service instances to match real-time traffic fluctuations, ensuring agility and fault tolerance.

Consequently, the deployment strategy has shifted towards co-locating high densities of these smaller service instances to maximize cluster-wide resource utilization. To achieve efficient bin-packing, these instances are typically constrained to moderate specifications (According to a recent report, 82.8% of monitored JVMs use between 1 and 8 cores, and 76.2% are allocated less than 4 GB of memory [39].) While this model optimizes infrastructure costs, it fundamentally constrains language runtimes' execution environment: the surplus CPU cycles previously relied upon for background maintenance tasks are largely eliminated, creating contention between application logic and runtime services like GC.

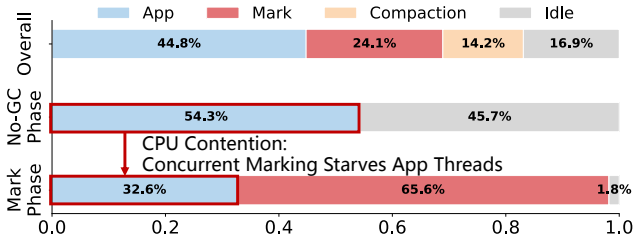
3 Motivation

In this section, we use a set of experiments to quantitatively demonstrate (1) how concurrent marking competes with application threads for CPU resources in resource-constrained environments and leads to performance fluctuations, and (2) why existing configuration adjustments cannot effectively solve these issues.

Experiment Setup. We conducted our experiments using SPECjbb2015 (abbreviated as SPECjbb), a benchmark representing typical online shopping workloads, across three GCs in OpenJDK 17. We provisioned the SPECjbb instance with 8 cores and 4 GB of RAM to reflect a resource-limited, multi-tenant environment. Notably, the 4 GB limit provides twice the minimum memory required by the workload, guaranteeing adequate space for allocation and garbage collection. SPECjbb



(a) SPECjbb2015 latency and throughput details. Note that SPECjbb2015 employs a queue for unhandled requests, which leads to rebounds in throughput after CPU contention finishes.



(b) CPU utilization breakdown during different GC stages.

Figure 1: Performance degradation caused by concurrent GC.

incorporates a built-in load-probing mechanism that automatically evaluates latency characteristics under varying loads and reports the maximum throughput satisfying its latency constraints (referred to as critical-jOPS).

Three collectors are selected for evaluation. *G1* serves as the mostly-STW baseline, utilizing a generational design with frequent pauses for young-generation reclamation. In contrast, *Shenandoah* and *ZGC* represent the concurrent category; they leverage sophisticated consistency protocols to achieve a "pause-less" execution model, confining STW interruptions strictly to sub-millisecond phase transitions.

Performance Analysis. The results presented in Table 1 reveal a counterintuitive phenomenon: although concurrent collectors succeed in reducing STW pauses, they yield only marginal improvements in critical-jOPS (3-8%) compared to G1. To investigate the root cause of this phenomenon, we conducted a detailed performance analysis of Shenandoah (selected over ZGC due to its lighter-weight concurrent algorithm and better critical-jOPS) under the IR=6819 configuration (IR = injection rate, in requests/s). In order to get the performance details, we instrumented SPECjbb to collect fine-grained performance metrics during testing, correlating them with system resource utilization statistics (summarized in Figure 1).

The results uncover a critical pattern: during non-GC periods, CPU utilization remains consistently low (45.7% Idle), indicating CPU underutilization. However, during concurrent marking, total CPU usage spikes to 98.2% as the application's CPU share drops from 53.3% to 32.6%, resulting in a sharp drop in application throughput (47%) and increased average

latency (10.5×). This observation suggests an explanation for the limited critical-jOPS improvement: while traditional STW collectors completely hand over CPU resources to either application or GC threads at different phases, concurrent GCs periodically introduce heavy GC tasks colocated with mutators. Although pauses have been reduced, those GC tasks still interfere with application threads, inducing recurring resource contention. These observations also align with prior reports [60, 66].

Why not overprovisioning? The most straightforward solution to this issue is CPU overprovisioning—allocating sufficient cores to accommodate peak demand from both application and GC threads. This approach would prevent performance fluctuations caused by CPU contention when GC activates, as incidentally observed in our Figure 1 experiment, where the system automatically settled at 6,819 req/s, a moderate load level that balanced jOPS and P99 latency. However, while CPU overprovisioning is simple and effective, it introduces significant efficiency concerns. As demonstrated in our earlier results, this method leads to severe underutilization during non-GC periods, with CPU utilization dropping below 50%—a substantial resource waste. A common variant is to pin GC threads to dedicated cores. This avoids contention but inherits the same idleness: the pinned cores must be sized for peak marking demand and sit idle outside marking windows.

An alternative overprovisioning solution is to grant extra memory to the application. For garbage-collected applications, expanding memory quotas can reduce GC frequency and consequently mitigate its performance impact. However, this approach also has its limitations. The CPU-to-memory ratio of current machines is essentially fixed in existing public clouds or private data centers, where memory capacity is already the primary bottleneck during resource allocation[19, 46]. Therefore, adding more idle memory to the application only for GC frequency reduction is not an effective solution.

Why not reduce GC Threads? GC Thread number is one of the most important parameters for GC performance tuning. Given that the root cause of CPU load fluctuations lies in the periodic activation of GC tasks, one possible solution is to reduce GC threads to stretch GC execution time, thereby smoothing overall system load. Table 2 presents performance data from SPECjbb tests under four different GC thread configurations.

Reducing GC threads from 8 to 6 and 4 initially demonstrates a decline in GC throughput (defined as live object size divided by marking time), confirming the ability to stretch GC duration through this method. However, the system exhibits an 11% increase in GC frequency (8 to 4), while P99 latency remains statistically unchanged and P50 latency even increases by 20%. This counterintuitive result is caused by *floating garbage*. Modern concurrent collectors such as Shenandoah and ZGC take a logical snapshot of the heap at the start of each marking cycle and treat any object that dies mid-cycle as live. Reducing the number of GC threads stretches the marking phase, enlarging this window so that more short-lived objects survive the cycle as floating garbage. Because each cycle reclaims less memory, the collector must run cycles more frequently to keep up with allocation. The CPU savings from fewer GC threads are thus offset by the higher GC frequency.

Table 2: Tail latency with different numbers of marker threads. Tested on SPECjbb2015 (PRESET mode, IR=6819 req/s).

GC Metrics (marking)				App Latency (ms ± 95% CI)		
Thr.	#GC	GB/s	CPU%	P50	P90	P99
2T	41	1.04	24.5%	$1650_{(oom)}$	$3600_{(oom)}$	$11500_{(oom)}$
4T	50	1.98	46.2%	4.8 ± 0.1	19.3 ± 3.9	76.7 ± 9.5
6T	46	2.48	54.6%	4.2 ± 0.1	26.6 ± 2.3	88.8 ± 16.3
8T	45	2.57	55.4%	4.0 ± 0.1	21.4 ± 1.4	78.3 ± 18.9

Opportunities. While local tuning falls short, modern cloud infrastructure presents two key opportunities to resolve GC-induced contention: *(1) Utilizing Idle Clusters Cycles.* In multi-tenant environments, GC bursts are rarely synchronized across all co-located runtimes. While a single runtime struggles with CPU deficits during its GC phase, neighboring runtimes may possess underutilized CPU cycles. This asymmetry creates an opportunity to aggregate these fragmented, idle resources into a shared pool. By offloading GC tasks to this isolated pool, we can achieve agile concurrent marking without contending with local application threads. *(2) The Bandwidth-Compute Gap.* The emergence of high-performance interconnects (e.g., RDMA, CXL) has fundamentally shifted the bottleneck. As shown in Table 2, concurrent marking is often bound by random memory access latency and synchronization overheads, yielding a modest scan speed of 2.6 GB/s in our tests. In contrast, modern 400 Gbps RDMA networks offer bandwidth orders of magnitude higher—theoretically sufficient to sustain traffic for 20 different marking tasks simultaneously. This vast bandwidth headroom makes it feasible to decouple GC to remote nodes, trading abundant network bandwidth for scarce local CPU resources.

Takeaway. Concurrent garbage collectors in multi-tenant environments compromise application stability primarily through CPU contention. Viewing the runtime holistically, this contention manifests as drastic, periodic fluctuations in CPU demand, making precise resource provisioning notoriously difficult. Consequently, the theoretically optimal solution requires elasticity: the runtime can access burstable CPU resources during GC phases (marking in particular) to reduce floating garbage, yet these resources should not be statically provisioned to avoid wastage during non-GC phases. This necessitates a consolidated approach: offloading GC tasks from multiple runtimes onto a shared, dedicated resource pool, where GC tasks are explicitly orchestrated to ensure efficient, interference-free execution.

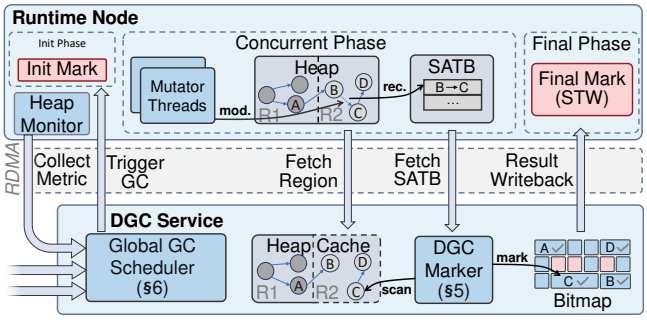

Figure 3: The workflow of DGC's disaggregated marking.

4 Disaggregated GC Service

4.1 Architecture Overview

This work presents Disaggregated Garbage Collection (DGC), a system designed to consolidate concurrent marking tasks from multiple runtimes onto a dedicated, isolated compute pool. By decoupling the marking workload from the application, DGC eliminates contention on CPU resources and accelerates marking throughput (Figure 2). The architecture comprises two core subsystems: a Disaggregated Marking Engine and a Global GC Orchestrator.

A strawman design for pooling would be adaptively increasing/decreasing the number of available cores for each language runtime, but this design faces two disadvantages. First, it contradicts the horizontal scaling mechanism used for fine-grained services and complicates resource management. Second, it cannot scale to a distributed environment. DGC instead employs a data-centric offloading strategy: its *disaggregated marking engine* accesses the runtime's heap through two distinct data planes for concurrent marking.

(1) Co-located Mode: For runtimes residing on the same physical host, the DGC service utilizes shared memory (SHM) as the data plane. By registering heap ranges and GC-related data structures into a memory segment visible only to DGC, the DGC service can directly access the runtime's state. This architecture enables the direct adaptation of standard concurrent marking algorithms, where intermediate metadata is exchanged via zero-copy SHM mechanisms and control signals are managed through simple RPCs. Notably, while currently implemented for single-host co-location, this SHM-based design conceptually extends to Hyper-Node systems providing shared memory semantics(e.g. CXL [30], UB [29]).

(2) Distributed Mode: For runtimes across physical boundaries, DGC employs RDMA-based Remote Marking, leveraging high-performance networking to traverse remote heaps efficiently (details in Section 5).

To serve multiple participating runtimes using a shared resource pool, the DGC system employs a *Global GC Orchestrator*. This component is composed of lightweight monitors embedded in each runtime and a centralized optimization solver. Using allocation-related profiles collected by monitors, the solver optimizes GC resource scheduling to ensure memory availability of all participating runtimes (details in Section 6).

4.2 Deployment Model and Assumptions

Operator-managed JVM stack. DGC is intended to be deployed as part of an operator-managed JVM stack. In this model, the JVM build, the DGC service, and the surrounding deployment infrastructure are owned by a single platform organization. Two industry practices fit this model. The first is the vendor-curated JVM distribution, exemplified by Alibaba Dragonwell [1], Amazon Corretto [3], and Azul Platform Prime [5]; these builds are produced and maintained by the same organization that supports their consumers.

The second is the internal Java platform operated by large enterprises, where a dedicated infrastructure organization maintains both the JVM runtime and the cluster management stack while application teams contribute only standard Java workloads. This practice is widely documented across major internet companies [8, 19, 23, 37, 48, 50, 60, 64]. In both practices, the JVM provider and the cluster operator share a single trust boundary, which allows DGC to read heap state across the operator's components and motivates a unified rather than per-tenant GC accelerator.

Knowledge required from the tenant application. DGC treats each served application as a black box and consumes only JVM-level metrics. The information includes heap free size, allocation rate, live-object size, and estimated marking duration. All of these metrics are already collected by Shenandoah's current monitoring infrastructure.

Hardware assumptions. The SHM data plane requires only that the served runtime and the DGC service share a host address space, or an address space that behaves like one (e.g., CXL [30] or UB [29] fabrics). The RDMA data plane requires that the DGC host and the served host both attach to an RDMA-capable fabric. Such fabrics are already standard in modern data centers; representative examples include AWS Elastic Fabric Adapter [47], and Microsoft Azure RDMA storage networks [6]. DGC therefore depends only on commodity data-center hardware.

5 RDMA-based Remote Marking

5.1 SATB-based Marking Algorithm

To address consistency maintenance in disaggregated marking, the remote marking engine adopts the Snapshot-at-the-Beginning (SATB) algorithm. SATB ensures correctness by effectively taking a logical snapshot of the heap at the start of the cycle. Any references overwritten during the concurrent marking phase are recorded by SATB write barriers to ensure that objects live at the start of the cycle remain reachable. Crucially, these barriers are active only during the marking phase, so DGC adds no steady-state overhead when GC is inactive. Prior work [31, 54] has shown that SATB barriers can ensure the correctness of marking even when GC threads are operating on a stale object graph.

Workflow. Figure 3 illustrates the workflow of the DGC's remote marking algorithm. The cycle begins with a lightweight Stop-The-World (STW) phase, during which the runtime records heap states and the GC root set to establish the logical SATB snapshot. Upon the resumption of the application, the DGC service receives an RPC to start data copying and concurrent marking. DGC adopts a configurable heap cache ratio on the GC node, which allows a tradeoff between marking performance and memory consumption. Throughout the marking phase, the accumulated SATB roots are periodically fetched from the runtime node and processed by the GC marker. Once the scanning converges, the liveness bitmap is returned to the runtime, which then enters a final, brief STW pause to process the small number of remaining SATB roots that were not yet synchronized, ensuring strictly consistent marking results.

Correctness. SATB correctness rests on a single invariant: every reference live in the snapshot is eventually visited by the marker, via heap traversal for unmodified edges or via the write-barrier buffer for overwritten ones. Since marking reclaims nothing, correctness depends only on the union of the two sources covering the snapshot, not on the completeness of either source alone. In the disaggregated setting, the DGC marker always observes a transient intermediate heap rather than a true snapshot. Under DGC-RDMA, it may further see an internally inconsistent view assembled from regions cached at different points in real time. The buffered SATB stream still supplies precisely the edges the marker's traversal might miss, so the marker converges to the same live-object set as an in-process collector.

5.2 Heap Cache Management

The heap cache manages a (partial) local copy of the served runtime's memory states, which can be directly accessed by GC threads of DGC. The heap cache is a copy system instead of a swap system, so it never affects the application's reads, writes, or execution. The cache originally supports two primitives: *retrieving* to fetch more memory states from the served runtime, and *eviction* to replace existing cached states with newly retrieved ones. A RDMA control thread is responsible for managing the heap cache, issuing RDMA read requests according to the primitives. A strawman design would be relying on existing OS-level remote memory paging systems [2, 45] to support those two primitives, but this design is intrusive to operating systems and remains unaware of the memory management behaviors inside language runtime systems, leading to frequent page faults and unacceptable overhead. To this end, DGC adopts a user-space software paging system and manages cached memory in a *region* granularity, which aligns with that in runtimes. The software paging approach also reduces the overhead of RDMA registration: during initialization, DGC pre-registers a fixed memory range as a local heap cache and employs a software address translation layer operating at the granularity of regions.

Region-based software paging. The *region* serves as the fundamental unit of memory management in mainstream collectors [12, 13, 63]. By aligning the cache management granularity with regions, DGC offers two advantages. First, it aligns seamlessly with the runtime's allocation patterns. Specifically, mainstream collectors like G1 and Shenandoah enable a per-region bump-pointer-style allocator, which induces strong temporal locality by grouping related objects to the same region. The locality is also analyzed by prior work, which indicates the number of inter-region references is usually limited [59]. Consequently, retrieving the whole region can improve the "hit rate" of local memory accesses compared with a page-based approach. Second, this approach is highly cache-efficient. For instance, in a 4GB SPECjbb heap with 2MB default region size, the software page table shrinks to merely 4KB (properly compressed based on alignment). This compact footprint allows the table to fit entirely within a modern CPU's L1d cache (48KB in our testbed), significantly reducing address translation overhead.

5.3 Handling Partial Object Graphs

Since the heap cache is empty at the beginning of marking, naively waiting for data copying would introduce significant overhead. Meanwhile, the size of heap cache may not accommodate the whole heap in the runtime node. To this end, DGC refines the original SATB-based GC algorithm to conduct marking when the cached memory states are not complete. The basic idea is to memorize pending references for uncached regions. During marking, DGC's GC threads identify those references by checking the status of regions and push them into a thread-local per-region pending queue. Once the region has been copied, DGC uses the RDMA control thread to aggregate pending queues for this region and dispatch them to a single GC thread, according to the current load. This design is aimed at preventing *bitmap contention*: concurrent scanning of the same region by multiple GC threads would trigger frequent cache coherence traffic on the shared marking bitmap.

Concurrency control. The switch point on the region state should be specially designed to ensure consistency between GC threads and the RDMA control thread. For example, if GC threads do not realize that a region is being evicted, they may introduce wrong marking results after the region has been replaced by RDMA read operations issued by the control thread. To this end, DGC introduces an 8-byte per-region entry for inter-thread synchronization: the high bits store the *state tags* (NotCached, OnTrans, Cached, and OnEvict) while the low bits store a counter serving as a reentrant read lock. Each *state tag* records the current status of DGC's local cache for the corresponding served-runtime region. When accessing an object, a GC thread first issues an atomic increment to the region entry to register its presence, and then validates whether the state tag is Cached. Similarly, it decrements the counter when finish processing the object. The RDMA control thread only changes the state tags when the corresponding counter is zero and leverages compare-and-swap operations to ensure the atomicity of its mutation operation. This concurrency control mechanism allows GC threads to safely initiate tasks with simple atomic instructions while ensuring that critical RDMA overwrites never interrupt an ongoing object scanning.

Running example. Figure 3 traces the following scenario step by step. Consider $A \in R_1$ (Cached) and $B, C, D \in R_2$ (NotCached), with references $A \rightarrow B \rightarrow C \rightarrow D$. The marker scans A, defers $A \rightarrow B$ into R_2's pending queue; the RDMA control thread later copies R_2, flips its tag to Cached, and dispatches the queue to a single marker, which then scans B. If a mutator *modifies* B and overwrites $B \rightarrow C$ before R_2 is copied, the marker would not see C from B alone in the heap cache; the SATB barrier *records* the original $B \rightarrow C$ at the moment of modification (upper part of Fig. 3), and the DGC service fetches this record over RDMA (middle part), so the marker still reaches C, follows $C \rightarrow D$, and sets all four objects in the bitmap (lower part).

5.4 Hotness-driven Paging Policies

To minimize RDMA traffic and avoid frequent retrieving on the same region, DGC uses *hotness scores* to determine which region should be retrieved and evicted. The score is calculated by the aggregate size of underprocessed objects (grey) within each region, which is grounded in our observation that larger objects typically encapsulate a higher density of outgoing references. Therefore, caching them exposes more work to GC threads, sustaining high throughput and preventing thread starvation. For regions not cached, DGC initially estimates the score using the number of pending references and the application's average object size, which can be profiled during each collection cycle. The score can be calibrated to the precise value once the region is retrieved. Furthermore, to prevent thrashing where regions are repeatedly swapped, DGC remains conservative on eviction and enforces a strict hysteresis threshold: A non-resident region is eligible for retrieval only if its score exceeds that of the eviction candidate by a configurable multiplicative factor.

Additionally, to mitigate thread starvation during the initialization phase, DGC introduces a *prefetch window*. This mechanism allows the RDMA controller to proactively populate the local buffer before marking threads start, strictly prioritizing those containing GC roots. Crucially, marking threads remain dormant during this interval. From the perspective of the global GC orchestrator, no CPU resources are allocated for the duration of the prefetch window, thereby preventing idle cycles and maximizing overall resource utilization.

5.5 Class Information Sharing

In addition to heap data, class information is also required during marking, as it stores the locations of all references inside an object. To minimize the cost of sharing this information, DGC embraces OpenJDK's application class data sharing mechanism (APPCDS [40]), which packs the in-memory Klass structures of all loaded classes into a single archive file, along with the reference-offset tables that GC uses to scan each object. When a served runtime first attaches, DGC preloads this archive at the same virtual address as the runtime, so that Klass pointers resolve identically on both sides without per-object translation.

Beyond the archive, Java runtimes can define new classes at runtime through reflection, custom class loaders, or lambda metafactories. Since every such class must be registered with the JVM's system dictionary before it becomes usable, DGC hooks this process: each newly defined Klass triggers a notification, and before the next GC cycle begins, the marker reads the new Klass data through SHM in co-located mode or one-sided RDMA in distributed mode. The marker therefore sees the full type system at the start of every collection.

6 Multi-Runtime GC Orchestration

The disaggregated marker of Section 4 solves only half of the problem. Concurrent GC is bursty: marking takes over the cycle for a short, busy interval, then stays idle until enough garbage accumulates to trigger the next cycle. A GC pool dedicated to a single served runtime would therefore sit idle most of the time, splitting the runtime's total CPU usage rather than reducing it. DGC recovers this efficiency by *time-division multiplexing* a single shared GC pool across many co-located runtimes. However, naive sharing would reintroduce the very contention that disaggregation was meant to eliminate: overlapping marking phases from different runtimes compete for GC threads and drag each other's tail latency back up.

To make sharing safe, DGC introduces a centralized *global GC orchestrator* that decides when each runtime's next GC cycle should start and with how many GC threads it should run. Three logical roles compose the orchestrator. A lightweight *monitor* embedded in each served runtime exposes its free-memory level, allocation rate, and the marking duration of historical cycles. A single *coordinator* reads the monitor state

across all runtimes and emits trigger decisions by solving the joint scheduling problem. A *trigger hook* on each served runtime's GC-trigger path applies the coordinator's decisions. The remainder of this section describes the design objectives that guide these decisions, the resulting scheduling problem, and how robustness is maintained when the system departs from steady state.

6.1 Design Objectives

Deferring marking as late as possible. As analyzed before, if the trigger point of SATB marking can be deferred, more objects can be included in the snapshot, resulting in less floating garbage and improved GC efficiency. Therefore, DGC's scheduler is designed to defer marking for all GC tasks without encountering any OOM issues.

Adjustable GC thread numbers. The number of GC threads is statically configured in state-of-the-art concurrent collectors to strike a balance between collection throughput and interference with mutators. In DGC's case, since the disaggregated GC tasks are running with dedicated computation resources, the static configuration approach is no longer viable. DGC thereby proposes to dynamically configure the number of GC threads for each task, according to its urgency and the system's resource availability. When a GC task starts late and requires finishing soon to avoid OOM issues, DGC can maximize its computation resources to improve the marking speed. However, since the SATB marking algorithm (graph traversal) does not scale well (see Table 2), the marginal benefit of adding more threads diminishes beyond a certain threshold. Therefore, when multiple GC tasks require serving simultaneously, the computation resources granted for each should be controlled to improve the overall CPU efficiency.

Avoiding Resource Contention. Since the memory footprint of marking is large, co-locating multiple GC threads into the same core leads to severe interference. To this end, the total number of active GC threads should not exceed the available core number at any moment.

6.2 Problem Formulation

According to the principles above, we formulate the scheduling algorithm as a constrained optimization problem below.

Decision Space: *(1) GC Trigger Time*: The time when the GC task should be triggered. *(2) DGC Thread Number*: The number of GC threads to be allocated for the task.

Constraints: *(1) Time Constraint*: Each GC should complete before the mutators exhaust all the available memory (i.e., OOM errors). *(2) Resource Constraint*: The total number of active GC threads should not exceed the number of available cores at any moment.

Algorithm Input: *(1) GC Completion Deadline*: The estimated GC completion deadline for each served runtime, calculated as the available free memory divided by its allocation rate. *(2) Estimated DGC Duration*: The estimated marking duration of each task under DGC, with different number of GC threads. *(3) Ongoing DGC Task Information*: The information of all ongoing GC tasks served by DGC, including the estimated completion time and the number of GC threads.

Optimization Goal: Defer the GC start time as long as possible. Since the start time can be represented as a monotone timestamp, the goal can be transformed to the sum of the GC start timestamps for all tasks.

Discussion: the estimated inputs. The input of algorithms relies on several estimated numbers, which are collected from runtime profiles in the served runtimes. The allocation rate has already been estimated by the runtime's statistical methods and thus can be directly reused by DGC. As for the estimated GC duration, it can be modeled as a linear function of the size of live objects. The function incorporates a thread-number-specific coefficient and a constant term, both of which vary across applications. Given that an application's live object set typically remains stable over short time periods, the number of live objects can be estimated by the historical marking results.

6.3 Efficient Solving Strategy

To address this optimization problem efficiently, we adopt a constraint programming (CP) approach that discretizes all parameters and integrates a dedicated CP-SAT solver. The resulting solving time is typically around 5 ms for single-instance scenarios, well within practical limits given the runtime's 10 ms allocation-rate monitoring tick.

For homogeneous workloads, scheduling decisions can be encoded as a small set of static priorities, because all served runtimes share comparable allocation rates and marking durations. Heterogeneous workloads break this assumption: GC deadlines, allocation rates, and marking durations all diverge across applications, and a static heuristic tuned for one combination typically fails on another. We therefore adopt CP-SAT as a general-purpose solver and leave the designing of simpler heuristics to future work.

6.4 Scheduling Robustness

The scheduler described so far operates in steady state. In practice, three non-steady states could arise: a freshly started runtime with no historical data, a sudden shift in allocation behavior, and an unreachable DGC service. We discuss each in turn.

Cold start. A freshly started runtime lacks the per-application information CP-SAT needs. DGC directly inherits Shenandoah's existing learning-phase convention: while the local heuristic itself is still warming up, the runtime triggers conservative local concurrent GC at default thresholds and DGC remains inactive. Once warmup completes, DGC takes over with conservative initial values for the linear duration coefficients in Section 6.2, refining them online by fitting against each subsequent completed DGC cycle.

Workload drift. Workload behavior may shift—a traffic surge, for instance, inflates the runtime's allocation rate and brings its GC deadline forward—and reusing a stale plan would risk OOM. The coordinator therefore re-solves the CP-SAT problem at every 10 ms scheduling tick against the latest memory state and allocation rate, possibly reordering pending GC tasks. The formulation also reserves deadline headroom to absorb moderate rises within a tick. When this headroom is exhausted, the runtime falls back to local concurrent Shenandoah for the affected cycle: CPU contention with mutators reappears, but worst-case performance stays bounded by baseline Shenandoah rather than risking OOM.

Fault Tolerance. When the DGC service becomes unreachable—whether crashed, slow, or partitioned—failures manifest in two ways depending on timing. If DGC dies while a marking task is in flight, the runtime simply sees the GC miss its deadline: memory keeps filling until OOM, the DGC call is cancelled, and the host falls through to Shenandoah's degenerated (STW) GC path, incurring a roughly 100 ms pause in our SPECjbb2015 experiments. Subsequent cycles no longer receive trigger signals from the coordinator and silently revert to local Shenandoah concurrent GC. Each trigger signal carries a version tag, so stale signals from a crashed coordinator are discarded rather than acted on. Recovery resembles a fresh startup: the new DGC service re-acquires each served runtime's memory layout and class information, after which the coordinator resumes issuing commands and the runtimes rejoin the DGC path.

7 Implementation

DGC is mainly implemented atop the Shenandoah garbage collector of OpenJDK 17 (version: jdk-17+35) in C/C++ and can support any unmodified Java applications. Our implementation has 10,383 LOC, including 946 lines specifically for the local version (referred to as *DGC-SHM*), 3,601 lines specifically for the remote version (referred to as *DGC-RDMA*), 959 lines for the GC scheduler, and the rest are for the common parts (e.g., class data sharing, GC workflow integration, RPC and RDMA support, etc.).

DGC's disaggregated GC service is implemented as a stripped-down version of OpenJDK's Java virtual machine (JVM). This enables DGC to reuse critical JVM components, including APPCDS and the class information resolution mechanism. The low-frequency control flow between the disaggregated marker instance and the served JVM is implemented with RPC, while the data flow is implemented with SHM or RDMA. To reach ideal marking performance, DGC reuses the well-optimized data structures in Shenandoah GC, including its work-stealing task queue, lock-free marking bitmaps, etc.

The GC scheduler is implemented with the CP-SAT solver [43] provided by Google OR-Tools [44]. The CP-SAT solver achieves high-performance solving by automatically reducing Constraint Programming (CP) problems to Boolean Satisfiability Problems (SAT). This capability enables its use for real-time GC scheduling in language runtime scenarios.

8 Evaluation

In this section, we evaluate DGC by answering five questions about its benefit and cost:

Q1. how does DGC cut tail latency and raise throughput across applications (§8.2)?

Q2. do the gains hold for heterogeneous runtimes sharing one marker pool (§8.3)?

Q3. what overhead does disaggregation incur, and how does DGC-RDMA perform under a tight budget (§8.4)?

Q4. does the benefit scale with the runtime count (§8.5)?

Q5. how much does each mechanism contribute (§8.6)?

The results show that, at an equal CPU budget, DGC raises critical-jOPS by 24% over Shenandoah and cuts tail latency by 64% on SPECjbb2015, with these gains holding under co-location and scaling at modest cost.

8.1 Experiment Setup

We ran experiments in a cluster of 2 servers with dual Intel Xeon Gold 6430 CPUs (32 physical cores each) and 128 GB of memory. Hyper-threading was disabled, and all servers were configured to performance mode to prevent CPU frequency fluctuation. Each server has a 200Gbps Nvidia BlueField-3 DPU working as an RDMA NIC, which is connected to the host via PCIe 4.0×16 connection.

Test Applications. We leverage the following applications to evaluate DGC:

• *SPECjbb2015* [11] serves as the de facto standard for assessing Java server performance, particularly in relation to garbage collection [13]. It simulates an online supermarket handling diverse requests, and the evaluated version is 1.0.4. SPECjbb2015 supports a multi-backend deployment mode, which natively enables distributed deployment with multiple JVMs. In our evaluation, we utilize this multi-backend mode to simulate a real-world scenario.

• *HBase* [4] is a distributed database designed for non-relational big data storage. The evaluated HBase version is 2.5.11. We use YCSB's two different mixed workloads (<50% read, 50% update> and <50% read, 50% insert>) [10] to evaluate the performance of DGC in HBase. HBase also supports a native distributed mode, which partitions the data into multiple regions and distributes them across multiple JVMs. In our evaluation, we utilize this multi-RegionServer mode to evaluate the performance of DGC.

• *DaCapo Bench* [7] provides a broad collection of Java applications. We evaluate DGC on the nine workloads in DaCapo 23.11-chopin that natively report per-request latency: `h2`, `tradesoap`, `tradebeans`, `lusearch`, `tomcat`, `spring`, `kafka`, `cassandra`, and `jme`, covering OLTP databases, online stock trading, text search, HTTP servers, messaging, and a 3D game engine. Following Jade [59]'s DaCapo throttle test

suite [58], we cap each workload's request rate at configurable target throughputs and measure per-request tail latency at each load level. We exclude DaCapo's remaining batch workloads. DGC's benefit comes from stabilizing the per-request CPU supply each served runtime receives over time, but this effect is invisible in end-to-end completion times—the only metric these batch benchmarks report.

Baseline GCs. Our evaluation mainly compares DGC (both DGC-SHM and DGC-RDMA) with Shenandoah and G1. Shenandoah is a concurrent collector integrated in OpenJDK 17. It serves as the codebase for DGC and thus has many implementation similarities. As shown in Table 1, Shenandoah also demonstrates the highest critical-jOPS performance in SPECjbb2015. Therefore, we selected Shenandoah as a representative state-of-the-art concurrent garbage collector to clearly illustrate the performance benefits of DGC.

G1 is currently the default garbage collector in JDK 17. It is a generational collector that is largely stop-the-world (STW): both young-generation collections and the compaction phase during full-heap GC (mixed GC) require STW pauses. Only the marking phase during mixed GC is designed to be concurrent. Although this design leads to frequent application pauses, it results in higher garbage collection efficiency. Due to its widespread adoption in various production scenarios, we used G1 as another baseline.

Memory configurations. For all applications, we first evaluate the minimum heap size that can run them with Shenandoah, then set the evaluation JVM heap size to be 2× of the minimum, to simulate a medium workload. DGC-SHM incurs negligible additional memory overhead and can be deployed directly. Conversely, DGC-RDMA relies on a local heap cache to store object graphs. In our primary evaluation, we assume sufficient remote memory availability and thus do not constrain DGC-RDMA's memory usage. We evaluate the impact of stricter memory configurations separately in Section 8.4, demonstrating that capping memory usage does not significantly compromise DGC-RDMA's performance gains.

CPU configurations. To ensure a fair comparison, baseline and DGC configurations consume the same total CPU budget. Baseline runs N JVMs, each allocated $8+c$ cores. DGC runs the same N JVMs each restricted to 8 application cores, plus one shared DGC service occupying $N \times c$ cores. Both deployments therefore consume $N \times (8+c)$ physical cores in total.

The value of c matches each workload's GC pressure under the 2×-minimum heap convention above. SPECjbb2015 and HBase have minimum heaps of several gigabytes; the 2× heap leaves ample allocation headroom, GC triggers are infrequent, and $c = 2$ cores per JVM are sufficient to absorb the marking demand. DaCapo benchmarks, by contrast, have minimum heaps of only tens to hundreds of megabytes; their 2× heap leaves only a thin allocation buffer, so the application reaches its GC trigger frequently and needs $c = 4$ cores per JVM to keep up. This accounting holds across all our experiments, so any throughput or latency improvement DGC demonstrates below stems from the change in GC mechanism rather than from extra CPU resources.

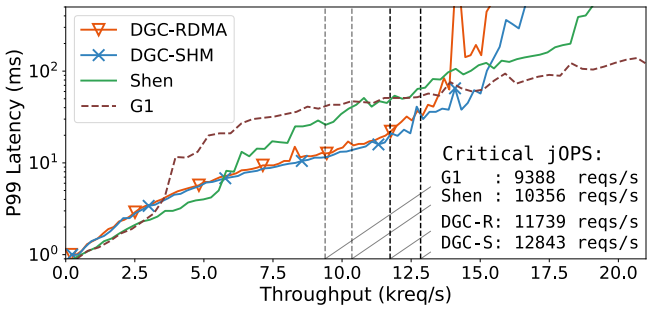

Figure 4: SPECjbb2015's P99 latency curve and Critical jOPS

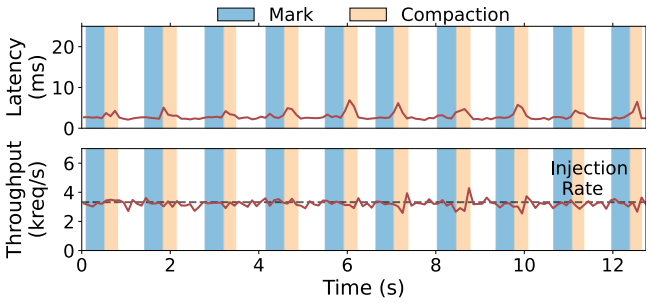

Figure 5: Latency details of SPECjbb2015 with DGC-SHM

8.2 Macro Benchmarks

We first demonstrate DGC's end-to-end performance improvements using macro-benchmarks. Since DGC enhances application performance by time-multiplexing CPU resources across instances to mitigate interference, we establish a minimal experimental setup: each application is deployed with two instances, paired with a DGC service.

SPECjbb2015. We first evaluate the performance of DGC on SPECjbb2015 with its default mode (HBIR_RT). which measures the latency under different issue rates, calculates the critical-jOPS (maximum achievable issue rate within an SLO limit) and reports a curve. The reported throughput and latency are the summary of the two backend clusters, which leads to a difference with previous results in Section 2.

As shown in Figure 4, DGC-SHM achieves the highest critical-jOPS, with 24.0% and 36.8% higher than Shenandoah and G1, respectively. The DGC-RDMA achieves the second highest critical-jOPS, 8.6% lower than DGC-SHM, but 13.4% higher than Shenandoah and 25.0% higher than G1.

From the P99 curve in Figure 4, it can be observed that G1 exhibits higher latency than other low-pause collectors due to its STW pauses. In contrast, both DGC-SHM and DGC-RDMA maintain lower P99 latency than Shenandoah when the issue rate is between 6k and 13k. In this range, the baseline Shenandoah suffers from high CPU contention

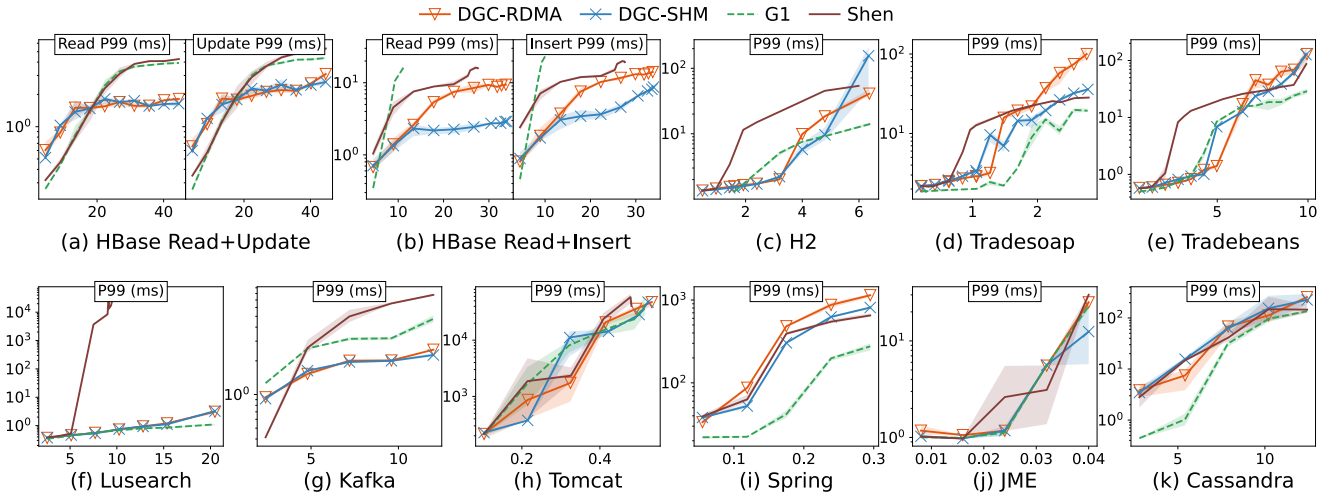

Figure 6: Throughput-latency curves on 2-host homogeneous deployments. (a)(b) HBase YCSB read-update / read-insert workloads, each pair sharing a y-axis. (c)–(k) DaCapo latency-reporting benchmarks. Bands show (min, max) across 3 reps.

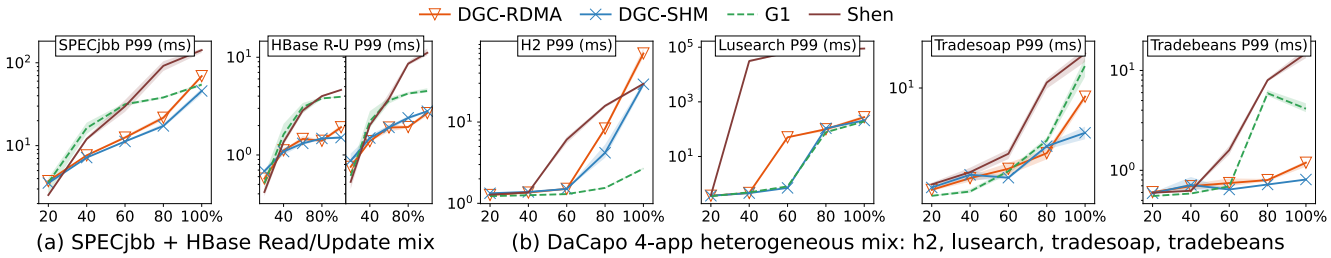

Figure 7: Mixed-workload P99 latency under different load levels; each mix shares one DGC service. (a) SPECjbb + HBase mix, with HBase Read/Update sharing a y-axis. (b) DaCapo 4-app heterogeneous mix. Bands show (min, max) across 3 reps.

between mutator and marker threads, whereas DGC mitigates this by utilizing dedicated physical cores for markers. Consequently, at Shenandoah's critical jOPS (10356 req/s), DGC-SHM and DGC-RDMA reduce P99 latency by 64.4% and 60.3%, respectively.

Additionally, it can be seen on the right side of the figure that DGC-SHM and DGC-RDMA trend towards P99 divergence earlier than the baseline GC. This behavior is attributed to the fact that, in our experimental setup, the DGC runtime operates with two fewer cores compared to the baseline runtime. As a result, DGC's performance degrades faster than the baseline under extremely high loads. This is the trade-off accepted by DGC to optimize application performance under moderate loads.

To identify the source of this performance improvement, we examined the phase-wise latency behavior of DGC under the same configuration used in Figure 1. As observed in Figure 5, the performance fluctuations during the marking phase are significantly smoothed out with DGC. Residual latency fluctuations appear only during the compaction phase, which are attributed to Shenandoah's load barriers.

HBase. We use HBase to further evaluate the performance of DGC in database scenarios. In this experiment, YCSB's two mixed workloads (<50% read, 50% update> and <50% read, 50% insert>) [10] are running on a two-RegionServer configuration, while the RegionServers are equipped with different collectors to evaluate the improvement of DGC.

As shown in Figure 6 (a) and (b), DGC-SHM and DGC-RDMA both achieve lower P99 latency than baselines under most of the issue rates. For the <read, update> workload, DGC-SHM's P99 read and update latencies are 58.3% and 40.3% lower than G1 under peak throughput, while DGC-RDMA's are 53.8% and 29.1% lower than G1. (G1 is the better one of the two baselines.) For the <read, insert> workload, DGC-SHM's P99 read and insert latency are 81.8% and 55.7% lower than Shenandoah under peak throughput, while DGC-RDMA's P99 read and insert latency are 41.4% and 28.5% lower than Shenandoah. G1 fails to achieve a similar peak throughput as Shenandoah or DGC, mainly due to frequent STW full GC (a fallback mechanism triggers when the concurrent marking in mixed GC fails to meet the allocation rate). In contrast, although Shenandoah induces shorter and fewer stop-the-world pauses, its concurrent GC phases cause a consistently slower

request processing speed. This affects a much larger number of requests and leads to worse P99 latency compared to G1. DGC not only maintains the low-pause advantage of Shenandoah but also resolves the CPU contention issue during concurrent GC. As a result, it demonstrates significantly improved tail latency.

DaCapo. Panels (c)–(k) of Figure 6 report P99 latency versus achieved request rate for the nine latency-reporting DaCapo benchmarks, each run as two homogeneous instances of the same workload. Five benchmarks (`h2`, `tradesoap`, `tradebeans`, `lusearch`, `kafka`) show a clear DGC-versus-Shenandoah separation: at the highest request rate each benchmark sustains under Shenandoah, DGC-SHM reduces P99 by 88.6%, 73.1%, 92.8%, four orders of magnitude, and 71.0% respectively. The remaining four benchmarks (`tomcat`, `spring`, `jme`, `cassandra`) show no meaningful separation between DGC and Shenandoah at any rate we tested. G1, by contrast, enjoys a sizable advantage on `tradesoap`, `spring` (i) and `cassandra` (k), where its sub-millisecond young-generation pauses dominate the tail; on the other seven benchmarks G1 is comparable to Shenandoah and DGC.

On these five benchmarks Shenandoah's concurrent marker runs on cores it shares with mutators, and the resulting interference shows up as P99 pressure on the application. The severity varies across the group. On `h2`, `tradesoap`, and `tradebeans` the application drives up to 1.8 GB/s of allocation, the marker stays active for 10 to 27% of wall-clock under high load, and Shenandoah throttles mutators with application-side pauses to keep heap occupancy bounded. This shows up in panels (c)–(e) as a P99 cliff: under Shenandoah, the tail transitions from a flat baseline to a sharp climb once IR crosses a benchmark-specific threshold. At the same IR, DGC-SHM keeps P99 2.3× to 2.7× lower than Shenandoah, and pushes the cliff IR itself out by 1.4× to 2.4×. On `lusearch` above ~5k req/s Shenandoah cannot keep up and falls back to several hundred stop-the-world Degenerated GC cycles per run, producing the multi-second P99. Shenandoah's achieved throughput saturates around 9.5k req/s under this fallback, whereas DGC-SHM scales smoothly up to 20k req/s while keeping P99 within the low-millisecond range. On `kafka` at 12k req/s Shenandoah's marker stays idle for over 98% of wall-clock, but `kafka`'s P99 is sub-millisecond, so even brief marker activity is visible in the tail. As result, DGC-SHM reduces P99 by 71.0% versus Shenandoah and 52.4% versus G1.

The other four benchmarks share a single property the first five lack: GC pressure stays low at every rate we tested. These benchmarks either keep most of their working set off-heap (`cassandra`), run with on-heap working sets of only tens of megabytes (`spring`, `tomcat`), or barely trigger GC at the achievable rates (`jme`). With so little allocation pressure, P99 is dominated by application-logic latency rather than by GC behavior, leaving DGC no contention to remove and Shenandoah none to suffer. G1's young-generation collector benefits from the same property: on a tens-of-megabyte young space its STW pauses are sub-millisecond and invisible in the tail. Shenandoah and DGC instead pay the constant cost of SATB write barriers and concurrent bookkeeping, a fixed tax that is unfavorable when there is little allocation to amortize against, which is why G1 takes the lead on `spring` and `cassandra`.

8.3 Mixed Workloads

The macro benchmarks above each evaluate a single application. We now stress DGC with two heterogeneous co-location scenarios in which multiple JVMs share a single DGC service, directly evaluate the multi-runtime orchestration described in Section 6. Figure 7 sweeps the offered load of every co-located runtime synchronously from 20% to 100% of a per-application target IR calibrated for this mix.

SPECjbb + HBase mix. Panel (a) of Figure 7 co-locates two SPECjbb backends with two HBase RegionServers (YCSB workload A) on a single host, reflecting a common enterprise pattern in which an online service shares hardware with a database. At 100% load, DGC-SHM reduces SPECjbb P99 from 142 ms (Shenandoah) to 46 ms (a 67.6% reduction), YCSB read P99 from 4.64 ms to 1.51 ms (-67.5%), and YCSB update P99 from 11.1 ms to 2.80 ms (-74.8%). DGC-RDMA achieves comparable reductions of 51.5%/58.5%/75.9% on the same three metrics. G1 is the second baseline, it stays 1.4–3× above DGC at the upper half of the IR range.

DaCapo 4-app mix. Panel (b) co-locates the four latency-reporting DaCapo benchmarks (`h2`, `lusearch`, `tradesoap`, `tradebeans`) on a single host. The mix amplifies the DGC-versus-Shenandoah gap relative to the homogeneous case in Figure 6. `lusearch` under Shenandoah collapses to a 64-second P99 already at 60% mix-load, whereas DGC-SHM holds the same workload at 708 μs; `tradebeans` and `tradesoap` at 100% load achieve 94.6% and 66.1% P99 reductions over Shenandoah. DGC-SHM also outperforms G1 by 80.5% on `tradebeans` and 60.0% on `tradesoap` at the same load point, but offers no significant advantage over G1 at other load levels, primarily because G1's generational design achieves higher collection efficiency on these smaller DaCapo workloads.

8.4 RDMA and Memory Efficiency

Figure 8 illustrates the SPECjbb2015 tail latency and corresponding RDMA traffic of DGC-RDMA with varying local heap cache sizes. To eliminate the noise caused by drastic load fluctuations in the HBIR mode, we configured SPECjbb2015 to the fixed-throughput (Preset) mode. The Injection Rate (IR) was fixed at 10,356, corresponding to the best Critical jOPS of the baseline Shenandoah collector (as shown in Figure 4), to explicitly demonstrate the performance uplift enabled by DGC. Additionally, the coordinator enforces strict time-multiplexing of the four GC cores between two Runtimes

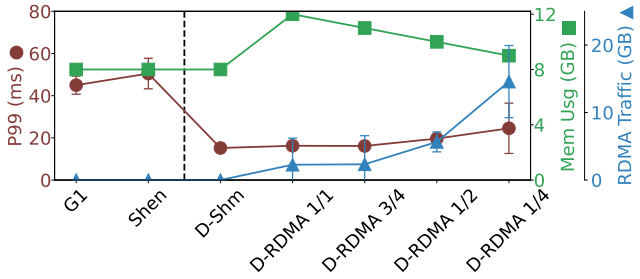

Figure 8: DGC-RDMA's P99 latency, memory usage, and RDMA traffic under different local cache settings.

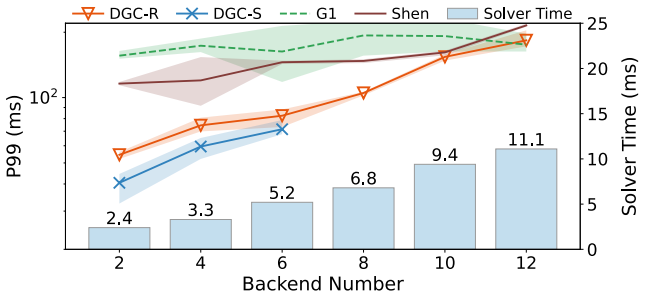

Figure 9: Scalability test results on SPECjbb2015 PRESET.

to prevent simultaneous DGC triggers and avoid doubling peak heap cache usage. Among the four evaluated configurations, even the most constrained setting (1/4 cache) achieves a 51.5% improvement in P99 latency over Shenandoah, since its RDMA traffic is still within the bandwidth limit. Notably, the 1/2 cache configuration strikes an optimal balance between memory overhead and RDMA traffic cost. Compared to the baseline of two 4GB heaps, it requires only 2GB of additional remote memory (a 25% overhead) to serve as the DGC node's local cache. Furthermore, it incurs an average RDMA traffic of only 5.52GB per GC cycle, representing a moderate 37% amplification relative to the 4GB full heap size.

8.5 Scalability Test

SPECjbb2015 homogeneous workload. To evaluate the performance of DGC as the number of runtimes increases, we conducted a series of experiments running SPECjbb2015 with varying numbers of backends in a distributed setup. The experiment adhered to the core allocation policy established earlier. To simplify the testing process, we used SPECjbb2015's PRESET mode, in which the benchmark runs at a fixed throughput and reports P99 latency. The average load per backend was set to 6819 req/s, as measured in Table 1, and the total system load was scaled proportionally with the number of backends.

The results are shown in Figure 9. DGC consistently demonstrated better P99 latency than Shenandoah across all scales, with the improvement of up to 43.3% and 50.9% at 6 backends. Since DGC-SHM requires the served JVM and the disaggregated marker to reside on the same node, it was limited to 6 backends (7 backends would require at least 70 cores per node, exceeding the 64 cores limit in our physical machines). DGC-RDMA mode was tested up to 12 backends, but the performance improvement began to diminish. Analysis of the GC logs indicates that the RDMA NIC bandwidth became a bottleneck at this point.

During the test, we also recorded the time taken by the CP-SAT solving process. The solving time remained efficient, taking only 11.1 ms even in the 12-backend scenario, which is sufficient for scheduling the GC tasks that last for hundreds of milliseconds.

Table 3: Performance breakdown on SPECjbb2015 PRESET

Garbage Collector	P99 (ms)	avg. Mark Time (ms)
DGC	81.5 ± 1.1	416.1 ± 2.8
DGC-noOPT	87.0 ± 10.8	406.9 ± 2.0
DGC-noCOOR	13800 ± 7132	641.2 ± 28.3
Shenandoah	121.3 ± 3.6	284.2 ± 1.6

8.6 Ablation Study

We evaluated the individual contributions of our two primary optimizations using SPECjbb2015's PRESET mode. Given the limited configurability of DGC-SHM, this ablation study focuses on DGC-RDMA, with results detailed in Table 3.

Impact of Pipelined Co-design. The "noOPT" configuration disables the pipelined marker-transfer co-design described in Section 5.2. Instead of concurrent execution, the marker is forced to wait for the entire heap to be copied before starting. This serialization raises P99 latency by only 6.7% over the full configuration (87 ms vs 81.5 ms). This gap confirms that our design effectively masks the majority of data transfer costs.

Impact of Global Scheduling. The "noCOOR" configuration removes the global GC scheduler, relying instead on local JVM heuristics. Without cross-JVM coordination, the per-cycle marking time exhibits a much wider spread. The local heuristic depends on a stable marking-time estimate to predict the next trigger point, so it can no longer place triggers accurately. As triggers diverge, free space is repeatedly exhausted before marking completes, and the system periodically falls back into degenerated GC. The served JVMs can no longer sustain the target injection rate, and end-to-end latency itself diverges (Table 3).

9 Discussion

Generalizability to other collectors. DGC's core mechanism—offloading concurrent marking under an SATB snapshot—is not specific to Shenandoah. It integrates directly with any SATB-style collector, including G1, Generational Shenandoah, LXR [67], and Jade [59], with only data-plane-level changes to the bitmap and SATB-buffer layouts; the correctness argument in Section 5.1 is collector-agnostic. Colored-pointer collectors such as ZGC can be supported by adding a lightweight SATB-style buffer purely to feed the remote marker, while the colored-

pointer machinery used for evacuation and remapping remains on the local collector.

Trust and cross-tenant isolation. DGC's orchestrator, marker, and served runtimes sit inside a single operator-managed trust boundary (Section 4.2); cross-tenant isolation between co-located runtimes is enforced by the same cgroup, NUMA, and namespace mechanisms that already isolate co-located JVMs. Within the DGC instance, the orchestrator serializes marking tasks across tenants on the shared marker pool (Section 6), so one tenant's marking cannot co-run with—and steal CPU from—another's.

Future work. DGC does not currently enforce memory-bandwidth or PCIe-level isolation between concurrent marking tasks; under sustained fan-in to a single NIC, RDMA-mode clients can mildly interfere through shared PCIe bandwidth, which finer-grained mechanisms such as MBA or per-queue-pair rate limiting would tighten. A second extension concerns the scheduler. DGC adopts CP-SAT to remain general across heterogeneous workloads (Section 6.2); identifying when a solver-free heuristic suffices would remove the external optimization dependency and shorten the scheduling tick.

10 Related Work

10.1 Concurrent garbage collection

Concurrent garbage collection (GC) is a critical component in modern Java Virtual Machines (JVMs) to ensure efficient memory management without significant pause times. Several state-of-the-art concurrent marking algorithms have been developed, including those used in the JDK's G1, Shenandoah, and ZGC collectors.

Other research works also focus on optimizing the concurrent marking GC algorithm. C4 [49] builds on Pauseless GC by incorporating a generational approach, while Collie [21] suggests leveraging hardware transactional memory (HTM) for atomic object relocation. Compressor [25] employs hand-over-hand compaction to maintain minimal physical memory usage. Block-free GC [42] introduces non-blocking handshakes for concurrent stack scanning and object copying. Jade [59] provides a group-wise collection mechanism to improve the performance of low-pause GC. Some other concurrent collectors, like LXR [67], use reference counting to discover dead objects but still need to conduct concurrent marking periodically.

10.2 Externalized Garbage Collection

Due to the increasing demand for high-performance computing and data processing, the use of specialized hardware to accelerate applications has become increasingly popular [22, 24, 26, 38, 52, 53, 57, 61, 62, 65, 69].

Previous research has also explored the idea of externalizing GC processes with specialized hardware. Martin Maas et al. [35] proposed a hardware accelerator that is located close to the memory controller, which can significantly improve the GC performance. Andrés Amaya et al. [14] further extended the idea in real-time scenarios. Thomas et al. [51] proposed to optimize the garbage collection with recently developed near-memory processing (NMP) hardware. DGC differs in two ways: it offloads GC onto commodity server CPUs over RDMA or shared memory, and it shares those GC resources across multiple runtimes rather than reserving them exclusively.

Maas et al. [33, 34, 36] also coordinate GC across multiple JVMs, but target *cooperating* workers of a single distributed application (e.g., Spark, Cassandra) by exploiting application-level events to decide when each node collects. DGC instead targets *unrelated, black-box* JVMs co-located by an operator, staggers their GC windows purely from JVM-level metrics, and additionally offloads the marking computation itself into a shared compute pool.

10.3 Disaggregation and Resource Pooling

Resource pooling, particularly memory pooling, has been widely studied [2, 9, 18, 20, 27, 28, 32, 45, 46, 56, 68].

Some works also focus on building a garbage collector for memory-disaggregated systems. Semeru [54] and Mako [31] are memory-disaggregated managed runtimes with a distributed garbage collector that is located on the memory node to minimize the memory swapping overhead. MemLiner [55] further reduces the memory swapping overhead by locating the garbage collector on the CPU node and prioritizing the marking task of objects in the CPU Node's local memory. These efforts primarily focus on leveraging disaggregated memory to address memory utilization issues. Their goals are orthogonal to those of DGC, which is chiefly concerned with mitigating CPU load fluctuations during garbage collection and improving CPU utilization through decoupled GC execution.

11 Conclusion

This work presents DGC, a disaggregated architecture to serve GC tasks of language runtimes in an external instance. DGC supports externalizing the costly marking task in GC to idle CPU cores locally or remotely and allowing multiple runtimes to share the GC service with minimal conflicts. The evaluation results on representative latency-sensitive applications show that DGC can significantly improve the application latency and goodput.

A Artifact Appendix

Abstract

This artifact reproduces the figures and tables of the paper by running the DGC-enabled OpenJDK 17 fork against SPECjbb2015, HBase + YCSB, and DaCapo workloads under the four GC variants compared in the paper: G1, Shenandoah, DGC-SHM, and DGC-RDMA.

Scope

The artifact lets the evaluator validate the central latency and throughput claims of the paper, namely that disaggregating the concurrent marking phase to dedicated cores (via SHM or RDMA) reduces tail latency on managed workloads compared to G1 and Shenandoah at the same total core budget.

Contents

The artifact tree is rooted at `dgc-artifacts/` and contains:

- `jdk17-snic-gc/` — the bundled OpenJDK 17 fork implementing DGC-SHM and DGC-RDMA.
- `osdi26-scripts/` — per-figure / per-table top-level driver scripts, analyzers, and parsers.
- `conf/gc/` and `conf/workloads/` — GC profiles (G1, Shenandoah, DGC-SHM, DGC-RDMA) and workload knobs.
- `lib/` — shared shell libraries for CPU/NUMA pinning, isolation, and per-suite runners.
- `hbase-conf/` — HBase + YCSB drop-in config.
- `plot/` — Python plotting scripts.

Hosting

The artifact is publicly hosted on GitHub at https://github.com/SJTU-IPADS/dgc-artifacts on the `main` branch.

Requirements

Hardware. A NUMA Intel x86_64 server with hyperthreading disabled. The paper's core-budget settings assume dual-socket Intel Xeon Gold 6430 (32 physical cores per socket; even cores on NUMA node 0, odd cores on node 1) with 128 GB of RAM. DGC-RDMA additionally requires an RDMA NIC; the paper uses a 200 Gbps NVIDIA BlueField-3 DPU.
Operating system. Ubuntu 22.04 LTS.
External dependencies. The artifact tree expects the following sibling directories: the prebuilt DGC JDK image, SPECjbb2015 v1.0.4 (commercial; SPEC license required), HBase 2.5.11 + YCSB 0.18.0, the DaCapo 23.11-chopin throttle fork (built in-tree), and Google OR-Tools v9.10. The repository `README` documents the exact layout, download URLs, and build commands.

B CP-SAT Problem Description

To address the challenge of scheduling multiple GC tasks that can execute with different thread configurations, the following problem is formulated.

Let $\mathcal{J} = \{1, 2, \ldots, N\}$ represent the set of garbage collection tasks, and $\mathcal{M} = \{1, 2, \ldots, M\}$ denote the available thread configurations for each GC operation. For each task $i \in \mathcal{J}$ and thread configuration $n \in \mathcal{M}$, we define the following parameters:

- $d_{i,n}$: duration of GC task i when using n threads
- $r_{i,n}$: number of threads required by task i in configuration n
- δ_i: GC deadline for task i (latest safe completion time)

The total available GC threads in the system is constrained by C, representing the maximum concurrent GC threads the system can support.

B.1 Decision Variables

The mathematical model employs several decision variables to capture the scheduling decisions:

$$
\begin{aligned}
s_i &\in \mathbb{Z}^+ && \text{start time of GC task } i \\
e_i &\in \mathbb{Z}^+ && \text{end time of GC task } i \\
x_{i,n} &\in \{0, 1\} && \text{binary variable indicating whether task } i \\
& && \text{uses thread configuration } n
\end{aligned}
$$

B.2 Constraints

The scheduling must satisfy several hard constraints to ensure system stability and prevent out-of-memory conditions. Each GC task must be assigned exactly one thread configuration:

$$\sum_{n \in \mathcal{M}} x_{i,n} = 1 \quad \forall i \in \mathcal{J} \tag{1}$$

The completion time of each task is determined by its start time and the duration of the selected thread configuration:

$$e_i = s_i + \sum_{n \in \mathcal{M}} d_{i,n} \cdot x_{i,n} \quad \forall i \in \mathcal{J} \tag{2}$$

To prevent out-of-memory errors, each garbage collection must complete before its safety deadline:

$$e_i \leq \delta_i \quad \forall i \in \mathcal{J} \tag{3}$$

The most critical constraint ensures that the total number of active GC threads never exceeds system capacity C at any time instant:

$$\sum_{i \in \mathcal{J}} \sum_{n \in \mathcal{M}} r_{i,n} \cdot \mathbb{I}(s_i \leq t < e_i) \cdot x_{i,n} \leq C \quad \forall t \in [0, T_{\max}] \tag{4}$$

where $\mathbb{I}(\cdot)$ is the indicator function and $T_{\max}$ is the maximum time horizon.

B.3 Objective Function

The optimization aims to maximize the sum of start times to provide scheduling flexibility while discouraging inefficient thread configurations (particularly the configuration that falls back to native concurrent GC):

$$\text{maximize} \quad \sum_{i \in \mathcal{J}} s_i - \alpha \cdot \sum_{i \in \mathcal{J}} \sum_{n \in \mathcal{M}_{\text{ineff}}} x_{i,n} \tag{5}$$

where α is a penalty coefficient and $\mathcal{M}_{\text{ineff}} \subset \mathcal{M}$ represents the set of inefficient configurations.

DeLFS: A Decentralized Log-Structured File System for Manycores

Taehwan Ahn[†], Chanhyeong Yu[†], Sangjin Lee, and Yongseok Son[*]
Systems and Storage Laboratory, Chung-Ang University

Abstract

This paper introduces DeLFS, a novel decentralized log-structured file system (LFS) designed for manycore scalability. DeLFS decentralizes metadata/data organization and management with an LFS-aware decentralized locking scheme that distributes lock ownership to eliminate global contention. In addition, DeLFS disentangles the critical path from the deferrable path to further increase concurrency. We implement DeLFS with three techniques in the Linux kernel and evaluate it on a 128-core machine. The experimental results show that DeLFS outperforms F2FS, MAX, and F2FSJ by up to 4.34×, 4.29×, and 4.50×, respectively, and delivers up to 2.00× higher sustained performance than ScaleLFS.

1 Introduction

Log-structured file systems (LFSs) [9, 11, 12, 15, 16, 18, 20, 21, 24, 27, 30, 34] are attractive for modern storage systems because their append-only, log-structured design transforms small, random updates into large, sequential write streams, achieving high write efficiency on flash-based storage devices [18, 24, 26]. Despite these advantages, existing LFSs face scalability challenges because they rely on centralized architecture and coordination for metadata and data management, where multiple global locks serialize file operations across many cores [17, 23]. This architecture limits concurrency and parallelism, thereby degrading I/O performance.

Challenges: Figure 1 shows the application throughput in various modern LFSs (i.e., F2FS [18], MAX [21], ScaleLFS [11], F2FSJ [9]) under a random write workload generated by a micro-benchmark (i.e., FIO [4]). As shown in the figure, the raw performance of the NVMe SSD [2] scales well with the number of cores, reaching up to 5.24 GB/s. However, the performance of existing LFSs remains limited to around 1.06 GB/s even as the number of cores increases. In particular, even when we combine ScaleCache [29], a scalable page cache, with F2FS and other LFSs (as detailed in Section 3.1), the performance unexpectedly remains almost unchanged or even degrades. We observe that this limitation mainly stems from severe lock contention caused by multiple global locks on metadata and data management, serializing I/O operations and restricting concurrency across cores.

Prior studies: Previous studies have explored LFSs to improve scalability and reduce garbage collection (GC) overhead. F2FSJ [9] introduces a decentralized, epoch-based journaling technique for F2FS with an ordered journal mode to reduce checkpointing time. MAX [21] is a multicore-friendly LFS that scales access to in-memory index and cache while maintaining multiple independent logs, but it still suffers from lock contention. ScaleLFS [11] presents a scalable GC that parallelizes the GC procedure and concurrent victim management. Our study is inspired by and in line with these studies in terms of investigating LFS scalability and performance. In contrast, our study focuses on establishing a holistic decentralized LFS architecture with LFS-aware locking.

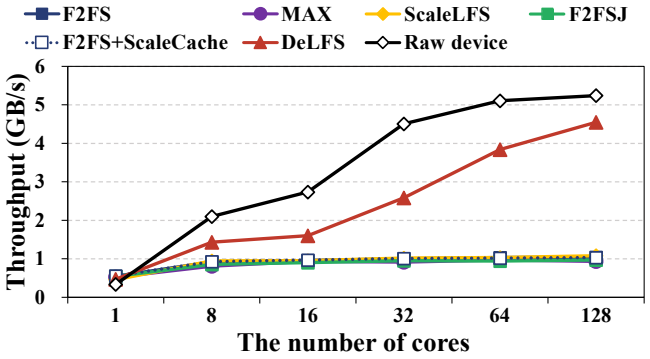

Figure 1: Scalability comparison of log-structured file systems.

Contributions: In this paper, we propose DeLFS, a decentralized log-structured file system designed to improve scalability on manycore systems. Our key idea is to *leverage the potential of distributing lock ownership across cores safely*, enabling a holistic, decentralized LFS architecture. Specifically, DeLFS first proposes *decentralized organization and management* of LFS resources by decomposing metadata and data layouts into per-core domains. This design enables a one(core)-to-one(resource) model and serves as the foundation of our decentralized architecture, where each core primarily operates on its own local metadata and data while minimizing cross-core interference.

Second, DeLFS adopts an LFS-aware *decentralized and decoupled locking* scheme that distributes lock ownership across cores while enabling deadlock-free acquisition. In addition, this scheme decouples certain updates into independently executable operations while still preserving atomic updates to decentralized resources. Thus, this locking mechanism eliminates global lock contention without compromising crash consistency. Finally, DeLFS presents lazy lock coordination, which disentangles critical and deferrable operations to further mitigate contention from inter-core decentralized lock sharing. To do this, DeLFS employs a lazy lock coordinator that handles deferred operations while preserving crash con-

(a) Throughput. (b) Tail latency (99th).

Figure 2: Throughput and tail latency with various LFSs.

sistency. As a result, DeLFS accelerates both application I/O and GC I/O processing by mitigating lock contention and improving core scalability.

We implement DeLFS with three techniques based on F2FS [18] and ScaleCache [29] in Linux kernel 6.6.8. We evaluate it on a 128-core machine with the NVMe SSD [2] using the micro [4] and macro [31] benchmarks and real-world application [10]. The experimental results show DeLFS outperforms F2FS, MAX [21], ScaleLFS [11], and F2FSJ [9] by up to 4.34×, 4.29×, 4.10×, and 4.50×. Note that, even with ScaleCache, the results show DeLFS outperforms F2FS, MAX, ScaleLFS, and F2FSJ by up to 4.55×, 6.32×, 3.99×, and 4.38×. Furthermore, DeLFS delivers up to 2.00× higher sustained performance than ScaleLFS. To the best of our knowledge, DeLFS is the first holistic, decentralized log-structured file system with an LFS-aware locking scheme across cores in modern many-core systems. Finally, we open the source code of DeLFS and baselines used in our evaluation at https://github.com/syslab-CAU/DeLFS to aid future studies in LFSs.

2 Background and Motivation

A log-structured file system (LFS) follows an append-only design, transforming small random writes into large sequential write streams. F2FS manages storage in segments (e.g., 2 MB) and divides the space into a random-write area for on-disk metadata (e.g., SIT (segment information table), NAT (node address table), and SSA (segment summary area)) and a sequential main area for node and data blocks, further separating node/data into hot, warm, and cold temperatures to exploit device parallelism. However, the organization and management of these metadata structures and related data structures are centralized and protected by coarse-grained global locks shared across all cores. As a result, the locks serialize metadata and data updates, preventing full exploitation of parallelism and limiting scalability on many-core systems.

3 Scalability Analysis

3.1 Scalability Analysis on Modern LFSs

To understand the scalability performance of modern LFSs (F2FS, MAX, ScaleLFS, and F2FSJ), both with and without ScaleCache [29], we run FIO with random write on our testbed under the evaluation scenario as described in Section 5.1 and 5.2. Figure 2 shows the throughput and tail latency of LFSs on varying numbers of cores. The LFSs do not scale well and exhibit almost the same throughput even as the number of cores increases. In addition, latency spikes significantly at 128 cores compared with 64 cores. Furthermore, even when combined with ScaleCache [29], the performance of LFSs still does not improve and can even degrade (see details in Section 3.2). Consequently, these results indicate that the design of existing LFSs has limitations.

3.2 Identifying Root Causes

3.2.1 Limitation of Page Cache Flushing

The first root cause of low I/O performance in modern LFSs is the serialized page-flushing path in the page cache. Under data-intensive write workloads, a single flusher thread flushes dirty pages for one inode at a time while throttling application threads, a mechanism originally designed for HDD-based systems [29]. On modern many-core servers with high-performance SSDs, this design cannot provide sufficient I/O parallelism, and the throttling intervals (e.g., `io_schedule_timeout()`) become the first bottleneck (Table 1). ScaleCache [29] addresses this blocking bottleneck with direct page flush (dflush), allowing application threads to flush pages in parallel. Accordingly, we evaluate modern LFSs with ScaleCache. However, as shown in Table 1, the throughput improvement is negligible or even negative, indicating that LFSs suffer from additional bottlenecks.

3.2.2 Scalability Obstacles in LFSs

We analyze the design of modern LFSs to identify the main obstacles that hinder the scalability on manycores.

Serialized I/O process: After the blocking bottleneck by the throttling mechanism is eliminated, modern LFSs encounter the next bottleneck caused by lock contention on the serialization mutex (`writepages`) in the writeback path, as shown in Table 1. This lock serializes writeback on a per-inode basis, forcing flushers to wait until the current holder completes submitting pages for its inode. This design aligns file and segment lifetimes by keeping pages of a file within a segment, thereby avoiding inter-file interleaving. Thus, this design enforces per-file writeback, which significantly limits I/O parallelism. To enable more parallel I/O, we can simply eliminate this serialization lock without compromising correctness or consistency, as it only relaxes the alignment between file and segment lifetimes. However, pages from multiple inodes may become interleaved within a segment, potentially degrading GC efficiency; we report that its impact on write amplification is minor (Section 5.2). Despite this increased parallelism, LFSs still suffer from the scalability bottleneck in multi-head logging management.

File system	Different file system variants	Throughput	Execution time	io_schedule_timeout()	serialization mutex (writepages)	curseg_mutex	io_rwsem	others
F2FS [18]	F2FS	1.05 GB/s	279.7s (100%)	269s (96.17%)	2.2s (0.8%)	0.3s (0.1%)	2.5s (0.9%)	5.7s (2.03%)
	F2FS+SC	1.00 GB/s	293.7s (100%)	0s (0%)	152.7s (52%)	0.3s (0.1%)	0.3s (0.1%)	140.4s (47.8%)
	F2FS+SC+Serialization-free	1.23 GB/s	238.7s (100%)	0s (0%)	0s (0%)	114.5s (47.95%)	5.7s (2.39%)	118.5s (49.66%)
MAX [21]	MAX	1.06 GB/s	277.1s (100%)	269.4s (97.21%)	1.7s (0.6%)	0.6s (0.2%)	1.9s (0.7%)	3.5s (1.29%)
	MAX+SC	0.72 GB/s	407.9s (100%)	0s (0%)	215.8s (52.9%)	0.5s (0.13%)	3.3s (0.8%)	188.3s (46.17%)
	MAX+SC+Serialization-free	0.71 GB/s	413.6s (100%)	0s (0%)	0s (0%)	0.5s (0.1%)	213.8s (51.7%)	199.3s (48.2%)
ScaleLFS [11]	ScaleLFS	1.11 GB/s	264.5s (100%)	253.2s (95.7%)	2.2s (0.83%)	0.3s (0.13%)	1.6s (0.62%)	7.2s (2.72%)

Table 1: Performance breakdown of modern LFSs on 128 cores (SC: ScaleCache [29]).

Multi-head logging management: When enabling parallel I/O without the serialized design and lock (i.e., serialization-free), the bottleneck shifts to lock contention (`curseg_mutex`) from the space allocation in multi-head logging management as shown in Table 1. F2FS adopts a multi-head logging scheme with six active logs, where each log head corresponds to a current segment (`curseg_info`). Each current segment sequentially allocates new blocks, thereby preserving the append-only write pattern. However, the number of current segments is fixed at six even on many-core systems. Moreover, most data-intensive writes are allocated from the warm-data log, and a mutex, the current segment lock (`curseg_mutex`) must be acquired whenever a block is allocated. As a result, this centralized lock becomes a severe bottleneck, as cores contend for it during block allocation. Note that MAX [21] targets this lock contention and solves it by the mlog scheme, which allocates the space in a round-robin manner. However, the bottleneck shifts to the I/O submit management.

Submit management: LFSs maintain six bio structures (block I/O descriptors [7]), each corresponding to one of the six log streams, so that I/O requests can be batched and managed on a per-stream basis. During a flush, dirty pages are classified by type and temperature and appended to the corresponding bio. Each appended page is checked for merge opportunities with existing pages; if mergeable, the LFS performs the merge while holding the I/O submit lock (`io_rwsem`) to ensure consistency of the bio's internal state. However, this design, which maintains only a fixed set of six bios and protects their operations with the lock per bio, limits parallel I/O on many-core systems. We observe severe contention on this lock in MAX, ScaleLFS, and F2FSJ as shown in Table 1. In particular, when the lock contention on `curseg_mutex` is mitigated, the lock contention on `io_rwsem` becomes the next dominant bottleneck.

Segment management: Even if the bottleneck in submit management is mitigated, additional bottlenecks can still arise in the I/O path, as shown in Table 4. For example, segment-level metadata management also introduces synchronization overhead. The SIT tracks the state of all segments in the main data area. It contains multiple SIT entries, each of which corresponds to a segment and maintains both the number of valid blocks within the segment and a bitmap representing the validity of each block. When a block is allocated for a data page, the associated SIT entry is updated to mark it as valid. However, to ensure correct updates, the SIT entries are protected by a single read-write semaphore, the SIT entry lock (`sentry_lock`). Thus, even if only one SIT entry needs to be updated, this coarse-grained lock must be acquired, thereby preventing concurrent access to the entire SIT.

Segment list management: Furthermore, segments are tracked using multiple bitmaps according to their validity state: segments with a mix of valid and invalid blocks are recorded in the dirty-segment bitmap, while segments whose blocks are all invalid are recorded in the pre-segment bitmap and are later reclaimed as free. However, both the dirty and pre-segment bitmaps are protected by a single mutex (`seglist_lock`). As a result, as the state of segments changes, moving segments across the segment bitmaps requires acquiring this lock, which limits concurrency.

Node management: Beyond segment management, LFSs also face a scalability bottleneck in managing the NAT. Inodes and internal nodes are tracked via NAT entries, which are cached in memory in a global tree protected by a read-write semaphore (`nat_tree_lock`) and managed by an LRU-style NAT list protected by a spinlock (`nat_list_lock`). While this NAT cache reduces storage I/Os for node lookups, its centralized locking becomes a scalability bottleneck (Table 4). MAX [21] mitigates NAT contention using file cells, but its overall scalability remains limited because other bottlenecks are not addressed.

Discard management: Finally, modern LFSs also suffer from scalability bottlenecks in discard management. A global discard command controller maintains a list of discard entries protected by a single mutex (`cmd_lock`). During write I/O, each newly allocated block must acquire `cmd_lock` to check and remove any matching discard entry before reuse. Because `cmd_lock` is a global lock shared by all discard operations, it becomes a major source of lock contention once other bottlenecks are alleviated (see Table 4).

4 Design and Implementation

Our key idea is to *leverage the potential that lock ownership can be distributed across cores safely*, enabling a robust and decentralized LFS architecture. The rationale behind this design choice is that there are a lot of LFS resources and their locks, each of which protects a large critical section. Thus,

it is hard to remove these locks, which may be less robust; instead, we split large resources and their locks and distribute the lock ownership of each resource across cores.

4.1 Design Goals of DeLFS

We design DeLFS to satisfy the following three goals.

Decentralizing LFS resources: To design a scalable LFS, DeLFS should holistically decentralize LFS resources to minimize interference from shared and global resources and maximize core and I/O parallelism.

Minimizing lock contention with safe synchronization: To minimize global lock contention, DeLFS should provide a lightweight locking mechanism to maximize concurrency while preserving correctness via safe synchronization.

Coordinating inter-core sharing: To support inter-core sharing when necessary, DeLFS should provide a coordination technique to avoid waiting on operations from other cores without sacrificing consistency.

4.2 Overall Architecture of DeLFS

Overall, DeLFS redesigns the centralized organization and management of LFS resources into a fully decentralized metadata/data organization and its management, where each decentralized LFS resource is efficiently protected by decentralized locking and orchestrated by decentralized lazy lock coordination across cores. DeLFS consists of the following three techniques and strategies to meet the goals.

Strategy 1: Decentralized organization and management. To minimize interference from shared and global resources among cores, DeLFS decentralizes LFS metadata and data management into per-core domains. Each core owns and manages its own subset of decentralized metadata (e.g., SIT, NAT, multi-head logging, SSA as $M_{0\text{-}0} \ldots M_{k\text{-}0}$ for $core_0$) and its local segments (e.g., $seg_{0\text{-}0} \ldots seg_{k\text{-}0}$ for $core_0$). This one-core–one-resource design reduces cross-core interference and forms the foundation of DeLFS's decentralized architecture.

Strategy 2: Decentralized and decoupled locking. On top of this organization, DeLFS decentralizes locks so that each core primarily acquires locks on its own decentralized resources, rather than contending for global locks. However, when inter-core access is required, naive decentralized locking can still cause cross-domain deadlocks and skewed contention. To address this, DeLFS introduces decentralized and decoupled locking (DDL), which decouples certain updates into individually executable operations while preserving atomicity and enforces a lock-update-unlock discipline on one resource at a time. This single-lock-hold property breaks potential deadlock cycles, reduces lock hold time, and allows lock ownership to be safely distributed across cores while preserving correctness through the existing LFS checkpoint mechanism.

Strategy 3: Lazy lock coordination. To further reduce blocking from inter-core decentralized lock sharing, DeLFS introduces lazy lock coordination. We observe that many operations can be split into a critical path and a lazily deferrable path without affecting correctness. DeLFS therefore employs per-core lock coordinators and delegates remote, deferrable lock-acquisition tasks to the coordinator of the core that owns the target resource, so that the critical path is no longer blocked by remote lock acquisition. These delegated operations are processed lazily but are guaranteed to complete before checkpointing, where DeLFS's checkpoint procedure waits for and cooperatively processes pending tasks at each coordinator. As a result, lazy lock coordination accelerates critical operations while preserving LFS crash consistency.

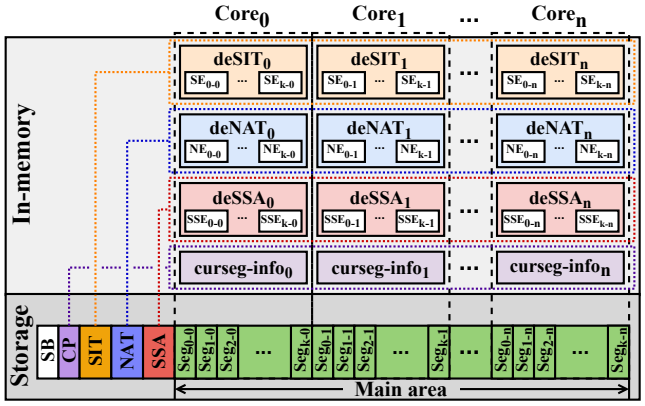

Figure 3: Decentralized organization of DeLFS (de: decentralized, SE: SIT entry, NE: NAT entry, SSE: SSA entry, Seg: Segment).

4.3 Decentralized Architecture

Decentralized organization: DeLFS decentralizes in-memory metadata and on-disk data and node segments into per-core domains, allowing each core to manage its own domain independently and thereby improving I/O scalability. For example, as shown in Figure 3, metadata structures such as $deSIT_0$–$deSIT_n$, $deNAT_0$–$deNAT_n$, $deSSA_0$–$deSSA_n$, and $curseg\text{-}info_0$–$curseg\text{-}info_n$ are decentralized across cores. Thus, each core primarily accesses its own metadata, avoiding contention on shared metadata structures. Specifically, per-core current segment information (curseg-info, curseg_info) allows each core to allocate space from its own multi-head log, naturally decentralizing node and data segment allocation. During page flushing, each core exclusively flushes all dirty data pages of a fetched inode to its own space. This isolates the inode's I/O path from other cores and prevents data pages from being interleaved across cores, further improving scalability and performance. Note that when a core does not have enough free segments in its own space, DeLFS allows it to allocate segments from the next core's domain in a round-robin manner, preserving space efficiency while maintaining decentralized organization. As a result, this architecture establishes a one(core)-to-one(resource) model that eliminates global metadata hot spots and enables highly parallel, low-contention I/O execution across cores.

Decentralized management: Figure 4 and 5 illustrate decentralized management and how the I/O operation is performed

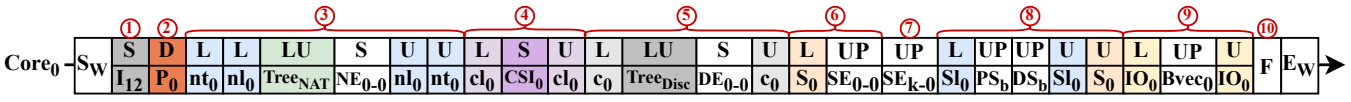

Figure 4: Decentralized management of DeLFS timeline ($\mathbf{S_W}$: start write, **S**: select, **D**: Dirty, **L**: lock, **U**: unlock, **LU**: lookup, **UP**: update, **F**: flush, $\mathbf{E_W}$: end write, $\mathbf{I_x}$: inode$_x$, $\mathbf{P_0}$: page$_0$, $\mathbf{nt_0}$: nat_tree_lock$_0$, $\mathbf{nl_0}$: nat_list_lock$_0$, $\mathbf{Tree_{NAT}}$: NAT tree, $\mathbf{NE_{0\text{-}n}}$: 0th NAT entry in core$_n$, $\mathbf{cl_0}$: curseg_mutex$_0$, $\mathbf{CSI_0}$: current segment information of core$_0$, $\mathbf{c_0}$: cmd_lock$_0$, $\mathbf{Tree_{Disc}}$: discard tree, $\mathbf{DE_{0\text{-}n}}$: 0th discard entry in core$_n$, $\mathbf{S_0}$: sentry_lock in core$_0$, $\mathbf{SE_{0\text{-}n}}$: 0th SIT entry in core$_n$, $\mathbf{Sl_0}$: seglist_lock$_0$, $\mathbf{PS_b}$: pre-segment bitmap, $\mathbf{DS_b}$: dirty-segment bitmap, $\mathbf{IO_0}$: io_rwsem$_0$, $\mathbf{B_{vec0}}$: bio vector$_0$).

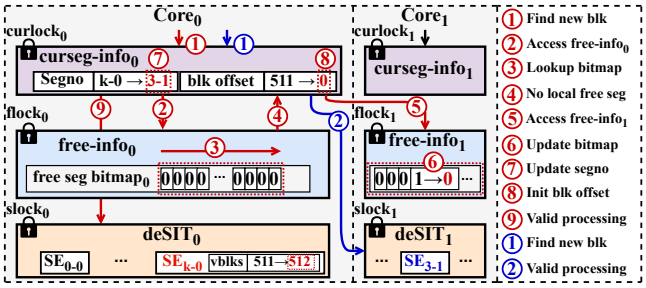

Figure 6: Cross-core space allocation.

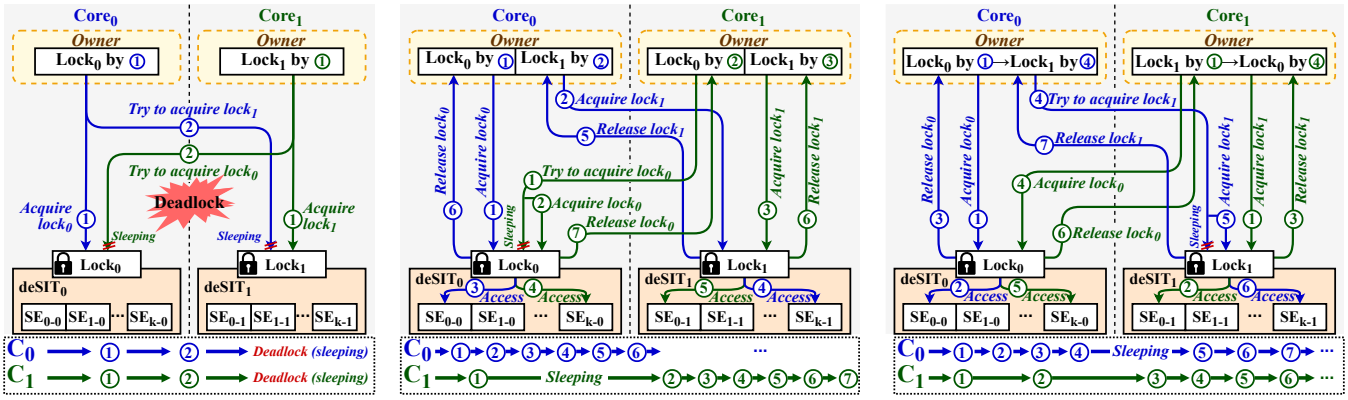
in DeLFS. In these figures, a core begins by selecting an inode (inode$_{12}$) to flush dirty data pages belonging to that inode (①). To flush dirty page$_0$ (②), the core first locates the corresponding NAT entry (NE$_{0\text{-}0}$) in deNAT$_0$ (③) and obtains the next writable block address from its own current segment (curseg-info$_0$), which provides the target segment (segno$_{0\text{-}0}$) and the target block offset (④). The core then increments the block offset in curseg-info$_0$ to prepare for the next allocation. After obtaining the target block, the core checks whether the block is associated with a discard entry (⑤). Then, the core updates the SIT entry for segno$_{0\text{-}0}$ by increasing its valid-block count and setting its bit in the valid-block bitmap (⑥). If there is an old block to invalidate, the core decreases the valid-block count and clears its bit in the valid-block bitmap (⑦). If the valid-block count becomes 0, the core sets its bit in the pre-segment bitmap and clears its bit in the dirty-segment bitmap (⑧). Finally, the core records the page and its destination block in bio-vec$_0$ and links it into bio-info$_0$ (⑨). This processing for dirty pages of the inode is repeated until all its dirty pages are processed. After this process is completed, the core flushes current bio-vec entries in its bio-info$_0$ to storage (⑩). Consequently, since each core uses its own decentralized current segment, the entire I/O path for an inode remains isolated to that core, so that its data pages are written using only segments owned by that core, without being interleaved with blocks from other cores.

Cross-core space allocation: Figure 6 illustrates how core$_0$ allocates free space from another core's area when its current segment is exhausted and no local free segments remain. In the I/O process, the core first obtains the block at offset 511 of SE$_{k\text{-}0}$ from curseg-info$_0$ (①); after this allocation, all 512 blocks of SE$_{k\text{-}0}$ are consumed. To prepare subsequent allocations, the core removes SE$_{k\text{-}0}$ from curseg-info$_0$, acquires the free-info lock (flock$_0$), and scans the free segments in free-info$_0$ for a replacement segment (②,③). Because all bits in free-info$_0$ are clear, indicating that no space assigned to core$_0$ is free, it releases flock$_0$ (④) and, following a round-robin policy, accesses the free-space domain of core$_1$ by acquiring flock$_1$ and checking free-info$_1$ (⑤). Then, it finds SE$_{3\text{-}1}$ marked as free and marks it as occupied (⑥), stores SE$_{3\text{-}1}$ into the segno of curseg-info$_0$ (⑦), and resets the block offset to 0 (⑧). After completing this replacement, the core proceeds to the next step (⑨). When a subsequent request for a block occurs (①), it checks curseg-info$_0$ to select block 0 in SE$_{3\text{-}1}$, updates the valid-block count of SE$_{3\text{-}1}$, and completes the allocation (②).

4.4 Decentralized and Decoupled Locking

Structure of decentralized locks: If a decentralized LFS resource is not shared across cores, no lock is required. However, even under a decentralized design, some resources must still be shared among application threads, GC threads, and the checkpoint thread. Thus, as shown in Figure 5, DeLFS devises per-core decentralized locking for each LFS resource and allows each core to acquire the corresponding lock whenever it accesses its decentralized resource. To do this, as shown in the figure, DeLFS provides de-



(a) Deadlock in decentralized locking. (b) Deadlock-free locking with strict ordering. (c) Decentralized and decoupled locking of DeLFS.

Figure 7: Comparison of decentralized locking and ordering (**deSIT$_0$**: decentralized SIT in core$_0$, **SE$_{k\text{-}0}$**: kth decentralized SIT entry in core$_0$, **Lock$_0$**: decentralized SIT lock$_0$ in core$_0$ (sentry_lock$_0$), **C$_n$**: Core$_n$).

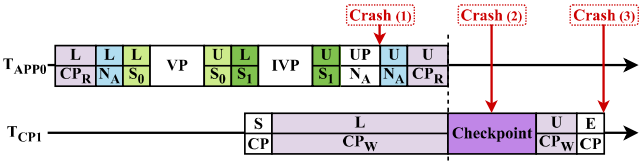


Figure 8: Crash consistency with DDL (**T$_{APP_0}$**: application thread in core$_0$, **T$_{CP_1}$**: checkpoint thread in core$_1$, **CP$_{R/W}$**: checkpoint reader/writer lock, **L**: lock, **VP**: valid processing, **IVP**: invalid processing, **U**: unlock, **UP**: update, **N$_A$**: node A, **S$_n$**: sentry_lock$_n$, **S**: start, **E**: end, **CP**: checkpoint).

centralized locks. For example, in core$_0$, the decentralized NAT tree is protected by nat_tree_lock$_0$ (ntlock$_0$), and the decentralized NAT list is protected by nat_list_lock$_0$ (nllock$_0$). Subsequently, the decentralized current segment, SIT, I/O submission, segment list, and discard management are protected by curseg_mutex$_0$ (curlock$_0$), sentry_lock$_0$ (slock$_0$), io_rwsem$_0$ (iolock$_0$), seglist_lock$_0$ (sllock$_0$), cmd_lock$_0$ (cmdlock$_0$), respectively.

Lock ordering and consistency: Furthermore, DeLFS preserves the original inner lock ordering of F2FS within each core as depicted in Figure 4 and 5. Specifically, when a core updates NAT, it first acquires the NAT-tree lock and, while holding it, acquires the NAT-list lock (③ in Figure 4); similarly, it acquires the SIT lock and, while holding it, acquires the segment-list lock (⑥,⑦,⑧ in Figure 4). Thus, the lock ordering within a core is preserved without consistency issues.

Lock ownership and potential issue: Each core has ownership of its decentralized lock associated with its own local resource instance and primarily acquires the decentralized lock, thereby reducing lock contention by localizing access. However, since decentralized resources can be shared among threads as mentioned, the lock ownership of a resource instance can be shifted across cores. In such cases, this shift in lock ownership can lead to a critical deadlock issue. For example, when a core naively attempts to acquire more than one lock across decentralized resources, the system can fall into a deadlock, which is described in more detail as follows.

4.4.1 Deadlock issue in decentralized locking

Deadlock issue: When accessing a resource in another core's domain, the core must acquire the decentralized lock for the target resource owned by another core. In this case, naive decentralized locking can incur a deadlock. For example, when updating the SIT for an overwrite page, there are two operations: (1) marking the newly allocated page as valid and (2) invalidating the old page. Thus, during write operations, each core allocates a new block for a dirty page in its own space but may also need to invalidate the corresponding old block if that block resides in another core's space. In this process, each core first acquires its own decentralized lock to update its own SIT entry to mark the new block as valid and, while holding this lock, then attempts to acquire the decentralized lock of the core that owns the old block in order to update that core's SIT entry and mark the old block as invalid. When multiple cores behave in this way concurrently, they can end up holding their own locks while waiting for each other's locks, which can create a circular wait and result in a deadlock.

Deadlock scenario: Figure 7a illustrates the deadlock scenario under decentralized locking. Core$_0$ and core$_1$ first acquire their own decentralized locks (lock$_0$ and lock$_1$) (①,①) to update their own SIT entries (deSIT$_0$ and deSIT$_1$) to mark the new blocks as valid. While holding these locks, core$_0$ then tries to acquire lock$_1$ (②), whereas core$_1$ tries to acquire lock$_0$ (②) simultaneously to perform the invalidation of the old blocks. Consequently, the two cores require more than one lock at the same time, thereby leading to a deadlock.

4.4.2 Deadlock-free locking with strict ordering

As a baseline for deadlock prevention, we consider a deadlock-free locking scheme with strict ordering called DFL. In this scheme, each core always acquires locks in ascending core-number order and releases them in descending core-number order. This strict lock-ordering discipline guarantees deadlock

freedom by eliminating cyclic lock dependencies, similar to conservative two-phase locking [5, 32].

Execution example: Figure 7b illustrates an example of how DFL avoids deadlock by enforcing a predetermined global lock order. As shown in the figure, we assume that $core_0$ needs to update both its own decentralized (de) SIT entry ($SE_{0\text{-}0}$) for valid processing and another core's deSIT entry ($SE_{k\text{-}1}$) for invalid processing. $Core_1$, in turn, performs the opposite: it updates its own deSIT entry ($SE_{0\text{-}1}$) for valid processing and $core_0$'s deSIT entry ($SE_{k\text{-}0}$) for invalid processing.

Strict lock ordering: However, note that even if $core_1$ is supposed to update its own deSIT entry for valid processing, it must first acquire $core_0$'s lock to keep the lock-ordering rule of DFL, which enforces that locks must always be acquired in ascending core-number order. Accordingly, under this rule, both cores first attempt to acquire the lock for $deSIT_0$ (①,①) in the ascending order. In this case, $core_0$ wins the contention and acquires the lock, while $core_1$ sleeps waiting for its release. After acquiring the lock for $deSIT_0$, $core_0$ acquires the lock for $deSIT_1$ (②) and performs the updates to $SE_{0\text{-}0}$ and $SE_{k\text{-}1}$ (③,④). Once both locks are released in the descending order (⑤,⑥), the sleeping $core_1$ wakes up, acquires the lock for $deSIT_0$ (②) and then the lock for $deSIT_1$ (③), and performs the updates to $SE_{0\text{-}1}$ and $SE_{k\text{-}0}$ (④,⑤). Finally, $core_1$ releases both locks in the descending order (⑥,⑦).

Scalability limitation: By doing so, DFL successfully prevents deadlock while preserving strong consistency, similar to F2FS, since it performs updates only after acquiring all required locks. However, this design forces cores to block while waiting on each other's locks. As a result, it can incur blocking overhead and degrade scalability on manycores, particularly when there is a large number of invalid pages and capacity is not enough (see Section 5.5).

4.4.3 Decentralized and decoupled locking in DeLFS

To mitigate blocking overhead while preventing deadlocks, DeLFS adopts a decentralized and decoupled locking scheme, called DDL, as its fundamental concurrency control mechanism. In this mechanism, note that the key principle of DDL is that each core never attempts to hold more than one lock of the same type at a time, which provides a loose lock ordering and prevents deadlocks. This principle is enabled by the fact that certain metadata updates can be decoupled while preserving both in-memory and crash consistency. For example, as mentioned in Section 4.4.1 and 4.4.2, overwriting a page requires updating two SIT entries. In this case, we observe that these two updates on disjoint SIT entries can be performed by decoupling valid processing on the new SIT entry from invalid processing on the old SIT entry. This is enabled by two properties: (1) The node is always updated to point to the new valid block only after both SIT entries have been updated under the node lock, ensuring that it always points to a valid block and maintains in-memory consistency (Figure 8); and (2) the checkpoint always recovers a consistent SIT state, guaranteeing crash consistency (Figure 8). With these properties, DDL performs two separate lock-update-unlock sequences: it first acquires the lock for one SIT entry, updates the entry, and releases the lock; it then acquires the lock for the other SIT entry, updates it, and releases the lock.

Procedure: Figure 7c depicts how DDL prevents deadlocks without forcing cores to block on each other's locks. We assume that $core_0$ needs to update $SE_{0\text{-}0}$ and $SE_{k\text{-}1}$, while $core_1$ needs to update $SE_{0\text{-}1}$ and $SE_{k\text{-}0}$. Both cores first acquire their own locks on $deSIT_0$ and $deSIT_1$, respectively (①,①). $Core_0$ then updates $SE_{0\text{-}0}$ (②) and releases its lock (③), and then tries to acquire the lock for $deSIT_1$. In this case, $core_0$ must wait for the lock on $deSIT_1$ (④) since $core_1$ still holds that lock. After $core_1$ completes the update and releases the lock (②,③), $core_0$ acquires the lock for $deSIT_1$ (⑤), updates $SE_{k\text{-}1}$ (⑥), and releases it (⑦). Meanwhile, $core_1$ acquires the lock for $deSIT_0$ (④), updates $SE_{k\text{-}0}$ (⑤), and releases it (⑥). By doing so, DDL reduces cross-core blocking on decentralized locks while guaranteeing deadlock-free execution.

Crash consistency: DDL updates only one SIT entry at a time and can therefore introduce transient inconsistencies between entries. However, DDL preserves correctness and eventually converges to a consistent state by leveraging the existing node lock, LFS checkpoint mechanism, and its reader-writer lock (i.e., cp_rwsem) which ensures eventual consistency. Specifically, as shown in Figure 8, when flushing a dirty page to the device, the application thread (T_{APP0}) first acquires the checkpoint reader lock (CP_R), the node (N_A) lock associated with the page, and the decentralized SIT entry lock in $core_0$ (S_0). Then, the thread performs valid processing for the associated SIT entry in $core_0$ and releases S_0. Subsequently, the thread acquires the decentralized SIT entry lock in $core_1$ (S_1), performs invalid processing for the associated SIT entry, and releases S_1. Meanwhile, during invalid processing, the checkpoint is triggered, at which point the checkpoint thread (T_{CP1}) acquires the checkpoint writer lock (CP_W). After this point, upcoming application threads cannot acquire CP_R and must wait until CP_W is released. Also, the checkpoint thread waits until the prior readers release all CP_R locks before starting the checkpoint. After invalidating the SIT entry, the application thread updates the location of the new page to the node and releases the node lock and CP_R; by doing so, the in-memory consistency is preserved. The checkpoint thread then performs the checkpoint, finalizes it with a commit record, and finally releases CP_W.

As shown in the figure, even if crash (1) or (2) occurs, since the checkpoint is not completed, the recovery restores the previous state. When crash (3) occurs, since the checkpoint includes the commit record, the recovery restores the newly updated node and SIT entries. As a result, the system eventually converges to the same SIT state as an atomic update, and DDL does not incur any crash consistency issues. Note that we observe that the checkpoint occurs infrequently due to the roll-forward recovery [19, 20, 27, 33], resulting in

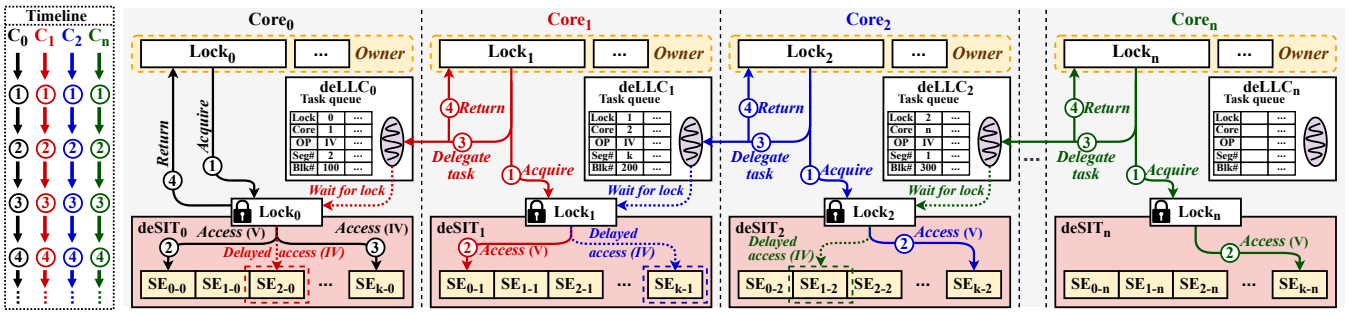

Figure 9: Decentralized lazy lock coordinator in DeLFS (**SE**: SIT entry, **deLLC**: decentralized lazy lock coordinator, **OP**: operation to execute, **V/IV**: valid/invalid processing, $\mathbf{C_n}$: core_n).

minimal checkpoint overhead and lock contention.

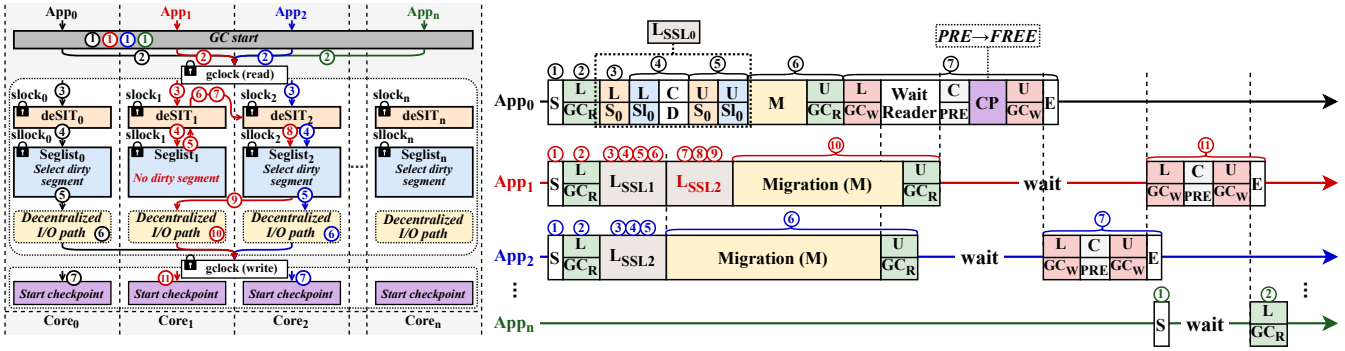
4.5 Lazy Lock Coordination

Even though DDL reduces the blocking overhead caused by the strict lock ordering of DFL, it can still incur substantial blocking because threads must wait on locks held by other cores. In particular, cross-core locking becomes frequent in two situations: (1) when a core has exhausted its local space and is forced to allocate from spaces owned by other cores, and (2) when a core needs to process an invalid page that resides in another core's space. In both cases, the core must acquire a decentralized lock for a resource owned by another core, and this cross-core waiting time can become large, especially under space exhaustion and heavy invalidation (see Section 5.5). For example, as shown in Figure 7c, core_0 must wait for lock_1, which is already held by core_1, even after it finishes valid processing for the new data page, which is a performance critical path.

To this end, DeLFS introduces a decentralized lazy lock coordinator (deLLC) that further mitigates cross-core blocking on decentralized locks while maintaining the DDL rule. In our design, the coordinator performs invalid processing for pages in remote spaces on behalf of the application thread. This decouples invalid processing from the critical I/O path of the application thread, avoiding blocking caused by remote lock acquisition. Specifically, application threads perform the local valid update under their own local locks, release those locks, and then delegate the invalid update to the corresponding coordinators for lazy processing. Thus, this design accelerates the I/O path of application threads. Note that deferring invalidation in this way may transiently leave two valid blocks, but it does not compromise either in-memory or crash consistency for the following reasons: (1) The valid update is always completed first under the node lock, ensuring that the node never points to an invalid block. Once the valid update and the node update are completed, the old block is no longer referenced, and (2) all deferred invalid processing is completed before the checkpoint is committed. As a result, deLLC guarantees consistency and is effective under both space exhaustion and heavy invalidation, since in both situations a core must frequently access decentralized locks owned by other cores.

Procedure: Figure 9 illustrates how deLLC operates. In this example, when a dirty page is flushed, the new page is allocated and marked valid, while the old page is marked invalid. The cores (core_0, core_1, core_2, and core_n) first acquire their local locks (①,①,①,①) to perform valid processing for their new pages (②,②,②,②). In the case of core_0, since both the new and old pages reside in its own decentralized SIT, the application thread can directly update both the valid and invalid bits for the corresponding SIT entries (e.g., $\text{SE}_{0\text{-}0}$ and $\text{SE}_{k\text{-}0}$) (②, ③) and then immediately return (④) without involving deLLC. For other cores, after completing the valid update (i.e., $\text{SE}_{0\text{-}1}$, $\text{SE}_{k\text{-}2}$, $\text{SE}_{k\text{-}n}$) (②,②,②), each thread delegates its invalidation task to the corresponding deLLC instance that owns the target SIT entries (i.e., $\text{SE}_{2\text{-}0}$, $\text{SE}_{k\text{-}1}$, $\text{SE}_{1\text{-}2}$) (③,③,③). After delegation, each thread immediately returns (④,④,④), leaving the invalid processing to the coordinators. By doing so, since the invalidation task is processed asynchronously by deLLC, this can accelerate the critical path of valid processing.

Crash consistency: DeLFS devises a checkpoint mechanism to support the asynchronous operation of deLLC. The checkpoint waits for and cooperatively processes all pending delegated tasks. Specifically, Figure 10 illustrates how DeLFS maintains crash consistency with the devised checkpoint mechanism. The initial procedure is similar to that of DDL until the application thread performs valid processing on the associated SIT entry in core_0. After that, in contrast to DDL, the thread delegates the task of invalidation to deLLC_1. Sub-



(a) GC procedure in DeLFS. (b) GC timeline in DeLFS.

Figure 11: Garbage collection of DeLFS (**slock$_0$**: sentry_lock of core$_0$, **sllock$_0$**: seglist_lock of core$_0$, **gclock**: gc_lock, **App$_0$**: application thread in core$_0$, **S**: start GC, **L**: lock, **U**: unlock, **C**: check, **M**: migration, **GC$_R$**: GC reader lock, **GC$_W$**: GC writer lock, **S$_0$**: slock$_0$, **Sl$_0$**: sllock$_0$, **D**: dirty segment, **L$_{SSL0}$**: handle segment and segment list lock/check dirty segment of core$_0$, **PRE**: pre-segments, **FREE**: free segments, **E**: end GC).

sequently, the thread updates the node with the new page location and releases the node$_A$ (N$_A$) lock and CP$_R$. Meanwhile, after releasing CP$_R$, under CP$_W$, the checkpoint thread starts cooperatively processing the pending tasks in deLLC$_1$, which accelerates the invalid processing. Note that this procedure ensures completion of all pending delegated tasks in all deLLCs. After this procedure, the checkpoint thread performs the checkpoint and writes the commit record. Similar to the case of DDL, when a crash occurs before or after writing the commit record, the recovery restores the previous or the updated state. By doing so, DeLFS safely disentangles the critical path from deferred invalidation work and thereby accelerates the critical path.

4.6 Decentralized Garbage Collection

As an LFS ages, free segments decrease, and once they fall below a threshold, the system triggers garbage collection (GC). In existing LFSs (F2FS, MAX, F2FSJ), GC is serialized: application threads are blocked and a single GC thread performs all GC work until enough free segments are reclaimed [11]. ScaleLFS improves this by using per-core GC daemon threads and per-core cold-data write streams to parallelize GC. However, it still (1) uses a global segment list, so each core must scan all segments to find a victim, and (2) does not optimize normal I/O, so GC can increase the total execution time, including both GC and foreground I/O (see Section 5.2). Meanwhile, DeLFS provides a holistic, decentralized GC procedure as described in Figure 11a and 11b as well as a decentralized normal I/O path. The key idea is to enable each core to perform GC procedure based on its own decentralized resources similar to the normal I/O path, effectively localizing GC. To do this, DeLFS leverages the GC reader lock during GC execution and the GC writer lock at checkpoint time.

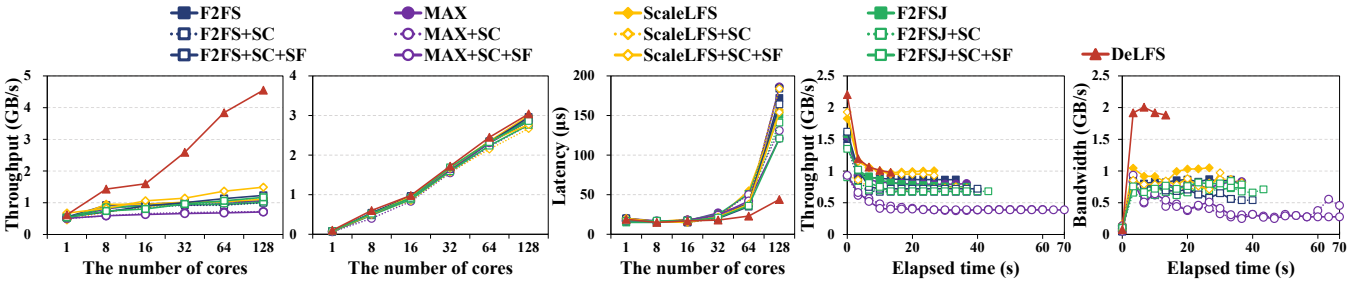
Specifically, when the number of free segments falls below the predefined threshold, DeLFS triggers GC, and application threads begin GC (①,①,①). Unlike serialized GC and ScaleLFS, these threads acquire the shared GC$_R$ lock (②,②,②), enabling concurrent and cooperative GC. Each thread then acquires its own deSIT lock (slock) and segment-list lock (sllock) (③,③,③) and selects a victim segment from its local segment list (④,④,④). If a core (core$_1$) has no dirty segment, the thread (app$_1$) releases its local locks (⑤,⑥) and, in round-robin order, moves to another core's domain (⑦,⑧) to help perform GC for that core. Each thread then performs migration independently through the decentralized I/O path (⑤,⑨,⑤) and releases GC$_R$ when its migration is done (⑥,⑩,⑥). The earliest thread to finish (app$_0$) releases GC$_R$ and then acquires GC$_W$ to block new GC starters, and waits until all remaining threads holding GC$_R$ release it. After app$_2$ and app$_1$ finish migration and release GC$_R$, no thread holds GC$_R$ anymore, so app$_0$, still holding GC$_W$, checks whether any pre-segments consisting only of invalid pages exist as a result of migration. Then, app$_0$ converts the pre-segments into free segments via the checkpoint process under the checkpoint writer lock and releases GC$_W$ (⑦).

Subsequently, app$_2$, which is waiting for GC$_W$, acquires GC$_W$, finds no remaining pre-segments because app$_0$ has already processed them, and immediately releases GC$_W$ (⑦). Likewise, app$_1$ finds no remaining pre-segments and completes GC (⑪). If app$_n$ attempts to start GC (①) while GC$_W$ is held, it cannot acquire GC$_R$ and must wait; once GC$_W$ is released, it starts a new GC cycle (②). Although localized GC may select a higher-cost victim segment than a globally optimal scheme, the impact on the total write amplification is minor in our evaluation (Section 5.2). Even when dirty segments are skewed across cores, GC gradually expands from local to other cores' segments, ensuring global reclamation progress. Finally, decentralized GC remains crash-consistent because all GC activities and checkpoints are safely synchronized by the GC locks.

5 Evaluation

5.1 Experimental Setup

Testbed: We use a 128-core machine equipped with two 64-core AMD EPYC 7713 processors and 96 GB of DRAM. For



(a) Random write. (b) Random read. (c) Tail latency (99th). (d) Application TP. (e) Device-level BW.

Figure 12: Throughput, tail latency, and GC performance of LFSs (SC: ScaleCache, SF: serialization-free, BW: bandwidth, TP: throughput).

LFS \ Combination	Baseline	SC	SC + SF
F2FS	2.42 %	9.56 %	51.5 %
MAX	2.29 %	8.73 %	45.3 %
ScaleLFS	2.99 %	8.26 %	49.37 %
F2FSJ	2.45 %	8.96 %	57.03 %
DeLFS	47.56 %		

Table 2: CPU utilization (SC: ScaleCache, SF: serialization-free).

storage, the machine is equipped with a FireCuda 530 NVMe SSD [2]. The SSD has a capacity of 2 TB and provides raw random write, read, and mixed random read/write throughput of 5.3 GB/s, 3.2 GB/s, and 3.5 GB/s, respectively.

Comparison: We compare DeLFS with modern LFSs, including F2FS [18], MAX [21], ScaleLFS [11], and F2FSJ [9], as well as their variants combined with ScaleCache (SC) [29] and the serialization-free (SF) scheme (mentioned in Section 3.2). We run all LFSs and their variants on Ubuntu 22.04 LTS with the Linux 6.6.8 kernel. For evaluation, we use FIO [4] as a micro-benchmark, filebench [31] as a macro-benchmark, and RocksDB [10] as a real-world application with YCSB [1]. We run each test ten times and report the average result.

5.2 Micro-benchmark

We present the performance results of DeLFS and modern LFSs using the FIO benchmark. We vary the number of threads from 1 to 128, and use a 2.2 GB file size per thread and a 4 KB request size. In the case of 128 threads, the total dataset size is 281.6 GB. We use this configuration as the default in all micro-benchmark tests unless stated otherwise.

Core scalability: Figure 12a shows the core scalability in the case of random write. The existing LFSs show almost the same performance, or even degrade even if the number of cores increases. Meanwhile, DeLFS scales performance well on various number of cores. Specifically, DeLFS achieves 4.34×, 4.29×, 4.10×, and 4.50× compared with F2FS, MAX, ScaleLFS, and F2FSJ at 128 cores, respectively. This is because the existing LFSs suffer from the first bottleneck (i.e., blocking overhead) by I/O throttling in dirty-page management as described in Section 3.2.1. To eliminate the blocking overhead, even when combining LFSs with SC, the existing LFSs still suffer from the serialization lock as the second bottleneck. Furthermore, even if the serialization lock is eliminated (i.e., serialization-free (SF)), contention on subsequent locks becomes the next bottleneck, as shown in Table 1. Thus, with the decentralized design, DeLFS can achieve 3.70×, 6.41×, 3.05×, and 3.89× higher throughput compared with F2FS+SC+SF, MAX+SC+SF, ScaleLFS+SC+SF, and F2FSJ+SC+SF at 128 cores, respectively. Consequently, these results demonstrate that DeLFS effectively scales performance as the number of cores increases by leveraging decentralized architecture and locking schemes.

Read-only performance: We evaluate the read-only performance of DeLFS while increasing the number of cores as shown in Figure 12b. Overall, the read performance of DeLFS is similar to that of the other LFSs. This is because all LFSs already achieve throughput close to the raw read performance since the read path allows multiple threads to issue read operations concurrently under read locks. Consequently, the design of DeLFS does not affect read performance.

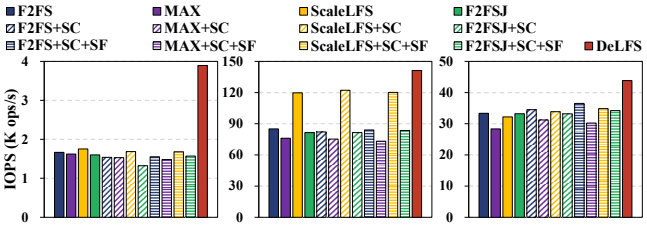
Tail latency: Figure 12c shows tail latency in all the LFS configurations while varying the number of cores. As shown in the figure, at 128 cores, when comparing the best-performing configurations among the LFS variants, DeLFS achieves 3.73×, 2.75×, 3.5×, and 2.75× lower tail latency than F2FS+SC+SF, MAX+SC+SF, ScaleLFS+SC+SF, and F2FSJ+SC+SF, respectively. In particular, while existing LFSs exhibit sharp latency spikes between 64 and 128 cores, DeLFS suppresses these spikes and keeps the latency much more stable. As a result, DeLFS outperforms the existing LFSs in terms of tail latency as well as throughput.

CPU utilization: Table 2 shows CPU utilization across all LFS configurations. As expected, the variant LFSs exhibit higher CPU utilization than the existing LFSs, since they can proceed without I/O throttling and the serialization lock. DeLFS shows the highest CPU utilization among the existing LFSs because it accelerates I/O processing with greater concurrency and parallelism. As a result, DeLFS achieves higher multi-core scalability at the cost of increased CPU utilization.

Garbage collection: Figure 12d and 12e present the application throughput and device-level bandwidth during GC. To fairly evaluate GC performance against ScaleLFS [11], we follow the experimental setup described in the study. Specifically, we use a 30 GB partition and run the experiment with 128 threads, each issuing 228 MB of random writes, resulting

Workload	# of files	# of threads	Avg. file size	R/W ratio	Description
Fileserver	12,800	128	10 MB	2:1	Data-intensive
Varmail	25,600	128	10 MB	1:1	Metadata-intensive
Videoserver	128	128	480 MB	9:1	Read-intensive

Table 3: Workload configurations for macro-benchmark.



(a) Fileserver. (b) Varmail. (c) Videoserver.

Figure 13: Throughput on macro-benchmark.

in approximately 28.5 GB of total writes. We then rerun the same workload as overwrites. As shown in the figures, DeLFS achieves up to 2.77× lower application-level execution time and delivers up to 2.32× higher device-level bandwidth than the compared systems. This is because DeLFS performs a decentralized GC procedure that localizes GC and reduces lock contention. Moreover, by improving both the write I/O path and the GC I/O path, DeLFS further reduces total application execution time compared with ScaleLFS. These results show that DeLFS improves both normal I/O and GC performance.

Write amplification factor: We quantify the effect of suboptimal GC victim selection by comparing the WAF of F2FS and DeLFS. In the above GC evaluation, the total WAF increases slightly by 1.2%, from 1.088 in F2FS to 1.101 in DeLFS. The resulting WAF of 1.101 is broadly consistent with the 13.7% average gap between application-level throughput (1.31 GB/s on average) in Figure 12d and device-level bandwidth (1.49 GB/s on average) in Figure 12e. Specifically, in the non-GC phase, both file systems exhibit a similar WAF of approximately 1.065, mainly due to metadata overhead. Meanwhile, the GC-induced WAF overhead is 0.036 in DeLFS and 0.023 in F2FS. However, this additional overhead contributes only 0.013 to the total WAF increase. Consequently, these results show that although DeLFS may make less-than-optimal victim-selection decisions, the impact on total WAF is minor.

5.3 Macro-benchmark

We use three filebench workloads as listed in Table 3.

Fileserver: Figure 13a shows the performance of the fileserver workload. DeLFS delivers 2.34×, 2.40×, 2.22×, and 2.43× higher performance than F2FS, MAX, ScaleLFS, and F2FSJ, respectively. Meanwhile, the existing and variant LFSs show similar performance, as in the micro-benchmark case. Since fileserver is a write and data-intensive workload, the LFSs are still constrained by bottlenecks in the write path. Consequently, this result demonstrates that DeLFS yields high performance gains under more realistic workload.

Varmail: Figure 13b shows the results for the varmail workload, where DeLFS achieves 1.66×, 1.86×, 1.18×, and 1.73× higher throughput than F2FS, MAX, ScaleLFS, and F2FSJ, respectively. In all systems except ScaleLFS and DeLFS, delete operations contend heavily on the SIT entry lock (sentry_lock). ScaleLFS alleviates this with atomic operations, while DeLFS removes this bottleneck via its decentralized architecture and locking. Thus, DeLFS is effective for both data-intensive and metadata-intensive workloads.

Videoserver: Figure 13c shows the results for the videoserver workload. In the figure, DeLFS delivers 1.31×, 1.55×, 1.36×, and 1.32× higher throughput than F2FS, MAX, ScaleLFS, and F2FSJ, respectively. Although videoserver is read-intensive, DeLFS still accelerates its execution because improvements in the write path can reduce interference between read and write operations. Consequently, DeLFS provides higher performance even for read-intensive workloads.

5.4 Real-world Application

To evaluate DeLFS with a real-world application, we run RocksDB with YCSB workloads A, B, F, and update-only [3]. Workload A uses a 1:1 read-to-update ratio, B uses a 9.5:0.5 read-to-update ratio, F uses a 1:1 read-to-read-modify-write ratio, and update-only issues 100% update operations. We use 1–128 client threads, 10 million records with 10 fields of 4 KB each, and 1.28 million operations per workload.

Workload A: Figure 14a shows that DeLFS achieves 1.78×, 1.60×, 1.81×, and 1.62× higher throughput than F2FS, MAX, ScaleLFS, and F2FSJ, respectively, at 128 cores. We observe that ScaleCache improves throughput by eliminating blocking overhead but the serialization-free scheme is ineffective because the next lock becomes the bottleneck. These results indicate that DeLFS is also effective for the real-world application.

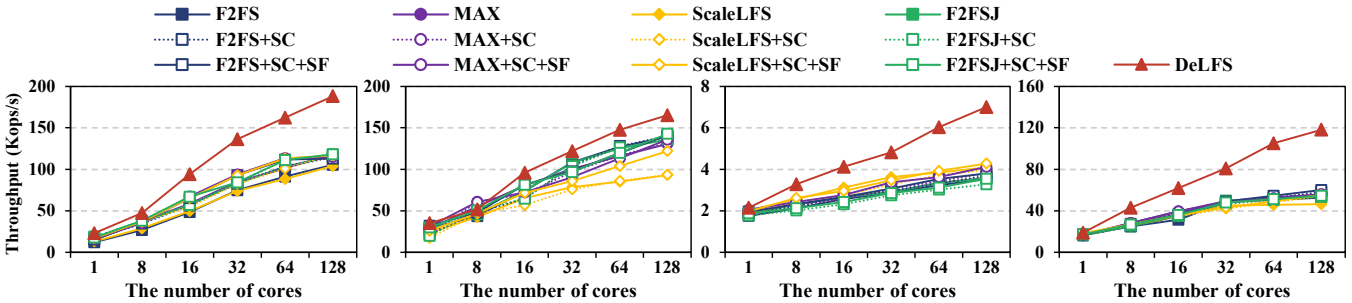
Workload B: As shown in Figure 14b, interestingly, even under the read-intensive workload, DeLFS improves performance by 1.19×, 1.26×, 1.77×, and 1.22× over F2FS, MAX, ScaleLFS, and F2FSJ, respectively, at 128 cores. These results indicate that an inefficient write path can significantly impact read performance even under small write workloads.

Workload F: Figure 14c indicates that DeLFS achieves up to 1.98×, 1.95×, 1.71×, and 1.96× over F2FS, MAX, ScaleLFS, and F2FSJ, respectively. Overall, DeLFS shows larger gains in workload F than in A because the read-modify-write requests in workload F stress both the write and read paths.

Update-only workload: Figure 14d shows DeLFS achieves up to 2.24×, 2.14×, 2.54×, and 2.20× higher throughput than F2FS, MAX, ScaleLFS, and F2FSJ, respectively. These results indicate that DeLFS is particularly effective for write-intensive workloads, the primary target of our design.

5.5 Performance Breakdown

Decentralized architecture: To illustrate the performance impact of DeLFS in more detail, we report the performance



(a) Workload A. (b) Workload B. (c) Workload F. (d) Update-only.

Figure 14: Throughput of various LFSs with YCSB workloads.

File system	Throughput	io_schedule_timeout()	writepages	curseg_mutex	io_rwsem	sentry_lock	nat_tree_lock	nat_list_lock	seglist_lock	cmd_lock	others
F2FS	1.05 GB/s	96.17%	0.8%	0.1%	0.9%	0.2%	0.1%	0.1%	0%	0.1%	1.53%

De-discard	4.55 GB/s	0%	0%	0.26%	0.90%	0.29%	0.29%	0.14%	0.30%	0.65%	97.17%

Table 4: Breakdown of DeLFS (De: decentralized, SC: ScaleCache, SF: serialization-free, LLC: lazy lock coordinator).

breakdown as shown in Table 4. As shown in the table, the bottleneck shifts from one lock to another as each decentralized scheme is applied. Finally, DeLFS minimizes the contention of target locks holistically. These results demonstrate that each technique successfully resolves its corresponding scalability bottleneck in the LFS operation.

Decentralized locking schemes: We compare the performance of DFL, DDL, and deLLC in Table 5. For this experiment, we first fill the SSD to 1.8 TB using FIO. We then overwrite the data using the default FIO workload (281.6 GB) and measure performance. During this process, approximately 73 million invalid pages are processed. deLLC outperforms DFL and DDL by 89.63% and 43.83%, respectively. Moreover, the total delegation time is only 1.32s, which is a minor overhead.

5.6 Overhead of DeLFS

Performance under aged state: To measure the overheads of DeLFS under an aged state, we age the file system following the methodology of prior work [8], as shown in Table 6. Specifically, we perform 300 pulls from the Linux git repository and a recursive grep test, and then run the fileserver workload under the aged state. As expected, aging decreases grep performance in both file systems. Interestingly, DeLFS achieves higher grep performance than F2FS in both the unaged and aged states as the number of threads increases, because it localizes blocks into core-local segments and improves read coalescing. In the fileserver evaluation, similar to the grep results, aging affects both file systems. Nevertheless, even in the aged state, DeLFS still outperforms F2FS by up to 1.96×. Overall, aging degrades performance compared with the unaged state, but DeLFS maintains its performance advantage even in the aged state.

Skewed space allocation: We evaluate the impact of cross-core space allocation as local space is gradually exhausted, focusing on the performance overhead caused by lock contention on remote cores. To generate sustained low-free-space pressure, we pre-fill the device at different capacity levels and run the fileserver workload, which continuously performs file creation and deletion while generating substantial writes as shown in Table 7. For the 75%, 50%, 25%, and 10% available space cases, DeLFS outperforms F2FS by 2.37×, 1.93×, 1.63×, and 1.17×, respectively. DeLFS performance gradually decreases as the available space decreases because local free-pool depletion incurs cross-core overheads. Especially in the 1% available space case, both file systems show almost the

Metric \ Scheme	DFL	DDL	deLLC
Throughput	1303 MB/s	1718 MB/s	2471 MB/s
Total execution time	226 s	171 s	119 s
Total delegation count	-	-	71,377,706
Total delegation time	-	-	1.32 s

Table 5: Performance under heavy invalid page processing.

Workload	Threads	F2FS		DeLFS	
		Unaged	Aged	Unaged	Aged
Grep test	1	1.2 s	1.23 s	1.16 s	1.2 s
	32	3.54 s	3.63 s	2.76 s	2.84 s
	64	8.05 s	8.12 s	4.45 s	4.65 s

DeLFS	# of create/delete	305 K	260 K	217 K	151 K	38 K
	Total writes	3.02 TB	2.60 TB	2.24 TB	1.57 TB	0.81 TB
	Throughput	3730 ops/s	3180 ops/s	2662 ops/s	1848 ops/s	468 ops/s

Table 7: LFS performance under various available space conditions.

same performance because the available capacity is severely limited. Nevertheless, these results show that even under severe free-space pressure with continuous file creation/deletion and large writes, DeLFS remains effective and maintains a performance advantage over F2FS in most capacity settings.

Memory consumption: DeLFS requires additional memory to support decentralized organization and management, but the overhead is small. Across multi-head logging metadata, checkpoint bookkeeping (per-log segno/blkoff), decentralized locks and their protected data structures (e.g., XArrays), and lock-coordinator/invalidation structures, DeLFS uses up to about 1.1 MB (1121.67 KB) of extra memory under our experimental setup. Given modern memory capacities, this additional overhead is negligible in practice.

Storage overhead: As the number of multi-head logging instances increases with the number of cores, the checkpointing process requires an additional 11.9 KB of space to store the segment number and block offset information maintained for each multi-head logging instance.

5.7 Crash Consistency

To validate crash consistency of DeLFS, we use CrashMonkey [25]. Specifically, we test DeLFS with checkpoint (`checkpoint_example`) and create/delete (`create_delete`) workloads. The results confirm that DeLFS successfully handles all test cases and maintains crash consistency.

6 Related Work

Scaling file and storage systems: SpanFS [13] scales file systems by composing a set of micro file-system services. ScaleFS [6] decouples in-memory and on-disk file systems to reduce lock contention. CJFS [28] and Z-Journal [14] improve the scalability of journaling file systems using concurrent and per-core schemes. uFS [22] is a semi-microkernel file system that scales through partitioned data structures and inode migration. ScaleCache [29] is a scalable page cache that provides concurrent XArray and direct page flushing. Our work aligns with these studies on scaling file and storage systems [6, 13, 14, 22, 28, 29]. However, unlike these studies, DeLFS targets LFSs and introduces a decentralized management and locking approach that eliminates centralized bottlenecks while accelerating both normal I/O and GC I/O paths.

Scalable LFSs: MAX [21] scales in-memory data-structure access and provides a concurrency-friendly on-disk format, but still limits parallelism. During flushing, MAX selects an mlog cell in a round-robin manner, searches a shared free bitmap, and sends data to the corresponding mlog. This one-to-all allocation model and shared metadata still incur high lock contention. F2FSJ [9] introduces an ordered-journal mode for F2FS to reduce checkpointing time by journaling metadata. Unlike F2FSJ, DeLFS targets data-intensive workloads where checkpoint overhead is relatively small; integrating F2FSJ-like journaling into DeLFS for metadata-intensive workloads remains future work. ScaleLFS [11] scales garbage collection with parallel GC and concurrent victim selection. In contrast, DeLFS decentralizes and localizes GC while reducing lock contention on the normal I/O path. As a result, DeLFS further improves sustained performance. In summary, our work is inspired by these designs and shares the goal of improving scalability, but DeLFS holistically decentralizes metadata and data management and employs decentralized, decoupled locking to scale on many-core systems.

7 Conclusion

We present DeLFS, a decentralized log-structured file system that overcomes the scalability limitations of existing LFSs and scales I/O performance on manycores. DeLFS holistically decentralizes metadata/data organization and management into per-core domains with a novel decentralized locking scheme. Furthermore, DeLFS disentangles the critical path from the deferrable path to further increase concurrency. Our evaluations show that DeLFS achieves up to 4.34×, 4.29×, 4.10×, and 4.50× higher throughput compared with F2FS, MAX, ScaleLFS, and F2FSJ, respectively.

Abstract

Rollout–training disaggregation is emerging as the standard architecture for Reinforcement Learning (RL) post-training, where memory-bound rollout and compute-bound training are physically disaggregated onto purpose-built clusters to maximize hardware efficiency. However, the strict synchronization required by on-policy algorithms introduces severe *dependency bubbles*, forcing one cluster to idle while the dependent phase is running on the other. We present WEAVE, a cluster scheduling framework that reclaims these bubbles through cross-cluster orchestration. WEAVE is built on the insight that the structural idleness of one job can be effectively utilized by the active phase of another. To realize this, we introduce the *co-execution group* abstraction, which partitions the cluster into isolated locality domains. This abstraction enables a *two-tier scheduling architecture*: an *inter-group scheduler* that optimizes job placement using conservative stochastic planning, and an *intra-group scheduler* that orchestrates a provably optimal round-robin schedule. The group abstraction also imposes a *residency constraint*, ensuring that massive model states remain cached in host memory to enable "warm-start" context switching. We evaluate WEAVE on a production-scale testbed with 328 H20 and 328 H800 GPUs. WEAVE improves cost efficiency by 1.84× over standard disaggregation and 1.38× over state-of-the-art co-located baselines, all while achieving 100% SLO attainment.

1 Introduction

The development of Large Language Model (LLM) is shifting from pre-training to *Reinforcement Learning (RL) post-training* [1,3,7], which unlocks reasoning capabilities in complex domains such as mathematics [2], coding [33], and tool use [9,54]. To achieve optimal performance and model stability, production deployments have converged on *synchronous, on-policy algorithms* [7,37,41] that prescribe a strict, iterative learning loop through three phases, each with a distinct resource bottleneck: (1) **rollout**, a *memory-bandwidth-bound* inference stage that generates token trajectories; (2) **training**, a *compute-intensive* stage that updates parameters from rewards; and (3) **synchronization**, a *network-bound* stage that propagates updated weights back to inference workers.

This paper targets the deployment that production on-policy RL post-training has converged on—a *disaggregated architecture* [11, 47, 52, 61] that splits rollout and training across two purpose-built clusters (Figure 1-top). The *rollout pool* consists of cost-effective, inference-optimized GPUs (e.g., NVIDIA H20), while the *training pool* uses high-performance, compute-optimized GPUs (e.g., NVIDIA H800). By matching hardware to phase characteristics, disaggregation resolves the resource mismatches that plague monolithic provisioning, achieving superior cost efficiency at comparable throughput despite the added cross-cluster synchronization.

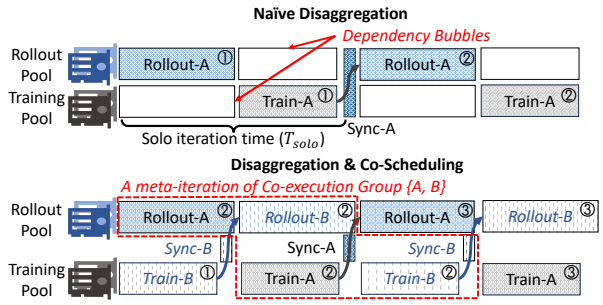

Figure 1: Comparison between existing disaggregated RL architecture and WEAVE's co-scheduling paradigm.

Disaggregation, however, introduces a fundamental efficiency challenge: *dependency bubbles*. The strict synchronization required by on-policy learning forces the training cluster to idle during rollout, and vice versa (Figure 1-top), wasting both pools. Existing systems such as AReaL [11], StreamRL [61], and AsyncFlow [18] eliminate these bubbles only by switching to *asynchronous, off-policy algorithms*, trading away the on-policy guarantee and admitting *sample staleness* that compromises model accuracy and convergence stability—an unacceptable trade for tasks that demand strict on-policy performance.

We present WEAVE, a cross-cluster scheduling framework for disaggregated RL post-training that mitigates dependency bubbles by lifting the optimization scope from the individual job to *cluster-level orchestration*. Our key insight is that the dependency bubbles inherent to one job can be filled by another job's active phase. WEAVE groups multiple jobs into a *co-execution group* and tightly weaves their rollout and training phases across the two resource pools (Figure 1-bottom), time-multiplexing both pools to maximize utilization while preserving the synchronous dependencies required by on-policy learning.

However, realizing this benefit in production is non-trivial

because of three challenges. (**C1**) Production RL jobs exhibit *extreme workload heterogeneity* across model sizes, response lengths, and interaction patterns (Figure 2), producing widely varying phase durations and resource demands. Naive time-multiplexing causes severe interference—for example, pairing two rollout-heavy jobs creates a bottleneck that substantially delays both (Figure 3). Finding an interference-free schedule across such heterogeneous workloads reduces to a Job-Shop Scheduling problem [25], which is NP-hard. (**C2**) Unlike standard deep-learning workloads with stable iteration times, RL rollouts are *highly stochastic*: LLM generation follows a long-tailed distribution [14, 19, 62] in which a few straggler requests *unpredictably prolong* phase durations, rendering static plans obsolete. (**C3**) Time-multiplexing is constrained by switching costs. RL post-training is inherently *stateful*, requiring each worker to manage hundreds of gigabytes of model weights and optimizer state per job (Table 2); reloading these states from disk or across the bandwidth-limited cross-cluster network on every switch incurs *cold-start latencies of up to 135 s* (Figure 4)—enough to wipe out any gains from co-scheduling. This combination—stateful workers holding hundreds of gigabytes of resident state, a strict cross-phase synchronization barrier, and long-tailed phase durations—is what makes generic VM, container, or GPU multiplexing inadequate here and motivates an RL-specific scheduler.

WEAVE addresses these challenges via a holistic algorithm–system co-design built around a near-optimal scheduling algorithm. The objective is to minimize total resource provisioning cost—and thus dependency bubbles—while honoring per-job SLOs, defined as the acceptable slowdown relative to *solo execution* (Figure 1-top). Although the global problem is NP-hard (**C1**), WEAVE makes it tractable by decomposing it into two decisions: *inter-group scheduling* chooses the jobs that co-execute, and *intra-group scheduling* orchestrates their execution sequences within a co-execution group. When a new job arrives, the inter-group scheduler scans existing co-execution groups for a placement that violates no group member's SLO; among SLO-compliant options, it picks the one with the minimum marginal provisioning cost, and otherwise provisions a new, isolated group. Within each group, the intra-group scheduler runs a round-robin schedule, which we prove is optimal for minimizing dependency bubbles in this context (§4.3).

To handle runtime stochasticity (**C2**), WEAVE pairs *conservative admission control* with *long-tail migration*. For inter-group placement, the scheduler assumes a worst case in which every response reaches the maximum token length, so SLO guarantees hold even under peak load (§4.2). At runtime, the intra-group scheduler adapts to the observed response distribution: it opportunistically migrates ongoing long-tail responses onto a small subset of GPU devices, freeing the bulk of the rollout pool so that the next job can begin pipelined execution immediately (§4.3).

To absorb switching overheads (**C3**), WEAVE introduces a *warm-start* mechanism that cuts switching latency by two orders of magnitude (Figure 4), making fine-grained time-multiplexing practical. WEAVE rightsizes each co-execution group so that the states of all member jobs—model weights, optimizer state, and execution context—fit in each worker's host memory; on a switch, the worker loads the cached state from host DRAM to the GPU rather than fetching it across the slow inter-cluster link or from disk.

To make these schedules executable, WEAVE introduces two system mechanisms. A *phase-centric control model* treats each RL phase as a first-class schedulable entity, exposing the job's internal dependency graph to the scheduler and transparently driving the state loads that warm-start requires (§5.1). A *topology-aware* model-synchronization scheme prevents the cross-cluster sync barrier from becoming a bubble multiplier (§5.2): it pipes a single model copy across the slow inter-cluster link via parallel point-to-point streams and then broadcasts within each cluster over the high-speed local fabric (e.g., NVLink, InfiniBand).

We implemented WEAVE atop ROLL [45] and evaluated it on a production-scale disaggregated testbed with a 328-GPU H20 rollout pool and a 328-GPU H800 training pool. Across micro-benchmarks at identical per-hour provisioning cost, WEAVE delivers 1.82–1.99× higher training throughput than disaggregation without co-scheduling (§6.2). On an end-to-end replay of a two-week production trace, WEAVE sustains the same workload at 1.38× lower provisioning cost than the state-of-the-art veRL [43] and 1.84× lower than naive disaggregation, while maintaining 100% SLO attainment (§6.4). Large-scale trace-driven simulations further show that WEAVE's combined inter- and intra-group scheduling runs within 6% of the theoretical optimum found by brute-force search (§6.5). Finally, WEAVE is robust to workload drift—static placement stays within 1.11× of an optimal dynamic-regrouping baseline—and sustains job failures by re-admitting recovered jobs as new arrivals (§6.6).

2 Background and Motivation

RL Post-Training Workload Characterization. RL post-training has become a cornerstone workload for modern AI infrastructure. In our production clusters, the volume of RL jobs nearly tripled within six months, growing from 5k monthly jobs in April to over 14k in September 2025, driven largely by the need to instill complex reasoning capabilities in LLMs [3, 7, 9, 41, 45]. Unlike LLM pre-training, which is a uniform stream of compute, the standard RL post-training workflow consists of repeated cycles over three phases, each with a distinct resource bottleneck. (1) **Rollout:** the actor LLM generates responses for a batch of input prompts, which are then evaluated to collect reward feedback. This phase exerts *high memory-bandwidth pressure* from KV-cache operations while having relatively *low arithmetic intensity*, so running it on high-end training GPUs severely underutilizes

their compute [11, 19, 61]. (2) **Training:** the actor LLM's parameters are optimized from the reward feedback. This phase is *compute-intensive* and demands both massive floating-point throughput and high-bandwidth interconnects (e.g., NVLink, InfiniBand) for gradient aggregation [44]. (3) **Synchronization:** updated parameters must be broadcast from the training workers to the rollout workers. Synchronization exists in any deployment, but disaggregating rollout and training across separate clusters forces the broadcast to traverse a comparatively slow inter-cluster link, turning this phase into a *network-bound* bottleneck.

The Case for Disaggregated RL. The divergent resource requirements of rollout and training create a fundamental inefficiency in traditional *monolithic, co-located deployments* [43], in which rollout and training are time-multiplexed on a single cluster of homogeneous, compute-optimized GPUs (e.g., NVIDIA H100/H800). This forces the memory-bandwidth-bound rollout phase to run on expensive compute-optimized hardware, inflating the total cost of ownership (TCO) [52, 61].

Disaggregation addresses this mismatch by splitting the RL workload across two purpose-built resource pools (Figure 1-bottom) [11,47,52,61]: training runs on costly, compute-optimized GPUs (e.g., H100/H800), while rollout is offloaded to cost-effective, inference-optimized GPUs (e.g., H20) that offer high HBM capacity and bandwidth at a fraction of the cost (Table 1). By aligning hardware with phase characteristics, disaggregation promises a superior TCO *in theory*.

Dependency Bubbles. While disaggregation addresses hardware mismatches, *dependency bubbles* undermine its efficiency in practice. State-of-the-art RL post-training relies on *synchronous, on-policy* algorithms to ensure training stability and model quality [7, 17, 37, 41]. This synchronization constraint enforces a strict phase dependency: the training pool sits idle while the rollout pool generates fresh experiences, and the rollout pool sits idle while the training pool updates parameters (Figure 1-top).

Existing systems such as AReaL [11, 52], StreamRL [61], and AsyncFlow [18] eliminate these bubbles by switching to *asynchronous, off-policy* algorithms. Decoupling rollout from training, however, introduces *sample staleness* that degrades model convergence and final accuracy, making these solutions unsuitable for tasks that demand strict on-policy performance. As a result, production deployments retain synchronous execution and absorb the resulting idleness.

Worse, this idleness can fully offset disaggregation's hardware savings. Our end-to-end evaluation (§6.4) shows that a naive disaggregated deployment (Solo-D) incurs *higher* provisioning cost than a monolithic co-located baseline (veRL)—$0.94k/h versus $0.71k/h—despite using cheaper GPUs for rollout. Without a scheduling mechanism to reclaim this lost capacity, disaggregation's theoretical TCO advantage is nullified by system-level inefficiencies.

Accelerator	Comp. (TFLOPS)	HBM Cap. (GB)	HBM B/w (TB/s)	Cost ($/h) [64]
H20	148	96	4.0	1.85
H800	989.5	80	3.35	5.28

Table 1: Performance specifications and cost-effectiveness of the GPUs used in our disaggregated clusters [61, 64].

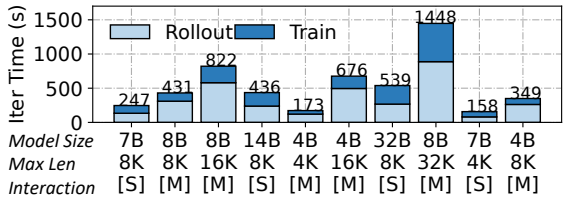

Figure 2: Top 10 popular RL post-training workloads in our production cluster: jobs' phase durations are highly diverse. [S], [M] refers to single/multi-turn interaction during rollout.

3 Scheduling Opportunities and Challenges

In this section, we identify a cluster-level opportunity for mitigating the dependency bubbles of disaggregated RL post-training. We then examine the algorithmic and system challenges of realizing it.

3.1 The Co-Scheduling Opportunity

For a single job, the dependency bubbles described in §2 are unavoidable: eliminating them would violate the synchronization requirements of on-policy algorithms. In *shared, multi-tenant* clusters that run diverse RL workloads, however, these per-job inefficiencies are aggregate capacity that can be reclaimed through cluster-level scheduling.

Our key insight is that the idle resources in one job's dependency bubbles can be utilized to execute the active phase of another. By orchestrating jobs into *co-execution groups*, the scheduler can tightly "weave" together their workflows, ensuring that the compute-intensive training phase of one job executes in parallel with the memory-bound rollout phase of another (Figure 1-bottom). This interleaved execution pattern effectively hides dependency bubbles, allowing the system to simultaneously saturate both the cost-effective rollout pool and the high-performance training pool, maximizing cluster-wide efficiency without compromising the synchronization requirements of on-policy learning.

3.2 Challenges

However, realizing co-scheduling at production scale is non-trivial for three reasons: workload heterogeneity (**C1**), runtime stochasticity (**C2**), and context-switching cost under memory-residency limits (**C3**).

C1: Workload Heterogeneity and Scheduling Intractability. First, production RL workloads are highly diverse, which

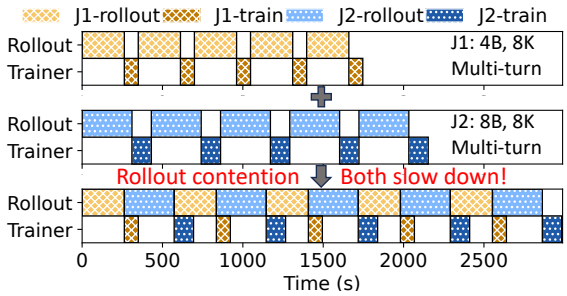

Figure 3: A bad case of naive time-multiplexing: two rollout-heavy jobs compete for a rollout node and both slow down.

complicates efficient co-scheduling. As shown in Figure 2, jobs in our cluster span a wide range of model sizes (3B–32B), response lengths (4k–32k tokens), and interaction modes (single- vs. multi-turn). This diversity translates into phase durations that range from 50s to over 900s and into pronounced *phase skew*: multi-turn agentic workloads, for instance, exhibit rollout phases 3×–4× longer than their training phases.

Naive time-multiplexing therefore often proves detrimental due to resource contention. Arbitrarily pairing two rollout-heavy jobs, for example, creates a bottleneck on the inference nodes, forcing both jobs to stall. As shown in Figure 3, such contention results in severe performance degradation, slowing down concurrent jobs by 1.40× and 1.64×, respectively. To avoid such interference, the scheduler must identify optimal packings that satisfy strict performance SLOs. However, mapping these heterogeneous, phase-skewed workloads to available resources reduces to a Job Shop Scheduling problem [15, 25], which is known to be NP-hard even under the simplifying assumption of deterministic phase durations.

C2: Stochastic Runtime and Skewness Bubbles. Second, RL workloads are inherently *stochastic*. Unlike pre-training, an RL rollout's execution time depends on the generated response lengths, which follow a *long-tail distribution* (Figure 12). This creates two challenges. First, the workload is *non-stationary*: response-length distributions drift across iterations as the model updates, and a few "straggler" requests routinely hit the maximum token limit [14, 61, 62]. Because training cost scales linearly with the number of generated tokens, rollout variance propagates into the subsequent training phase and makes static orchestration plans obsolete.

Second, long-tail responses induce *skewness bubbles* within a rollout [61, 62]: early-finishing GPUs idle while waiting for stragglers, serializing batch completion. The scheduler therefore faces a dynamic variant of the Job Shop Scheduling problem, in which task durations are unpredictable and time-varying, and execution is subject to significant intra-phase fragmentation.

C3: Context Switching Overhead and Memory Residency. Third, the granularity of time-multiplexing is fundamentally constrained by context-switching cost. Unlike stateless LLM inference [12], RL post-training is *stateful*: it maintains a large working set of model weights, optimizer states, dataset pipelines, and environment states. Reconstructing this state on every switch—known as a *cold start*—incurs prohibitive overheads from both data- and control-plane re-initialization. As shown in Figure 4, a cold start of a rollout or training phase on an 8-GPU node (H20 for rollout, H800 for training) takes up to 135 seconds and degrades end-to-end RL training throughput by up to 45%.

Size	7B	14B	32B	70B
Rollout	275.7	445.4	490.3(TP2)	391.2(TP8)
Train	240(TP2)	456.1(TP2)	520.4(TP8)	458.7(TP8PP4)

Table 2: Memory footprint (GB) required for caching rollout or training actors on an 8-GPU node across model sizes.

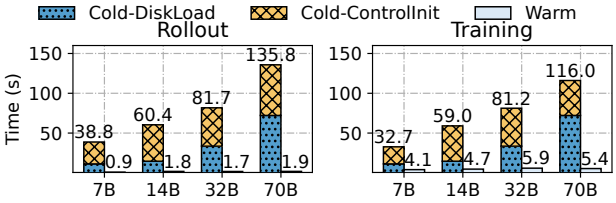

Figure 4: Cold and warm start latency for rollout (**left**) and training (**right**) across model sizes on an 8-GPU node (H20 for rollout, H800 for training).

Unlike serverless systems that mitigate cold starts via high-speed RDMA state transfers [12, 56, 58], disaggregated RL setups are bottlenecked by limited cross-cluster Ethernet bandwidth. The only viable alternative is a *warm-start* strategy that keeps job states cached in local host DRAM. This reduces switching latency by up to 71.5× (Figure 4), but at the cost of severe memory pressure. A single phase's state consumes hundreds of gigabytes (Table 2), so even high-memory nodes (1–2 TB) admit only two to five resident jobs at a time. This per-node footprint is determined by the per-GPU state held on the node, not by the model's total parameter count: larger models use higher tensor or pipeline parallelism to fit GPU HBM and therefore spread state across more GPUs, while smaller models more often replicate state per node via data parallelism. Table 2 confirms this: the 70B configuration (TP8PP4) fits in no more host DRAM than the 32B configuration, so scaling model size does not further tighten the residency budget. The scheduler therefore faces a tight *residency constraint* and must optimize utilization within a bounded memory budget.

4 The WEAVE Scheduling Design

We present WEAVE, a cluster scheduling framework that reclaims dependency bubbles for disaggregated RL post-training through cross-cluster orchestration. WEAVE adopts a holistic algorithm-system co-design: we decouple the logical scheduling policy (§4) from the underlying system design (§5). This section details the core scheduling algorithms.

4.1 Co-Execution Group

WEAVE's scheduling objective is to minimize provisioning cost by re-using dependency bubbles in already-paid-for capacity, while strictly adhering to job performance SLOs and node memory constraints. To achieve this, we introduce the *co-execution group* abstraction. A co-execution group is a set of jobs that *share* a specific pair of rollout and training resource pools via *time-multiplexing*. Within a group, all rollout phases execute on the group's assigned rollout workers, and all training phases execute on the group's training workers. By partitioning jobs into *disjoint groups*, WEAVE transforms the intractable global co-scheduling problem into a collection of independent, parallel sub-problems within groups. This decomposition keeps scheduling tractable at production scale (**C1**), and pinning jobs to specific group nodes keeps their working sets resident in host DRAM so that context switches are served by warm starts rather than slow disk or cross-cluster fetches (**C3**).

The co-execution group abstraction naturally leads to a *two-tier scheduling hierarchy*: (1) *inter-group scheduling* (§4.2), which assigns arriving jobs to groups to minimize provisioning costs while satisfying memory and SLO constraints, and (2) *intra-group scheduling* (§4.3), which orchestrates the runtime execution order of job phases within a group to minimize dependency bubbles.

4.2 Inter-Group Scheduling

Problem Formulation. We model the cluster as a collection of disjoint co-execution groups. We define a co-execution group G as a tuple (J_G, R_G, T_G, Φ_G), where J_G is the set of active RL jobs in the group, R_G and T_G denote the sets of rollout (e.g., H20) and training (e.g., H800) GPUs provisioned for the group, and $\Phi_G = \{P_j\}_{j \in J_G}$ is the set of resource placements, where P_j specifies the exact subset of rollout and training nodes job j is pinned to. This pinning P_j strictly determines where the job's state is cached to enable its warm start.

The inter-group scheduler solves the following *online placement problem*: upon the arrival of a job j, it must assign j to a co-execution group—either an existing one or a newly created one—and allocates specific resource placement P_j. To make optimal placement, we define the provisioning cost of a group, $\text{Cost}(G)$, as the aggregate hourly cost (Table 1) of all allocated GPUs in its rollout and training pools (R_G and T_G). The scheduler's objective is to minimize the *marginal provisioning cost* Δ incurred by admitting job j:

$$\min_G \Delta = \text{Cost}(G') - \text{Cost}(G),$$

where G' represents the group's state after accommodating job j. This formulation naturally encourages "packing" jobs into existing dependency bubbles (where $\Delta = 0$) over provisioning new hardware (where $\Delta > 0$). The placement decision is subject to two critical constraints:

1) Memory Residency. To guarantee warm starts (**C3**), the aggregate working set of all jobs pinned to a specific node must not exceed that node's host memory capacity.

2) SLO Attainment. The placement must satisfy the performance SLOs of both the new job and all existing jobs. The SLO is defined by each job as the *tolerance for co-execution slowdown* (e.g., 1.1×) relative to solo execution.[1] Formally, for every job k in the updated group G, we require:

$$T_k^{\text{co-exec}} \leq \text{SLO}_k \times T_k^{\text{solo}}.$$

Here, T_k^{solo} is the estimated iteration time when job k is running alone (Figure 1-top), which is simply the sum of its rollout and training phase durations; $T_k^{\text{co-exec}}$ is the expected iteration time under co-execution, which is derived by simulating the intra-group schedule (§4.3).

Making Placement Decisions. Navigating the search space to find an optimal placement is non-trivial due to both workload heterogeneity (**C1**) and runtime stochasticity (**C2**). WEAVE addresses these complexities with three strategies.

1) Handling Stochasticity via Conservative Planning. To guarantee SLO compliance despite the volatile, unpredictable job execution time (**C2**), WEAVE decouples admission control from runtime optimization. The inter-group scheduler acts as a "gatekeeper" that makes placement decisions based on *worst-case execution bounds*. Specifically, for an arriving job j, we estimate its phase durations (T_j^{roll} and T_j^{train}) assuming that every generated response reaches the *maximum token limit* defined in the job configuration. By planning against this upper bound, we ensure that the chosen placement satisfies the SLO constraints even under the most adverse stochastic conditions. If the actual runtime durations are shorter, which is typical, the intra-group scheduler dynamically reclaims the resulting slack to improve utilization (§4.3).

2) Optimal Placement Search. With these conservative estimates, WEAVE performs a global search to minimize the marginal provisioning cost Δ. For each arriving job, the scheduler iterates through all candidate groups and evaluates three placement strategies:

- *Direct Packing:* Inserting the job into existing dependency bubbles within a group without provisioning new resources (Figure 5-top). This maximizes utilization of already-paid-for capacity.
- *Rollout Scaling:* If a group has available training capacity but is bottlenecked on inference, which is common with rollout-heavy agentic workloads, WEAVE scales up the group's rollout pool by provisioning *just enough* rollout nodes to accommodate the new job (Figure 5-middle).
- *Isolated Provisioning:* As a fallback, WEAVE provisions a new, isolated group for the new job (Figure 5-bottom).

The scheduler iterates through these strategies[2], selecting the

[1] We assume a tight SLO, e.g., tolerance for up to 2× slowdown.

[2] Online reconfiguration of distributed parallel groups is possible (e.g., Tenplex [46]), but still incurs non-trivial overhead relative to a DP scaling, and thus is not supported by mainstream RL frameworks. WEAVE therefore defers training-pool scaling and simply matches the arriving job's DP degree to the existing training-pool size.

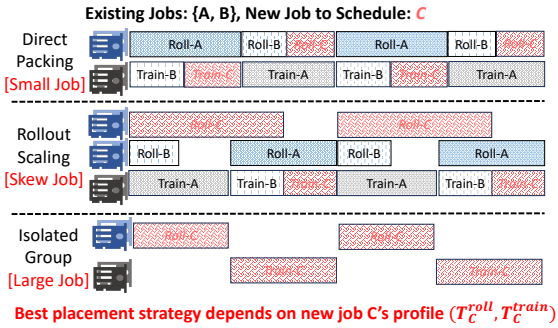

Figure 5: Placement strategies of the inter-group scheduler.

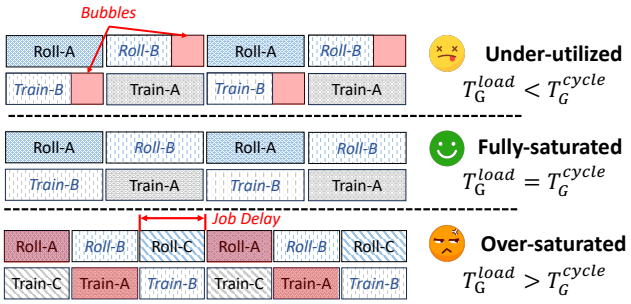

Figure 6: Status of a co-execution group. WEAVE only places new jobs into under-utilized groups with unsaturated dependency bubbles and avoids creating over-saturated groups.

valid placement that minimizes the marginal cost Δ while satisfying both the memory residency and SLO constraints.

3) Pruning Saturated Groups. To ensure this search remains tractable at production scale (**C1**), WEAVE proactively prunes the search space. Before evaluating specific placements, the scheduler filters out groups that are already *saturated*, where the aggregate job load saturates or exceeds the group's bottleneck resource capacity, and adding more work to the group would lead to performance degradation.

Formally, for a group G, let $T_G^{\text{cycle}} = \max_{j \in J_G} T_j^{\text{solo}}$ be the natural cycle iteration time dictated by the *longest job* in the group. We define the group's bottleneck load T_G^{load} as the total time required to process all phases on the bottleneck node. Since all training nodes have identical phases, while rollout nodes may differ[3] (see Figure 5), we have

$$T_G^{\text{load}} = \max\left(\sum_{j \in J_G} T_j^{\text{train}}, \max_{n \in \Phi_G}\left(\sum_{j \text{ on node } n} T_j^{\text{roll}}\right)\right).$$

If $T_G^{\text{load}} \geq T_G^{\text{cycle}}$, the group is saturated, containing no "slack" to absorb new work (Figure 6). Such groups are pruned immediately as any further addition would force delays.

Algorithm Summary. We integrate these strategies into a unified online scheduling logic detailed in Algorithm 1. The algorithm takes a new job j and the set of existing groups

[3]Within each group, WEAVE scales each job's data-parallel degree so that all jobs use the same number of training GPUs and every training node in the group executes the same multiset of training phases; rollout placements may still differ because each job is pinned to its assigned rollout node(s).

Algorithm 1 Inter-Group Scheduling Algorithm

Require: Job to schedule j, all existing groups $\{G_i\}_{i=1}^n$.
Ensure: Best group G^*, best placement P_j^*.

1: **procedure** SCHEDULE($j, \{G_i\}_{i=1}^n$)
2: $\Delta^* \leftarrow \infty$, $G^* \leftarrow$ None, $P_j^* \leftarrow$ None ▷ Initialize best values
3: **for** each group G in $\{G_i\}_{i=1}^n$ **do** ▷ Try all existing groups
4: **if** $T_G^{\text{load}} \geq T_G^{\text{cycle}}$ **then** ▷ Skip saturated groups
5: **continue**
6: $\mathcal{P} \leftarrow$ GENERATEPLACEMENTS(G)
7: **for** each resource placement P_j in $\mathcal{P}$ **do**
8: **if** j.mem_req $\geq \min_{\text{node} \in P_j}$(node.mem_avail) **then**
9: **continue** ▷ Per-node memory constraint violated
10: **if** exists $k \in \{j\} \cup J_G$, s.t., $T_k^{\text{co-exec}} > \text{SLO}_k \times T_k^{\text{solo}}$ **then**
11: **continue** ▷ SLO constraint violated
12: $\Delta \leftarrow \text{Cost}(G \cup \{(j, P_j)\}) - \text{Cost}(G)$
13: **if** $\Delta < \Delta^*$ **then**
14: **Update** $\Delta^* \leftarrow \Delta$, $G^* \leftarrow G$, $P_j^* \leftarrow P_j$
15: $\Delta \leftarrow \text{Cost}(\{j\}, \{\})$ ▷ Try to place j in a new group
16: **if** $\Delta < \Delta^*$ **then**
17: **Update** $\Delta^* \leftarrow \Delta$, $G^* \leftarrow \{j\}$, $P_j^* \leftarrow \{\}$
18: **return** G^*, P_j^*

as input. To find the optimal placement, the algorithm first iterates through all existing groups (line 3), discarding those that are already saturated (line 4). For each remaining candidate group, it evaluates potential placement strategies—direct packing or rollout scaling—for the job (line 6); placements that would violate memory constraints (line 8) or SLO constraints (line 10) are discarded. The algorithm evaluates the marginal cost for each feasible placement (lines 6–12) and updates its records if the placement leads to a lower cost (lines 13–14). Finally, the algorithm compares its records against the baseline cost of provisioning a fresh, isolated group (lines 15–17) and returns the group and job placement that yield the lowest costs.

Running Example. Suppose the cluster currently hosts two active co-execution groups G_1 and G_2, and a new job E arrives for scheduling. Group G_1 is already saturated and gets pruned immediately. Group G_2 still has slack, and contains jobs C and D: C is pinned to nodes (`roll-1`, `train-1`), while D is pinned to (`roll-2`, `train-1`). Thus, C and D use separate rollout nodes but share the same training node. For this group, GENERATEPLACEMENTS produces only a few candidates $\mathcal{P}$. It first tries *direct packing*, e.g., placing E onto (`roll-1`, `train-1`) to share resources with C, or onto (`roll-2`, `train-1`) to share with D. It then tries *rollout scaling*, which keeps E on `train-1` but allocates a new rollout node, e.g., (`roll-3`, `train-1`). Finally, the scheduler compares these feasible placements against *isolated provisioning*, which creates a new group containing only E. Any candidate that violates memory residency or any job's SLO is discarded, and the scheduler chooses the lowest-cost feasible option.

The algorithm allows for highly efficient decision-making. Since $|\mathcal{P}| = O(|R_G|)$ for each group and the SLO check on line 10 is a constant-cost simulation of one meta-iteration (§4.3, Theorem 1), the per-group work is $O(|\mathcal{P}| \cdot |J_G|)$. Since individual groups are small in practice ($|J_G|$ typically below

ten), the overall search complexity is effectively *linear* in the number of active groups. As empirically demonstrated in §6.5, this heuristic allows the scheduler to make optimal decisions in sub-seconds even in clusters with thousands of jobs.

4.3 Intra-Group Scheduling

Once the inter-group scheduler assigns a job to a group, the intra-group scheduler is responsible for orchestrating the runtime execution sequence. Its primary objective is to maximize resource utilization—and thereby minimize dependency bubbles—within the assigned resource pools.

The Round-Robin Policy. WEAVE employs a *cyclic round-robin schedule*. Within a co-execution group, the scheduler defines a *meta-iteration* in which every active job executes exactly one rollout phase and one training phase (Figure 1). These phases are orchestrated sequentially on their assigned resource pools. For example, in a group with jobs $\{A, B\}$, the rollout pool executes $\text{Roll}_A \rightarrow \text{Roll}_B$, while the training pool executes $\text{Train}_A \rightarrow \text{Train}_B$.

While simple, this policy is *optimal* under the preconditions enforced by WEAVE. Recall that the inter-group scheduler (§4.2) proactively prunes any group where the aggregate load exceeds the natural cycle time ($T_G^{\text{load}} \geq T_G^{\text{cycle}}$). For the remaining groups, their optimality is provable.

Theorem 1 (Utilization Optimality) *For any unsaturated or full group G, a meta-iteration schedule that executes each job's phases exactly once in a round-robin order maximizes the aggregate utilization of both rollout and training pools.*

Proof Sketch. The optimality rests on the definition of an *unsaturated (or full) group*: the bottleneck node's total workload T_G^{load} is no more than the longest job's standalone cycle time T_G^{cycle}. Intuitively, this implies that we can pack all other jobs' corresponding phases (e.g., their rollouts) into the longest job's dependency bubbles (e.g., its idle rollout nodes during training). This ensures a round-robin cycle that executes each job's phases exactly once to complete in time T_G^{cycle}. We then show any deviation from this simple schedule is *suboptimal*. (1) *Executing less is impossible*: Omitting any job from the cycle leads to more bubbles and starvation, which is trivially non-optimal. (2) *Executing more is inefficient*: Repeating any job phase prolongs the cycle time as the added phase can only start after finishing the slowest job. However, this added duration is disproportionately larger than the useful work added, leading to a net decrease in utilization.

Therefore, the round-robin schedule, which executes all required work in the shortest possible cycle time, is utilization-optimal. We provide a formal proof in Appendix 8.

Long-Tail Migration. While the round-robin schedule is optimal for deterministic workloads, production RL phases are highly stochastic (**C2**). Specifically, rollout durations follow a *heavy-tailed distribution* where the completion time of an input batch is dictated by a small number of "straggler" responses that reach maximum token limits [14,19,61,62]. This phenomenon creates significant *intra-phase fragmentation*: as the majority of responses finish early, most GPUs in the rollout pool idle wait for the few stragglers to complete, creating "skewness bubbles" (Figure 7-top).

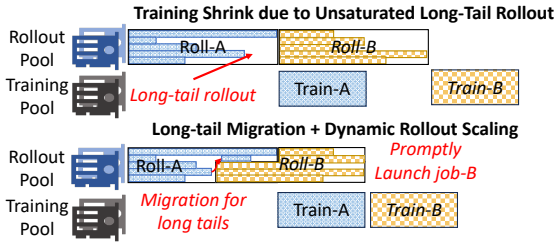

Figure 7: Long-tail migration effectively handles dynamism.

To reclaim this fragmented capacity, WEAVE employs *long-tail migration* to dynamically adapt the schedule at runtime. The intra-group scheduler continuously monitors the progress of active rollout phases. When a phase enters a *tail-bound state*, triggered when a threshold of responses (e.g., 80%) have completed, the system interrupts the execution, consolidates the remaining long-tail responses onto a small subset of workers[4], and immediately starts the *next* job's rollout phase on the newly freed rollout GPUs (Figure 7-bottom). This mechanism effectively pipelines the tail of one job with the head of the next, ensuring high utilization and faster completion. It is also the runtime counterpart of the conservative admission in §4.2: worst-case planning reserves rollout capacity for stragglers that rarely materialize, and this mechanism converts the unused reservation into useful work for the *next* job in the round-robin order. We will show in §6.3 that long-tail migration is semantics-preserving: it changes *where* the tail finishes, not *what* the rollout produces, and does not alter the underlying RL learning signal or convergence.

5 The WEAVE System Design

Figure 8 shows WEAVE's architecture. It is organized around three pieces: a *control plane* (the two-tier scheduler, a per-job phase shim, and runtime hooks), a *data plane* (the disaggregated rollout and training GPU pools, with each job's working set cached in host DRAM for warm starts), and a *cross-cluster sync channel* that carries model updates from the training pool to the rollout pool. WEAVE is implemented in ∼5.2k lines of code atop ROLL[5] [45], with controllers in Python and the placement search in C++.

[4]Migration moves only the *remaining requests* of a tail-bound rollout phase, not the job's model or KV cache, so sampling RNG (random number generator), tokenization, and batch composition are preserved; the target workers are a subset of the same homogeneous rollout pool, so numerical results match what the original placement would have produced.

[5]We choose ROLL [45] as the underpinning RL runtime because it exposes per-phase entry points suitable for shim-based enforcement; any disaggregated RL runtime with comparable hooks could serve as the substrate.

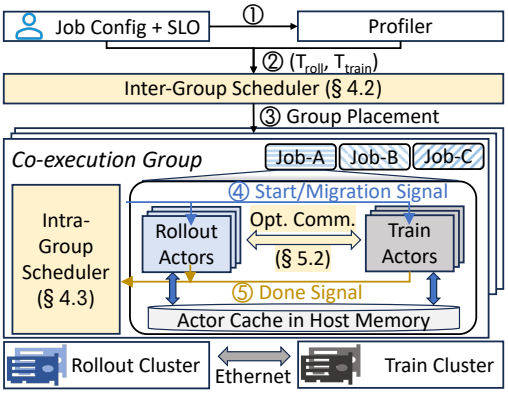

Figure 8: WEAVE's system architecture.

Workflow. The system operates as a closed loop (Figure 8). Upon job submission, WEAVE first launches a lightweight profiler (①)—a one-shot timing pass that runs the user's rollout and training functions at the job's configured maximum token limit—to generate worst-case duration estimates for the job's rollout and training phases (②). These estimates are fed into the inter-group scheduler (§4.2), which identifies the optimal co-execution group and resource placement to minimize marginal cost (③). Once placed, the job comes under the control of the intra-group scheduler (§4.3). This runtime controller orchestrates the round-robin meta-iteration (④), driving phase switches through the per-job phase shim and triggering long-tail migrations based on real-time feedback from its runtime hooks (§5.1). Once a phase completes, WEAVE offloads its state to the actor cache in host DRAM, releases GPU resources, and launches the next job's waiting phase from the scheduler queue (⑤). Model-update traffic between the *Train* and *Rollout* pools crosses a slow cross-cluster link; WEAVE routes it through a topology-aware scatter-then-broadcast (§5.2) so that sync does not itself become a new bubble.

5.1 Phase Control

Conventional cluster schedulers treat a job as the atomic unit of resource allocation, which is too coarse for interleaving distinct RL phases of different jobs on the same hardware. WEAVE instead schedules at the granularity of *individual phases*: each phase is a first-class schedulable entity with its own admission, state, and runtime controls.

Execution and Switching. We model each RL job as a dependency graph of phases. After a one-time initialization (`Init`) of the job states (e.g., models, datasets), the job enters a cyclic dependency loop: `Rollout` → `Train` → `Sync`. WEAVE exposes this internal structure to the scheduler via a declarative Python API. Users simply annotate their phase functions with a `@weave.phase` decorator, which injects a *transparent runtime shim* to manage the execution lifecycle.

When a phase is invoked, this shim first blocks execution until it acquires a run permit from the intra-group scheduler. Upon approval, it performs a *warm start* by loading the phase's resident working set from host DRAM into GPU memory. Once the user function completes, the shim immediately offloads the updated state back to host memory and releases the occupied GPUs, making the hardware instantly available for the next phase in the group's queue. Crucially, WEAVE optimizes this switching process by decoupling data plane state from control plane context. Naively terminating a process after a phase completes would force the system to tear down and rebuild expensive control plane (e.g., NCCL communicators, environment handles) upon every switch. Instead, WEAVE employs a *lightweight suspension* strategy: after offloading, the shim places the process into a sleep loop while retaining its control plane context without consuming GPU resources. On the next wake-up, resuming the phase only requires reloading its cached state onto the GPU, avoiding expensive cold starts from disk and control-plane re-initialization.

Runtime Hook. The system exposes a runtime hook interface `@weave.runtime_hook`. This interface serves two critical roles. First, it drives the round-robin schedule: the intra-group scheduler maintains a FIFO queue for each worker node. When a job's phase completes, the hook signals the scheduler to enqueue the job's next phase onto the alternate resource pool's queue (e.g., moving from rollout to training) and starts the next waiting phase on the now-idle devices. Second, it enables the long-tail migration (§4.3). By exposing internal token generation progress, the hook allows the scheduler to detect tail-bound states and externally trigger migration, dynamically reconfiguring resources in real-time.

5.2 Topology-Aware Model Synchronization

To mitigate the cross-cluster bandwidth bottleneck, WEAVE employs a *topology-aware* communication strategy to efficiently synchronize model parameters from the training cluster to the rollout cluster. State-of-the-art RL frameworks (e.g., veRL [43]) rely on flat collective operations like `AllGather` to propagate model updates. While efficient in monolithic clusters, this approach is pathological in disaggregated setups. It treats the slow cross-cluster Ethernet link and the fast intra-cluster InfiniBand/NVLink fabric as a single uniform network. Consequently, it forces every rollout worker to independently fetch a full copy of the model parameters over the slow cross-cluster link (Figure 9-top), causing a severe bottleneck while leaving local high-speed fabrics idle.

Inspired by LLM auto-scaling and multi-casting systems [4, 13, 56, 58, 65], we exploit the heterogeneous bandwidth and redundant model copies, a unique characteristic of disaggregated RL post-training, to reduce synchronization cost. WEAVE replaces the flat collective with a *hierarchical two-stage transfer*. ① In the first stage (**inter-cluster scatter**), it partitions the updated model into N disjoint shards, where N is the number of training GPUs. Each training GPU transmits a unique shard to a corresponding rollout GPU via parallel

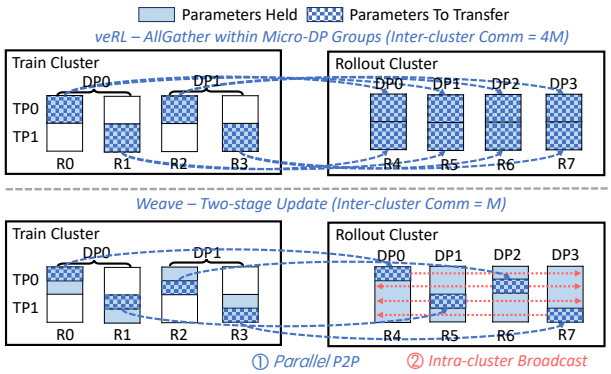

Figure 9: A synchronization example from the training cluster (TP=2, DP=2) to the rollout cluster (DP=4), where WEAVE sends exactly one copy across the cross-cluster network. M denotes the number of total parameters.

point-to-point (P2P) streams. This ensures that *exactly one full copy* of the model traverses the slow cross-cluster link. ② In the second stage (**intra-cluster broadcast**), the receiving GPUs immediately disseminate their shards to all other rollout workers using the high-bandwidth InfiniBand/NVLink fabric. This two-stage pipeline effectively mitigates the slow cross-cluster bottleneck, minimizing overall synchronization time and fully utilizing network hierarchies.

5.3 Reliability and Robustness

Fault Isolation. To ensure production-grade reliability, WEAVE enforces strict fault isolation. Each job runs in a dedicated Ray [30] instance with an isolated runtime environment, and jobs communicate with the scheduler exclusively through a Redis [38] control channel; they never exchange messages directly. A crash in one job is therefore contained within its pod, preventing error propagation and keeping the other jobs in the same co-execution group unaffected. WEAVE treats a recovered job as a *new arrival*: upon resubmission, it re-runs admission and placement via Algorithm 1 and restores the last completed iteration from checkpoint, so the rest of the cluster does not need to halt or regroup. Figure 19 reports end-to-end behavior under an injected crash.

Robustness to Workload Drift. A job's rollout and training profile can *drift* during its lifetime, e.g., as response length grows with training. WEAVE absorbs drift with its admission-time placement rather than an online regrouping loop, for three reasons. First, global repartitioning at every drift event is NP-hard [25] and incurs substantial migration and restart overhead—nearly 9% of trace time in our experiments (§6.6). Second, the conservative admission policy of §4.2 reserves capacity against worst-case token lengths, so moderate drift only shifts *which* bubbles are consumed, without breaching the group's saturation budget. Third, long-tail migration can also absorb the rollout drifts, keeping the round-robin cycle still near-optimal on the drifted workload (Theorem 1). If a job drifts far enough that its group crosses $T_G^{\text{load}} \geq T_G^{\text{cycle}}$, we simply stop and resubmit *that job*; Algorithm 1 re-places it through normal admission without disturbing the rest of the cluster. §6.6 shows static placement stays $> 95\%$ SLO attainment and within $1.11\times$ the provisioning cost of an optimal yet unimplementable dynamic-regrouping baseline.

Job	Turns	Model	Len[6]	Bsz	N_T	N_R
Type-A	Single-Turn	Qwen-2.5-7B	8K	256	8	8
Type-B	Single-Turn	Qwen-2.5-14B	8K	256	8	8
Type-C	Single-Turn	Qwen-2.5-32B	8K	256	16	16
Type-D	Multi-Turn	Qwen-3-8B	8K*	256	8	8
Type-E	Multi-Turn	Qwen-3-14B	16K*	64	8	8

Table 3: Experimental job configurations. N_T and N_R denote training and rollout GPUs.

6 Evaluation

We evaluate WEAVE through five research questions. **RQ1 (Co-Execution Mechanism):** Can WEAVE co-execute job groups with diverse phase profiles (§6.2)? **RQ2 (Performance Breakdown):** How much do long-tail migration and topology-aware model sync each contribute to performance (§6.3)? **RQ3 (Performance at Scale):** What cluster utilization and provisioning cost does WEAVE achieve on a production workload trace (§6.4)? **RQ4 (Scheduling Quality):** How close to optimal is WEAVE's scheduler (§6.5)? **RQ5 (Robustness):** How robust is WEAVE to phase profile drift and job failures (§6.6)?

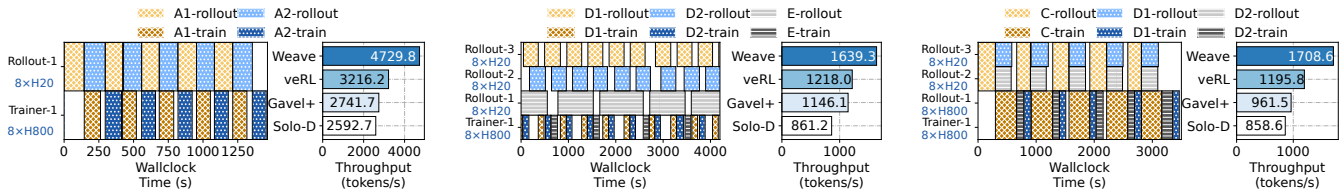
6.1 Experimental Setup

Cluster Setup. Our testbed has two geo-distributed, heterogeneous clusters: the training cluster (`Cluster-T`) uses compute-optimized NVIDIA H800 GPUs, while the rollout cluster (`Cluster-R`) uses lower-cost H20 GPUs. Each cluster has a 400 Gbps InfiniBand fabric, but cross-cluster traffic traverses a bandwidth-constrained 20 Gbps Ethernet link. Table 1 lists hardware specifications and hourly costs; an H800 GPU is $2.85\times$ more expensive than an H20 GPU.

Workloads. We construct workloads from production traces. For **micro-benchmarks** (§6.2–§6.3), we define a suite of five representative job types (Table 3) using Qwen [53] models (7B–32B) with varying batch sizes, sequence lengths, and rollout/training GPUs. They cover single-turn RLVR on DeepMath-103K [41] and multi-turn agentic reasoning on Math-Orz57K [23]. For **at-scale evaluation** (§6.4), we replay a two-week trace of 200 heterogeneous jobs with model sizes from 3B to 32B and datasets spanning mathematics [41], software engineering [33], games [8], and in-house tasks.

Baselines. We compare WEAVE against three baselines.

[6] For multi-turn workloads, Len is the per-turn output length.



(a) Temporal Mux (single-turn, Type-A×2). (b) Train Mux (multi-turn, Type-D×2 + E). (c) Spatial Mux (mixed, Type-C + D×2).

Figure 10: Micro-benchmarking results. For each benchmark, the left panel is a Gantt chart showing the co-execution timeline; the right panel shows WEAVE achieves up to 1.99× higher training throughput under the same cluster provisioning cost.

- *Solo Disaggregation (Solo-D):* The standard disaggregation, where jobs run on dedicated rollout and training pools without time-multiplexing.
- *Co-location (veRL [43]):* The traditional monolithic approach, where all phases run on the high-performance training cluster (`Cluster-T`) using veRL. It avoids network bottlenecks but suffers from hardware mismatch.
- *Gavel+ [31]:* An enhanced version of the heterogeneity-aware Gavel scheduler [31], modified to support RL post-training. It optimizes resource allocation at the job level (calculating optimal GPU fractions) but lacks fine-grained control to interleave phase-level executions.

6.2 Micro-Benchmarks

We use three micro-benchmarks to show how WEAVE reclaims dependency bubbles (§4.3) and handles failures across multiplexing scenarios. Each benchmark compares training throughput against the baselines under the same per-hour cluster provisioning cost.

Temporal Multiplexing. First, we evaluate co-executing two jobs with similar structures (Type-A), an ideal case in which jobs are fully complementary. As shown in Figure 10a, WEAVE interleaves their execution and keeps both rollout and training clusters fully utilized. Consequently, WEAVE improves end-to-end training throughput by 1.82×, 1.73×, and 1.47× over Solo-D, Gavel+, and veRL, respectively, under the same cluster provisioning cost. Solo-D and Gavel+ leave one resource pool idle, while monolithic veRL underutilizes expensive H800 compute during memory-bound rollout.

Handling Rollout-Heavy Jobs. Next, we target rollout-heavy workloads by co-scheduling two Type-D jobs ($T_D^{\text{roll}} \approx 2.5T_D^{\text{train}}$) and one Type-E job ($T_E^{\text{roll}} \approx 6T_E^{\text{train}}$). In this scenario, WEAVE scales the rollout pool to 24 H20 GPUs, dedicates one inference node to each rollout phase, and time-multiplexes a single H800 training node across training phases in round-robin order (Figure 10b). This schedule achieves 1.90×, 1.43×, and 1.35× higher throughput than Solo-D, Gavel+, and veRL under the same budgets. Solo-D performs poorly because prolonged rollouts leave expensive training nodes idle. WEAVE's gains over Gavel+ and veRL are smaller than in (a) because the skewed rollout-heavy pattern leaves some bubbles unfilled (Figure 10b-left).

Micro-benchmark	Solo-Disagg	Ideal	WEAVE
(a) Temporal Mux	257.7s	240.8s (-6.6%)	261.8s (+1.6%)
(b) Train Mux	525.4s	490.3s (-6.7%)	552.0s (+5.1%)
(c) Spatial Mux	574.6s	516.7s (-10.1%)	630.8s (+9.8%)

Table 4: Micro-benchmark iteration time. WEAVE incurs at most 10% overhead over isolated execution; 'Ideal' is the performance ceiling when all phases run on H800 GPUs.

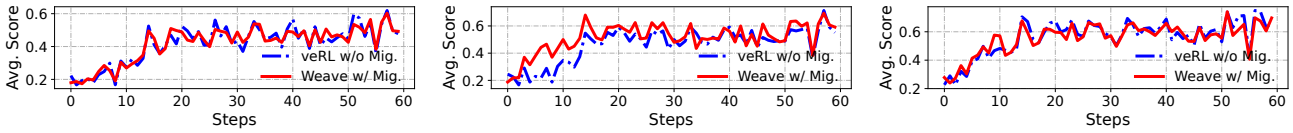
Spatial Multiplexing. Finally, we test heterogeneity by co-scheduling one large Type-C job (requiring 16 × H20 + 16 × H800) with two smaller Type-D jobs (each requiring 8 × H20 + 16 × H800). As shown in Figure 10c, WEAVE identifies idle resources created by the large job's rollout phase and "packs" the two smaller jobs into these bubbles. This spatial packing maximizes aggregate utilization, delivering 1.99×, 1.78×, and 1.43× higher throughput than Solo-D, Gavel+, and veRL. Unlike the baselines, WEAVE can dynamically consolidate diverse jobs onto available capacity.

Interference Overhead. We quantify co-execution cost by measuring per-iteration slowdown from inter-job contention (Table 4). Because the inter-group scheduler prunes placements that would violate residency or SLOs (§4.2), WEAVE is only 1.6–9.8% overhead over solo execution. Even against an idealized co-location upper bound, where each job runs all phases on expensive H800 GPUs with zero network cost, WEAVE is only 8.0–18.1% slower. This confirms that our optimizations mask most context-switching and synchronization costs while excluding contention-prone placements.

6.3 Ablation Study

We next isolate the contribution of WEAVE's runtime optimizations: long-tail migration and topology-aware model synchronization.

Long-Tail Migration. First, we evaluate whether request migration reclaims rollout bubbles without changing RL outcomes (§4.3). Figure 12-left shows that rollout generation lengths are heavy-tailed across model sizes and output lengths: a small fraction of straggler requests remains after most requests complete. Figure 12-right shows that migrating these tail requests to a small GPU subset reclaims the resulting



(a) Qwen2.5-7B. (b) Qwen2.5-14B. (c) Qwen2.5-32B.

Figure 11: Training reward scores for Qwen2.5-7B, 14B, and 32B under veRL without migration and WEAVE with migration.

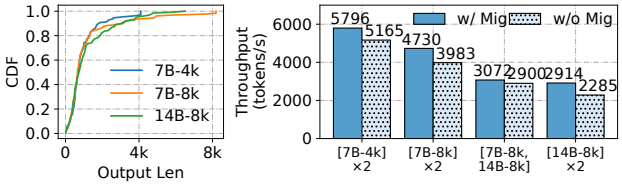


Figure 12: **Left**: the long-tail distribution of LLM generation length in the rollout phase. **Right**: effectiveness of request migration in mitigating long-tail rollouts.

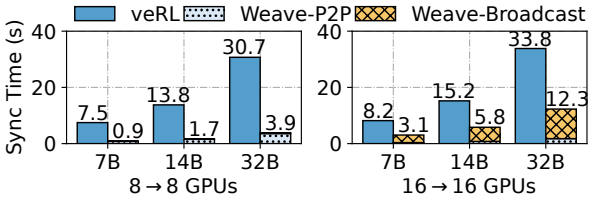

Figure 13: Model synchronization time. **Left**: single-node transfer from 8 H800 to 8 H20 GPUs. **Right**: multi-node transfer from 16 H800 to 16 H20 GPUs. WEAVE's topology-aware model sync is up to 8.33× faster than veRL [43].

"skewness bubbles." WEAVE can then start the next job's rollout on the freed GPUs, improving end-to-end throughput by 1.06×–1.28×. The gains are largest for longer output sequences (e.g., 14B-8k), where stragglers are more pronounced, and more modest when paired jobs have dissimilar phase durations (e.g., 7B-8k with 14B-8k), which already reduce contention on rollout nodes.

We also test whether migration changes the learning outcome. Figure 11 compares WEAVE with disaggregation and migration against a clean veRL baseline that runs on a monolithic H800 cluster without either mechanism, using Qwen-2.5 models at 7B, 14B, and 32B scales. For all three model sizes, WEAVE's average per-step reward tracks veRL throughout training and stays within measurement noise. This is expected because WEAVE only migrates rollout requests between homogeneous GPUs (e.g., H20-to-H20), never across heterogeneous devices, avoiding hardware-induced variability. Thus, long-tail migration improves throughput without measurably degrading rollout reward or training convergence.

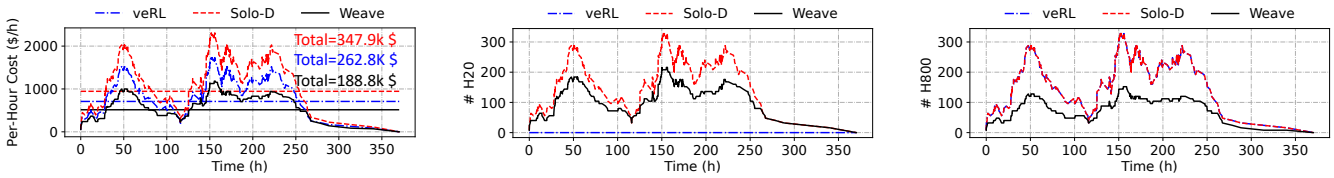
Topology-Aware Model Sync. Next, we evaluate topology-aware model synchronization in geo-disaggregated setups (§5.2). For a single-node update (8 H800s → 8 H20s), WEAVE is 7.87×–8.33× faster than veRL (Figure 13). The gain comes from sending one copy of the model parameters over the slow inter-cluster link and using local NVLink for the intra-cluster broadcast; veRL redundantly fetches independent copies for each rollout GPU. The benefit persists at multi-node scale: for 16 H800s → 16 H20s, WEAVE remains 2.62×–2.75× faster, showing that the protocol mitigates the bandwidth bottleneck introduced by disaggregation.

6.4 WEAVE at Scale

To evaluate WEAVE at production scale, we replay a two-week trace from one cluster tenant. The trace contains 200 heterogeneous RL post-training jobs using Qwen-family models, with both single- and multi-turn interactions across diverse datasets. Model sizes range from 3B to 32B, maximum response lengths range from 4k to 32k tokens (mean: 12.1k), and the mean job duration is 27.9 hours. We assign each job an SLO sampled uniformly from $(1, 2)$ relative to its solo runtime, and compare WEAVE with industry-standard solo disaggregation (Solo-D), which uses 1:1 rollout and training GPUs, and the monolithic co-located baseline (veRL).

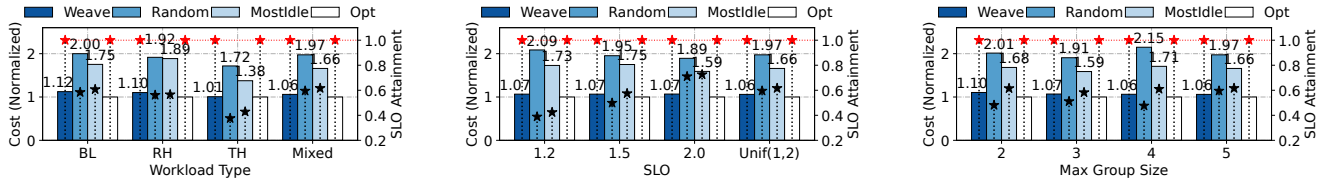
WEAVE accommodates all jobs for $510/hr (total: $188.8k), reducing cluster provisioning cost by 1.84× over Solo-D and 1.38× over veRL while meeting all job SLOs (Figure 14a). The admission decisions also show where the savings come from: among the 200 job arrivals, 60.5% use direct packing to share both training and rollout resources with existing groups, 15% share training resources while scaling the rollout pool, and only 24.5% form new resource groups. Thus, Algorithm 1 usually absorbs arrivals into existing groups, minimizing the marginal provisioning cost of each job.

WEAVE improves resource efficiency by reducing dependency bubbles by 24.4% on the rollout cluster and 43.1% on the training cluster relative to solo disaggregation. The reduction is larger for training because production jobs are typically rollout-heavy, leaving more idle time on training GPUs (Figure 14b and Figure 14c). At peak, WEAVE uses only 152 H800 training GPUs, while both veRL and Solo-D requiring 328 H800s (2.16× more). For rollout, WEAVE uses 216 H20 GPUs at peak, a 1.52× reduction from the 328 H20s required by Solo-D. Although veRL avoids separate rollout GPUs, WEAVE remains 1.38× more cost-effective overall by offloading memory-bandwidth-bound rollouts to cheaper H20 GPUs and filling the resulting dependency bubbles through co-scheduling.



(a) Cluster provisioning cost. (b) Number of rollout (H20) GPUs. (c) Number of training (H800) GPUs.

Figure 14: **[Testbed]** Cluster provisioning cost and GPU usage of WEAVE and baselines under real-world production workloads, where WEAVE reduces total provisioning cost by 1.38× and 1.84× compared to veRL and Solo-D, respectively.



(a) Sensitivity to workload types. (b) Sensitivity to job SLOs. (c) Sensitivity to group residency.

Figure 15: **[Simulation]** Sensitivity analysis of WEAVE's inter-group scheduler.

6.5 Scheduler Performance

We then evaluate the optimality and scalability of WEAVE's inter-group scheduler (§4.2) via large-scale trace simulation.

Experimental Setup. We use job arrival patterns from a 300-job, 580-hour segment of the Microsoft Philly multi-tenant training cluster trace [26], the average job duration is 14.4 hours, and the longest is 142.9 hours. While the trace dictates arrival times and durations, we synthesize the job characteristics to model modern RL post-training workloads. As detailed in Table 6, we define three job profiles based on the ratio of rollout time (T_{roll}) to training time (T_{train}). (1) **Balanced (BL):** Balanced T_{roll} and T_{train}, representative of single-turn workloads like RLHF [32] or RLVR [41]; (2) **Rollout-Heavy (RH):** $T_{\text{roll}} \gg T_{\text{train}}$, modeling multi-turn workloads such as agentic reasoning [33]; and (3) **Train-Heavy (TH):** $T_{\text{train}} \gg T_{\text{roll}}$ for evaluation completeness, but is rare in real-world RL training.

For each profile, we generate jobs of three sizes (Small, Medium, Large), resulting in nine distinct job configurations. We test each profile individually and also use a **Mixed** workload, which contains a uniform mix of all nine configurations, to simulate a realistic production environment.

Baselines. We compare WEAVE against following baselines:

- *Offline Optimal (Opt).* Assigns arriving jobs to *offline optimal* placements found via a brute-force search over all possible groupings and placements–including job reordering and re-grouping that are infeasible in online deployments–and serves as a theoretical upper bound.
- *Random.* Assigns arriving jobs to a random group (or a new one) that can accommodate them. The job is placed on random rollout and train nodes within this group.
- *Greedy (Most-Idle).* Assigns arriving jobs to the group with the highest idle-time percentage. Within that group, it places the job on the most idle rollout and train nodes.

Sensitivity Analysis. To determine how sensitive the scheduler's quality is to its key parameters, we vary a single parameter while all others are set to a default configuration[7].

Impact of Workload Characteristics. Figure 15a shows that WEAVE's near-optimal performance holds across all workload types. It consistently achieves 100% SLO attainment with a cost overhead of just 1.01×–1.12× relative to the optimal. In contrast, the baselines perform poorly across workloads, with Greedy slightly outperforming the Random strategy. The Random strategy's cost is 1.72×–2.00× optimal with only 37–58% SLO attainment, while the Greedy scheduler is slightly better but still inadequate, reaching 1.38×–1.89× optimal cost for 42–61% SLO attainment.

Impact of Job SLOs. We vary the job SLO requirements, testing both uniform SLOs (all jobs set to 1.2, 1.5, or 2.0) and heterogeneous, job-specific SLOs drawn from `Unif(1, 2)`. As shown in Figure 15b, WEAVE's performance is highly stable against SLO tightness, always achieving 100% attainment with a consistent, near-optimal cost. Conversely, the baselines are highly sensitive to the SLO target and more expensive (1.59×–2.09× optimal). As the SLO target loosens from 1.2 to 2.0, the SLO attainment for Random and Greedy improves from 38%/43% to 71%/73%, respectively. This shows that while looser SLOs make it easier for naive heuristics to succeed by chance, they still fail to provide guarantees.

Impact of Group Residency. Since node memory capacity directly limits the group size, we evaluate its impact by varying the maximum allowed group size from 2 to 5. Figure 15c shows that performance is relatively insensitive to the maximum group size for all methods. Across all configurations, WEAVE consistently maintains the lowest cost and 100% SLO attainment, while the baselines remain signifi-

[7]Default configuration: mixed workload types, heterogeneous SLOs drawn from `Unif(1,2)`, and a max group residency of 5.

Decision	Number of Concurrent Jobs						
Lat. (ms)	5	9	13	100	500	1000	2000
WEAVE	5.6	6.5	7.6	41.9	198	318	591
Opt.	113	>1min†	>5h†	—*	—*	—*	—*

† Represents latency exceeding 1 minute and 5 hours, respectively.
* Not applicable; computation is intractable at this scale.

Table 5: Decision latency (ms) vs. number of concurrent jobs. WEAVE scales well; Brute-force Opt's latency grows exponentially and quickly becomes impractical.

cantly defective (only 48%–61% SLO attainment) and more expensive (1.59×–2.15× optimal). This suggests that even small group sizes (e.g., 2 or 3) provide sufficient packing flexibility for WEAVE to find efficient placements; larger groups do not bring improved performance or cost efficiency.

Scheduler Scalability and Latency. We evaluate WEAVE's decision latency and scalability, with results presented in Table 5. WEAVE demonstrates near-linear scalability: its decision time is only 591 ms for 2,000 jobs, confirming that Algorithm 1 efficiently handles production-scale workloads. In stark contrast, the brute-force optimal solver exhibits exponential growth in latency, exceeding five hours for just 13 jobs–rendering it infeasible for any practical workload size.

6.6 Robustness to Drifts and Failures

We finally evaluate WEAVE's robustness against *workload drift*, where a job's rollout and training times change over its lifetime, and *job failures*.

Handling Workload Drift. We evaluate drift using the real-world trace from §6.4. To model long-term non-stationarity, we derive drift templates from production training traces across model sizes. Figure 16 shows representative 7B–32B examples; we omit the remaining model sizes for brevity. For each model family, we instantiate seven templates: no drift, increasing drift at 0.5×/1.0×/1.5×, and decreasing drift at 0.5×/1.0×/1.5×. The increasing 1.0× template is the observed training behavior; the other templates are scaled or mirrored versions of it. We evaluate three settings: **Increasing**, where each job samples from {no drift, increasing 0.5×, 1.0×, 1.5×}; **Decreasing**, defined analogously; and **Mixed**, where each job samples from all templates.

We compare WEAVE's static placement against an *optimal dynamic regrouping* baseline that periodically recomputes placements for all active jobs. The baseline checks for global regrouping every hour and uses brute-force search to find the exact optimal grouping under the jobs' current drifted profiles[8]. When regrouping changes a job's placement, we charge the measured migration and restart cost, 197–419 s for 7B–32B jobs. We do *not* charge the solver time for brute-force regrouping, making the baseline stronger than any practical online implementation.

[8]We choose a one-hour period because more frequent regrouping only increases restart overhead and does not improve this baseline in practice.

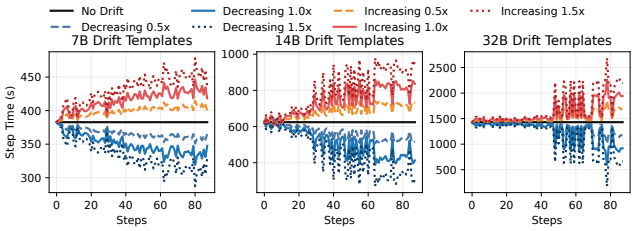


Figure 16: Workload drift templates for 7/14/32B models.

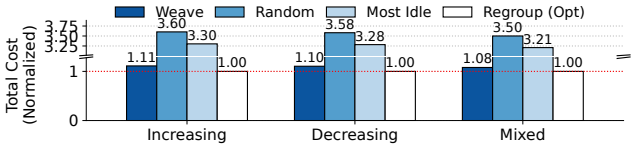

Figure 17: Normalized cost under workload drifts.

Figure 17 shows that static WEAVE stays close to this optimal baseline. Relative to dynamic regrouping, static WEAVE incurs only 1.11×, 1.10×, and 1.08× higher provisioning cost under increasing, decreasing, and mixed drift, respectively, while maintaining 98.6%, 98.7%, and 95.6% SLO attainment. Drift-agnostic baselines perform much worse: Random incurs 3.50×–3.60× the regrouping cost, and Most-Idle incurs 3.21×–3.30×. Figure 18 explains why static placement is usually sufficient. Static WEAVE has only modestly lower rollout utilization than dynamic regrouping (at most 5.9%), but achieves higher training utilization in all settings: drift is driven mainly by rollout-length changes, so regrouping improves rollout-side balance while each restart pausing directly reduces training-side utilization.

These results clarify when WEAVE needs adjustment under drift. Online global regrouping is often unnecessary: in our 370.2-hour trace, it spends 32.9 hours on migration and restart alone, even before solving the regrouping problem. Each regrouping step also requires solving a global NP-hard repartitioning problem, making it difficult to deploy as a frequent online control loop. Dynamic regrouping is therefore useful only when drift is severe and persistent enough to amortize both restart and re-optimization costs. In practice, when one job drifts substantially, the simpler operational response is to stop and resubmit only that job with its updated profile; WEAVE then places it through normal admission without perturbing the rest of the cluster.

Handling Job Failures. Figure 19 shows failure handling in the Train Mux setting from Figure 10b. At $t = 2180$ s, we manually kill job E to emulate a failure. The other jobs in the group (D_1 and D_2) continue unaffected and keep their two-job interleaving pattern. At $t = 4480$ s, we recover and resubmit job E. WEAVE treats the recovered job as a *new job*: it reruns admission and placement, restores the last failed iteration from checkpoint, and resumes training. Depending on cluster state at recovery time, WEAVE may place the recovered job in a different co-execution group; in this run, it is placed back into the original group. After resubmission, the three

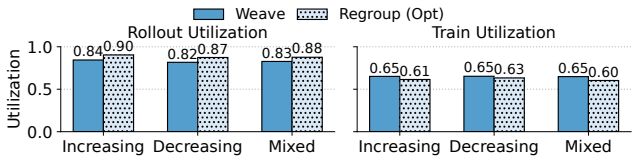

Figure 18: Rollout and training cluster utilization for WEAVE and regrouping under workload drifts.

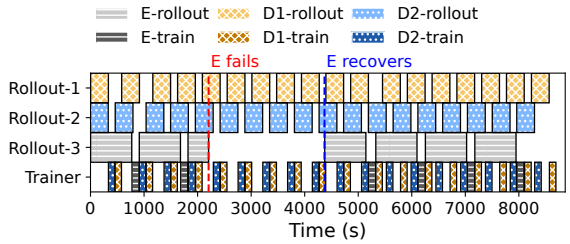

Figure 19: WEAVE's behavior under job failures.

jobs return to the original interleaving pattern and continue execution.

7 Discussion and Related Work

Applicability. WEAVE applies to any RL training regime that exposes a *structural dependency bubble* between rollout and training, the idle window its inter-job scheduler is designed to reclaim. This condition holds for the standard on-policy algorithms, including PPO [39], GRPO [41], and DAPO [57]. It also holds for off-policy regimes that retain such a bubble, such as one-step off-policy training [61], where each training step still waits for a bounded rollout window to complete. The boundary of applicability is reached when this bubble disappears: fully asynchronous RL training (e.g., AReaL [11] and AsyncFlow [18]) overlaps rollout and training continuously, leaving no inter-job idle time for WEAVE to reclaim. Within its applicable regimes, WEAVE's cluster-level orchestration is orthogonal to intra-job optimizations: parameter relocation [29], request-level tail batching [14], and speculative decoding [5, 19, 24, 36] all act within a single job or phase and compose directly with WEAVE.

Deep Learning Workload Scheduling. Extensive research has focused on scheduling for general-purpose deep learning clusters. These works aim to improve fairness [16, 28, 50], GPU sharing efficiency [49, 51], heterogeneity awareness [31, 42], and job goodput [35, 59]. However, these systems universally treat the entire job as the atomic unit of scheduling and assume stable, predictable iteration times. WEAVE is the first phase-centric co-scheduling system for stochastic RL post-training jobs.

RL Post-Training Frameworks. Recent systems have focused on optimizing the performance of a *single, individual* RL post-training job. While early frameworks used static resource partitioning [22, 27, 55], subsequent work improved utilization via co-location [43], multi-controller designs [48], long-tail mitigation [14, 62], and asynchronous algorithms [11, 18, 61]. Different from these single-job optimizations, WEAVE addresses the complementary part by taking a global, cluster-level perspective, orchestrating multiple concurrent jobs via co-scheduling.

Disaggregated Systems. WEAVE builds on the principle of disaggregation, a concept explored in OS kernels [40] and serving systems [21, 34, 60]. The most direct parallel is the prefill-decode disaggregation in LLM inference [21, 34, 60]. Within this domain, recent serving systems have also explored efficient resource management, but all in a single-job scope [6, 10, 20, 63]. In contrast, WEAVE introduces the first scheduling framework specifically designed for multi-tenant clusters, a scenario not addressed by prior works.

8 Conclusion

This paper presents WEAVE, a multi-tenant cluster scheduler tailored for disaggregated RL post-training. WEAVE introduces a two-tier scheduling mechanism that near-optimally partitions RL jobs into co-execution groups and orchestrates their execution in a tightly-woven pattern. It effectively reduces dependency bubbles caused by disaggregation, thereby minimizing cluster provisioning costs. Extensive evaluation using real-world production traces demonstrates that WEAVE achieves up to 1.84× cost savings while maintaining 100% performance SLO attainment.

Appendix

Proof of Meta-iteration Schedule's Optimality. To show the utilization-optimality of the meta-iteration schedule for unsaturated groups, we first formally define the utilization of a group with meta-iteration time T_{meta}, where its rollout (U_R) and training utilization (U_T) are:

$$U_R = \frac{\sum_{j \in J_G} T_j^{\text{roll}}}{T_{\text{meta}}}, \quad \text{and} \quad U_T = \frac{\sum_{j \in J_G} T_j^{\text{train}}}{T_{\text{meta}}}.$$

Since the meta-iteration schedule repeats, it suffices to analyze a single meta-iteration where every job's rollout and training phase executes once. Recall that $T_G^{\text{cycle}} = \max_{j \in J_G} T_j^{\text{solo}}$ is the solo iteration time of the slowest job, and let j_1 be the job attaining this maximum so that $T_G^{\text{cycle}} = T_{j_1}^{\text{roll}} + T_{j_1}^{\text{train}}$. For simplicity, the following proof considers only one rollout node and one training node, while the optimality generalizes to multi-node settings. By the definition of a non-overloaded group, we have

$$T_G^{\text{cycle}} = T_{j_1}^{\text{roll}} + T_{j_1}^{\text{train}} \geq \max\left(\sum_{j \in J_G} T_j^{\text{roll}}, \sum_{j \in J_G} T_j^{\text{train}}\right).$$

This directly implies that the total rollout work of all other jobs can fit within j_1's training phase, and vice-versa:

$$\sum_{j \in J_G \setminus j_1} T_j^{\text{roll}} \leq T_{j_1}^{\text{train}}, \quad \sum_{j \in J_G \setminus j_1} T_j^{\text{train}} \leq T_{j_1}^{\text{roll}}.$$

Consequently, job j_1's execution time decides the entire schedule's cycle time, yielding the cycle time as $T_{j_1}^{\text{solo}}$.

Conversely, any schedule that repeats a job is sub-optimal for a non-overloaded group because it extends the meta-iteration's duration but adds proportionally less work, leading to a net decrease in resource utilization. We show this by trying to add a repetition of any job k to the meta-iteration schedule. Repeating job k adds work to both pools and necessarily prolongs the cycle time by at least T_k^{solo} due to waiting for the longest j_1, causing the new utilization U' lower than the original U. We can bound the change in utilization, $\Delta U = U' - U$, as follows. The change for the rollout and the training pool, ΔU_R and ΔU_T, is bounded by:

$$\Delta U_R = U_R' - U_R \leq \frac{\sum_{j \in J_G} T_j^{\text{roll}} + T_k^{\text{roll}}}{T_{j_1}^{\text{solo}} + T_k^{\text{roll}}} - \frac{\sum_{j \in J_G} T_j^{\text{roll}}}{T_{j_1}^{\text{solo}}},$$

$$\Delta U_T = U_T' - U_T \leq \frac{\sum_{j \in J_G} T_j^{\text{train}} + T_k^{\text{train}}}{T_{j_1}^{\text{solo}} + T_k^{\text{train}}} - \frac{\sum_{j \in J_G} T_j^{\text{train}}}{T_{j_1}^{\text{solo}}}.$$

Therefore, the total change in utilization is

$$\begin{aligned}
\Delta U &= \Delta U_R + \Delta U_T = U_R' - U_R + U_T' - U_T \\
&\leq \frac{T_k^{\text{train}} T_{j_1}^{\text{solo}} - T_k^{\text{solo}} \sum_{j \in J_G} T_j^{\text{train}} + T_{j_1}^{\text{solo}} T_k^{\text{roll}} - T_k^{\text{solo}} \sum_{j \in J_G} T_j^{\text{roll}}}{T_{j_1}^{\text{solo}} (T_{j_1}^{\text{solo}} + T_k^{\text{solo}})} \\
&= \frac{T_k^{\text{solo}} (T_{j_1}^{\text{solo}} - \sum_{j \in J_G} T_j^{\text{solo}})}{T_{j_1}^{\text{solo}} (T_{j_1}^{\text{solo}} + T_k^{\text{solo}})} \leq 0.
\end{aligned}$$

This proves that any repetition degrades overall utilization, making the round-robin schedule utilization-optimal for non-overloaded groups.

Mixed	All	All	All

Workloads for Simulation. Table 6 details the job profiles used in § 6.5.

[Simulation] End-to-end Performance. This part reports the end-to-end performance of WEAVE's scheduler under a realistic setting with Mixed workloads with heterogeneous job SLOs. As illustrated in Figure 20, WEAVE, achieves 100% SLO attainment by design, matching the theoretical Offline Optimal scheduler. In contrast, the heuristic-based baselines struggle significantly: the Random and Greedy (Most-Idle) schedulers meet the SLOs for only 60% and 62% of jobs, respectively. This is because WEAVE's cost-based optimization (§ 4.3) explicitly prunes any placements that would violate a job's SLO by assigning it an infinite cost.

In terms of resource efficiency, the average cost of WEAVE is at 0.87K $/h, only 1.06× higher than the Offline Optimal. In contrast, the baselines are far more expensive. The Random and Greedy strategies incur average costs of 1.62K and 1.36K $/h, respectively (1.97× and 1.66× of optimal). This high cost is driven by their sub-optimal group partitioning, where their costs spike to over 5K $/h by scaling out to 1400 GPUs. WEAVE, however, manages load with a peak cost of only ∼1.8K $/h, requiring at most 504 GPUs, demonstrating its effectiveness at identifying SLO-aware, cost-efficient placements in a complex, online setting.

Abstract

Reinforcement learning (RL) has demonstrated immense potential in advancing artificial general intelligence, agentic intelligence, and embodied intelligence. However, the inherent heterogeneity and dynamicity of RL workflows often lead to low hardware utilization and slow training on existing systems. In this paper, we present RLinf, a high-performance RL training system based on our key observation that the major roadblock to efficient RL training lies in *system flexibility*. To maximize flexibility and efficiency, RLinf is built atop a novel RL system design paradigm called *macro-to-micro flow transformation* (M2Flow), which automatically breaks down high-level, easy-to-compose RL workflows at both the temporal and spatial dimensions, and recomposes them into optimized execution flows. Supported by RLinf worker's adaptive communication capability, we devise *context switching* and *elastic pipelining* to realize M2Flow transformation, and a profiling-guided scheduling policy to generate optimal execution plans. Extensive evaluations on both reasoning RL and embodied RL tasks demonstrate that RLinf consistently outperforms state-of-the-art systems, achieving 1.07×∼2.43× speedup in end-to-end training throughput.

1 Introduction

The rapid progress of large language models (LLMs) has reached a point where further scaling the model alone yields diminishing returns. To push intelligence beyond pretraining, reinforcement learning (RL) has emerged as a crucial paradigm. Recent advances such as RLHF [8, 38], GRPO [49], and RL for embodied agents [24, 25] and Deep Research [35, 69] all rely on RL to align LLMs with human preferences, improve reasoning, and enable autonomous interaction with complex environments. OpenAI and others predict that RL workloads will soon consume more computational resources than LLM pretraining [37], making RL training efficiency the most critical system concern.

*Corresponding author. Email: yu-wang@tsinghua.edu.cn

However, efficient RL training for various scenarios such as reasoning, agentic and embodiment at the scale of modern large models is challenging, which combines highly heterogeneous components with diverse workload characteristics and resource demands, such as LLM generation, inference and training, reward models, critic models, agent tooling and embodied environment simulators. For instance, LLM training consumes more accelerator (e.g., GPU) memory than LLM generation and inference (prefill-only generation) to maintain gradients and optimizer states, while LLM generation shows high dynamicity in response lengths, leading to low accelerator utilization. Moreover, components like LLM training support diverse parallelization strategies (e.g., data, tensor, pipeline parallelism), whereas others scale only via instance replication and may yield computation workloads distinct from common tensor computation in LLM, e.g., embodied simulators [10, 54] that require CPU for physics simulation and GPU graphics pipeline for 3D rendering.

Single execution mode of existing RL training systems fails to capture this diversity, leading to suboptimal efficiency. Collocated execution, where components sequentially occupy accelerators [51], suffers from the long-tail problem due to varying generation lengths, leaving accelerators idle. Disaggregated pipelining, where components run concurrently on separate accelerators with pipelining [13], mitigates the long-tail issue but introduces memory and computation imbalance (§2.2). Neither mode is universally optimal. Many RL workloads demand hybrid scheduling of the components to maximize efficiency, i.e., mixing collocation and pipelining in a more flexible way. However, supporting such flexible execution modes for a single programmed workflow is a significant challenge, as they often require different program structures and communication patterns. Also, identifying the right scheduling for a given workflow usually requires considerable manual tuning.

In this paper, we present RLinf, an RL training system that maximizes system flexibility to achieve efficient execution of a logically programmed RL workflow. At its core is a new paradigm called *macro-to-micro flow transformation*

(M2Flow), i.e., macro logical flow with micro execution flow, which decouples the logical programming of RL workflows from their physical execution planning. With M2Flow, developers program RL workflows imperatively, using a natural programming interface to define how components communicate and synchronize at a coarse granularity. RLinf then automatically transforms this logical flow into a fine-grained execution plan tailored to the workload and hardware at both spatial and temporal dimensions. By decoupling program semantics from execution modes, M2Flow lets developers preserve clean, intuitive workflows while the system explores a vast scheduling space, including temporal multiplexing, spatial pipelining, and hybrid scheduling.

RLinf achieves this through three key mechanisms. First, a *worker* abstraction that encapsulates each RL component for flexible placement, and built-in adaptive communication that allows direct and efficient communication between components regardless of worker and data placement. Second, elastic pipelining and automatic context switching that enable M2Flow transformation and expand the scheduling space, achieving pipeline granularity tuning and temporal accelerator multiplexing without modifying the logical workflow. Third, a profiling-guided scheduling policy that automatically selects efficient execution modes, balancing utilization across heterogeneous components. Together, these capabilities deliver high flexibility, efficiency, and programmability.

We implement RLinf using Ray for cluster management and worker process launch on remote nodes. Apart from the core mechanisms, RLinf also provides rich support for common RL components, algorithms, and models to facilitate RL workflow programming (§4). We extensively evaluate RLinf on both reasoning and embodied RL training across diverse models (e.g., Qwen2.5-1.5/7/32B [40], Qwen3 [59], OpenVLA [24], OpenVLA-OFT [23]) and varying scales. Our evaluation shows that RLinf improves end-to-end throughput (i.e., tokens per second) by up to 1.7× compared to state-of-the-art RL training systems in reasoning RL, and by up to 2.43× in embodied RL. We have open-sourced the full codebase of RLinf to accelerate RL innovations in the LLM era.

This paper makes the following contributions:

- Analysis of representative RL algorithms and scenarios, identifying characteristics of modern RL workflows and highlighting inefficiencies in current systems.
- A novel RL system paradigm M2Flow that decouples logical workflow programming from execution planning, enabling intuitive programming with flexible execution.
- A cohesive set of mechanisms, i.e., worker abstraction, elastic pipelining, context switching, adaptive communication, and a profiling-guided scheduler, that jointly realize M2Flow and enable efficient RL training.
- Comprehensive evaluations of RLinf across various RL workloads show that RLinf significantly improves efficiency and flexibility compared to existing approaches.

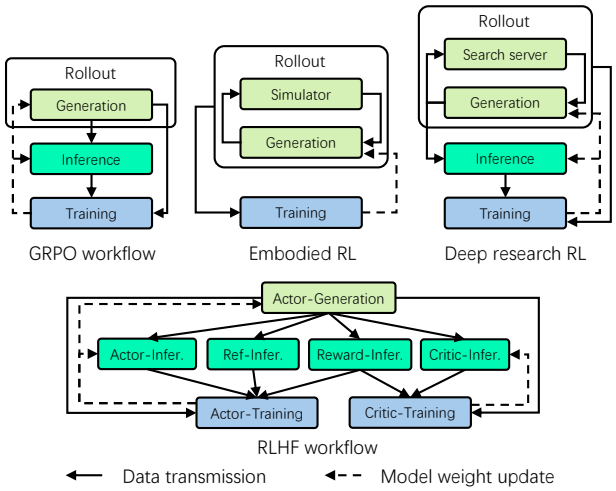

Figure 1: Diverse RL workflows in various scenarios.

2 Background and Motivation

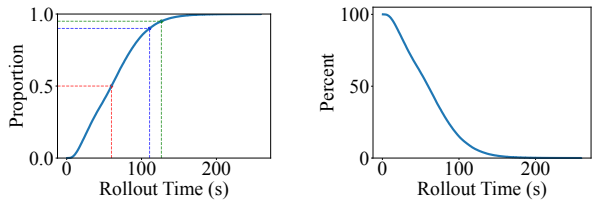
2.1 RL Workflows in LLM Era

Various RL Algorithms and Scenarios. With the slowdown of scaling gains in large language models, reinforcement learning has become increasingly important for advancing LLM intelligence. Unlike traditional RL, RL in the LLM era often involves multiple LLMs in the loop. Given the scale of modern models (tens to hundreds of billions of parameters), fitting RL training into available accelerators (e.g., GPUs) is already challenging. Figure 1 illustrates four representative RL workflows across different scenarios and algorithms.

The simplest is GRPO [49], an RL algorithm designed to reduce reliance on reward models. It involves a single LLM that generates multiple responses, e.g., 8, for a query (i.e., `Generation`), computes logarithmic probabilities for these responses (i.e., `Inference`), and uses the results as training data to update the same model (i.e., `Training`). The updated weights are then synchronized back for inference and generation, completing one training iteration.

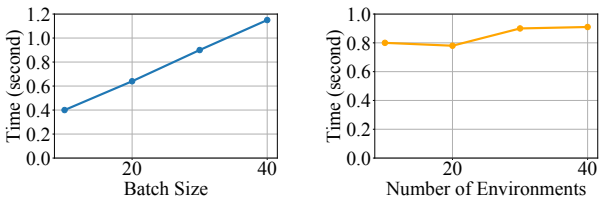
In contrast, the RLHF [38] workflow adopts PPO [48], resulting in a more complex design involving four LLMs. The actor model serves as the core policy, generating responses to queries. The reference model remains fixed to constrain the actor from drifting too far from its initialization. The reward model assigns scalar rewards to generated responses, while the critic model estimates expected rewards to stabilize training. Actor and critic are trainable, whereas reference and reward models are frozen. These components interact closely, as shown in the figure.

Beyond algorithms, RL workflows also vary by application scenario. In embodied intelligence [24,25], RL relies on simulators that simulate the physical world. An LLM interacts with the simulator by generating actions and receiving feedback,



(a) CDF of response time. (b) Unfinished responses.

Figure 2: The distribution of response lengths and the number of unfinished responses over time in the generation phase of a math RL experiment.



(a) Generation time. (b) Simulator time.

Figure 3: The execution time of generation and simulator with different batch sizes respectively, batch size in simulator is the number of environments.

producing trajectories that serve as training data. Similarly, in Deep Research [35, 69], RL improves model performance through interaction with a search server that retrieves online information. The resulting rollout results are fed into training, while inference follows the GRPO workflow.

Characteristics of RL Workflows. RL workflows consist of heterogeneous components with distinct demands on GPU memory, computation cores, accelerator types, and parallelization strategies. For example, training requires substantially more GPU memory than inference to maintain gradients and optimizer states. Unlike training, generation often underutilizes GPU cores, as its matrix and vector multiplications are bottlenecked by memory bandwidth. Some components (e.g., simulator) run on CPUs, or use GPUs for non-tensor computations (e.g., 3D rendering). Parallelization also differs significantly, e.g., LLM training exploits data, tensor, and pipeline parallelism, whereas simulators typically scale only through multiple instances. Maximizing overall utilization across such heterogeneous components is a great challenge.

Further, RL workflows exhibit complex dependencies, primarily through data flow and weight updates. Data flow can occur at different granularities, e.g., per response between generation and inference, or at least a micro-batch of responses between generation and training. Some workflows even introduce cyclic data flows, such as in embodied RL and Deep Research (Figure 1), which further complicates coordination. Weight updates, in contrast, act as barriers that synchronize generation and training. These complex dependencies require more fine-grained scheduling.

2.2 Inefficiencies in Diverse RL Workflows

We analyzed different RL workflows to identify the source of inefficiencies as follows.

Dynamicity in Rollout Wastes Computation. The rollout phase is inherently dynamic. Lengths fluctuate across responses of the same query, and even more so across different queries. Embodied tasks such as grasping can take different numbers of steps. In deep research, generating a report may involve varying numbers of search interactions. Since rollouts are executed in batches, these variations create a long-tail problem where a few slow queries block the entire phase from proceeding to inference or training. The problem commonly exists in the collocated mode (e.g., veRL [51]), where generation, inference, and training sequentially share GPUs by swapping between CPU and GPU memory. We conducted an experiment of a 7B math reasoning RL training [40] on 8 nodes with 8 H100 GPUs each, as shown in Figure 2. The number of unfinished responses quickly shrinks to less than 5%, where a very small set of long-tail responses stalls the generation, leaving many GPUs underutilized or idle. Scaling out with more GPUs worsens the problem as idle time grows.

Pipelining alleviates this by allocating fewer GPUs to generation and leaving the rest for inference and training. In this setup, inference and training start once partial samples are ready. However, pipelining introduces its own inefficiency since inference and training must wait for the first batch to be generated. Thus, neither approach is universally optimal, and supporting both collocated mode and pipelining within a single framework remains a significant challenge.

Simple Execution Modes Cannot Fit Diverse Components. Collocated and pipelined modes are two extremes, i.e., all components on the same GPUs versus fully disaggregated GPUs. Some RL workloads, however, do not fit neatly into either mode. Their diverse component characteristics require more flexible orchestration. Take embodied RL (Figure 1) as an example. Figure 3 shows computation profiles of generation and simulator. The execution time of simulator increases slightly with the number of environments and its GPU utilization remains low (i.e., <24%), while its memory usage grows linearly with the number of environments. In contrast, generation scales linearly in both runtime and memory with batch size, while keeping GPU cores highly utilized (i.e., >70%). Training consumes more memory, but its execution time is only one-third as long as generation's.

This profile rules out simple execution modes. The simulator should scale with as many parallel environments as possible to reduce its total runtime. However, this prevents collocation with generation due to memory contention. A better choice is running on disaggregated GPUs with pipelining for higher efficiency. Training, in contrast, would waste com-

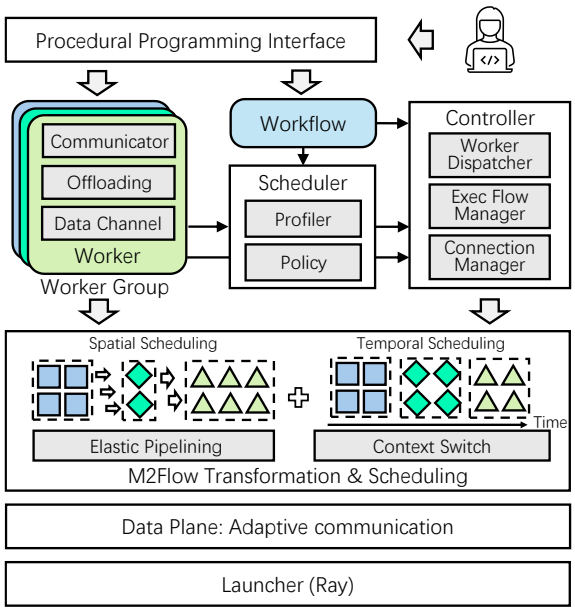


Figure 4: The architecture of RLinf.

pute if fully disaggregated, so it should share GPUs. After rollout, simulator and generation are swapped to CPU, and training takes over the GPU. The result is a hybrid mode that combines collocation and pipelining to balance efficiency.

Identifying Suitable Orchestration is Challenging. The orchestration of the hybrid mode depends on the analysis of the components. However, finding the most suitable orchestration for a given RL workflow is challenging, as the characteristics are diverse and the dependencies are complex. Manually enumerating options is tedious, time-consuming, and risks overlooking better choices. Moreover, no clear guidelines exist to identify the most suitable orchestration.

2.3 Flexibility as a Key to Efficiency

Maximizing computation efficiency for an RL workload requires flexible orchestration that aligns with component and workflow characteristics. However, adjusting the execution mode without changing the programmed workflow is challenging. Collocated and disaggregated pipelining modes differ significantly. Collocated mode operates at coarse-grained, phase-level execution. Each phase starts after the previous phase is complete. However, disaggregated pipelining runs at fine-grained, batch-level with precise timing to minimize pipeline bubbles. Mixing these modes further increases complexity. We advocate a system design that bridges this gap, enabling RL developers to maintain an intuitive, logically organized workflow while achieving high execution efficiency with flexible execution modes.

3 RLinf Design

3.1 Overview

In pursuit of efficient, flexible, and intuitive RL systems, we propose a new design paradigm termed M2Flow, i.e., *macro logical flow executed with micro execution flow*. In this paradigm, developers program the complex RL workflow by imperatively specifying the logical communication flow among the RL components at a coarse granularity (macro logical flow), while the system automatically transforms the workflow into a fine-grained execution flow (micro execution flow). Essentially, M2Flow decouples programmable code logic from the physical execution and scheduling of the individual RL components, so as to maximize the efficiency while minimizing the programming complexity.

Figure 4 shows the architecture of RLinf that realizes M2Flow. As illustrated, RLinf provides an easy-to-use procedural programming interface for users to construct RL workflows imperatively, which describe the data communication and interaction among the RL components. RL components are then encapsulated as *workers* in RLinf, each implementing the main logic of this component. Workers are equipped with communication functionality to freely communicate with each other, as well as a resource offloading mechanism to enable temporal multiplexing of hardware resources. This worker abstraction enables RLinf to retain substantial scheduling flexibility at both the spatial and temporal dimensions, while following the procedural workflow. Spatial scheduling assigns workers to accelerators, temporal scheduling determines their execution periods, and spatio–temporal scheduling governs their pipelined execution granularity.
